In this group productivity increased extensively during the period from 1925 to 1928, inasmuch as 72 per cent of the companies effected increases ranging from 1.3 to 88 per cent, whereas only 28 per cent of the companies experienced decreases ranging from 0.5 to 51.5 per cent.[5] Productivity was less than 10 per cent higher for 19 companies, from 10 per cent to 20 per cent higher for 21 companies, from 20 to 30 per cent higher for 18 companies, and more than 30 per cent higher for 21 companies; it was less than 10 per cent lower for 16 companies, and more than 10 per cent lower for 15 companies.

Likewise productivity increased extensively during the three-year period from 1928 to 1931, inasmuch as 58.1 per cent of the companies effected increases ranging from 0.5 to 112.2 per cent, and 41.9 per cent of the companies experienced decreases ranging from 1.1 to 57.6 per cent.

More than half the companies that had a higher productivity in 1928 had a still higher productivity in 1931; more than half that had a lower productivity in 1928 had a higher productivity in 1931. A summary follows.

	Number of companies	Percentage of total
Total number of companies	110	100.0
A—Increase in Productivity:		
1 Productivity in 1928 from 1.3 to 83.5 per cent higher than in 1925	79	71.9
2 Productivity in 1931 from 0.5 to 112.2 per cent higher than in 1928	64	58.1
3 Higher productivity in 1928 followed by higher productivity in 1931	46	41.9
4 Higher productivity in 1928 followed by lower productivity in 1931	33	30.0
B—Decrease in Productivity:		
1 Productivity in 1928 from 0.5 to 5.5 per cent lower than in 1925	31	28.2
2 Productivity in 1931 from 1.1 to 57.6 per cent lower than in 1928	46	41.9
3 Lower productivity in 1928 followed by higher productivity in 1931	18	16.4
4 Lower productivity in 1928 followed by lower productivity in 1931	13	11.8

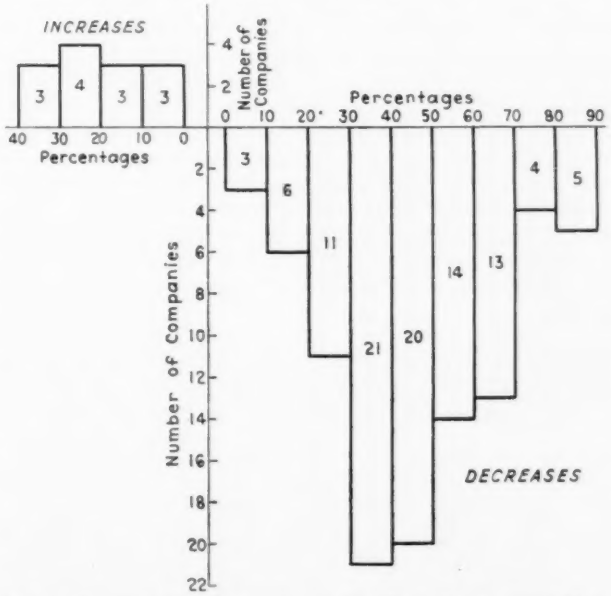

FIG. 2 PERCENTAGES OF INCREASES AND DECREASES IN THE NUMBER OF KILO MAN-HOURS WORKED BY 110 COMPANIES, FROM 1928 TO 1931

Reduction in Kilo Man-Hours Required. The marked advance in technological developments and managerial technique during recent years has had such a pronounced influence upon industrial operation that the changing aspects of the business cycle seem to have little, if any, effect upon continuing progress.

[5] The percentages are derived by comparing the rates of the terminal years of each period, and not by the use of the least square method of determining straight line trends.

When measured by the integrated factor of productivity, a steady improvement may be noted throughout three phases of business conditions: (*a*) a period of stability from 1922 to 1925; (*b*) a period of expansion from 1925 to 1928; and (*c*) a period of recession from 1928 to 1931. In all three periods productivity, as indicated by our studies, has steadily increased. During the period of stable conditions the productivity of 359 companies, employing 254,529 workers, increased 14.4 per cent, the range of increase being from 0.1 to 46.1 per cent for 34 industries.[6] The experience of 110 companies, employing 169,458 workers, already presented, indicates that productivity likewise increases during periods of expansion and recession.

The results of continuously increasing productivity are, either wholly or partially:

a A greater quantity of product will be turned out by the same working force in working periods of the same length

b A constant quantity of product can be turned out by a reduced working force in working periods of the same length

c A constant quantity of product can be turned out by the same working force in shorter working periods.

The greater quantity of product that was turned out in 1928 as compared with that turned out in 1925 indicates the first result during a period of expansion. The previous discussion of the decrease in employment from 1928 to 1931 shows the second result during a period of depression.

The following kmh analysis indicates what the reduced number of kmh required each year would have been during an eight-year period, from 1923 to 1931, if a constant quantity of product output had been maintained by 50 manufacturing companies employing 67,824 workers in 1923, and by two railroad companies employing 51,787 workers in 1923.

The number of kmh required by the 50 manufacturing companies in 1931 would have been individually from 2 to 69 per cent less than the requirement in 1923. In 1923 the 50 companies required 180,767 kmh, which would have been reduced by 56,070 kmh to 124,697 kmh in 1931, a reduction of 31 per cent. Consequently if these companies had maintained a constant output during the eight-year period without shortening the length of the work day or work week, approximately one-third of the 67,824 workers, or 21,127, would have been released. What actually happened was that the employment decreased with some fluctuation from 180,767 kmh in 1925 to 178,498 kmh in 1929, after which it decreased rapidly by 33.6 per cent to 118,515 kmh in 1931.

TABLE 1 ACTUAL AND REQUIRED NUMBER OF WORKERS, NUMBER OF KILO MAN-HOURS, AND LENGTH OF WORK WEEK FOR 50 MANUFACTURING COMPANIES FOR EACH YEAR FROM 1923 TO 1931 TO MAINTAIN CONSTANT PRODUCTION AND TO FURNISH STEADY EMPLOYMENT TO 67,824 WORKERS

Year	Average number of workers actually employed	Number of workers required to maintain constant production in constant length of work week	Actual number of kilo man-hours worked per year	Number of kilo man-hours required per year to maintain constant production	Actual number of man-hours worked per worker per year	Number of man-hours required per worker per year to maintain constant production and steady employment	Average length of actual work week in hours	Average length of work week in hours required to maintain constant production and steady employment
1923	67,824	67,824	180,767	180,767	2670	2670	51.2	51.2
1924	64,295	66,200	164,398	176,433	2560	2610	49.2	50.2
1925	66,789	61,000	171,855	162,962	2570	2400	49.5	46.0
1926	68,629	56,500	166,274	150,350	2420	2220	46.6	42.6
1927	66,492	55,300	156,455	147,142	2360	2180	45.3	42.0
1928	66,621	51,000	163,538	135,894	2460	2000	47.1	38.4
1929	73,300	49,100	178,498	130,819	2440	1930	46.8	37.1
1930	69,808	49,000	155,710	130,554	2220	1920	42.6	36.9
1931	58,211	46,700	118,515	124,697	2040	1840	39.2	35.4

[6] "Safety and Production," A Report by American Engineering Council, New York, 1928, p. 76.

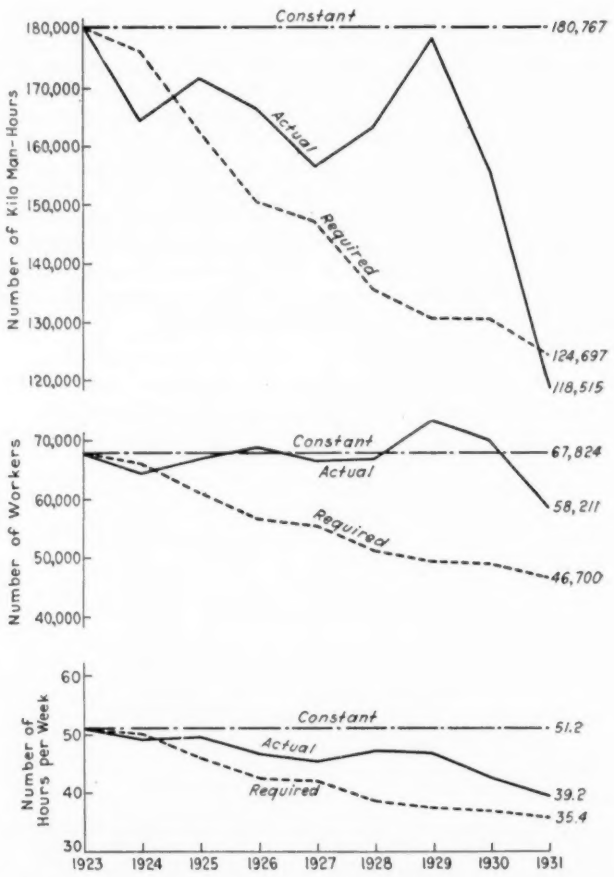

FIG. 3 TRENDS OF ACTUAL AND REQUIRED NUMBER OF WORKERS, NUMBER OF KILO MAN-HOURS, AND LENGTH OF WORK WEEK FOR 50 MANUFACTURING COMPANIES FOR EACH YEAR FROM 1923 TO 1931 TO MAINTAIN CONSTANT PRODUCTION AND TO FURNISH STEADY EMPLOYMENT TO 67,824 WORKERS

The average number of workers employed increased by 8.1 per cent from 67,824 workers in 1923 to 73,300 in 1929, and afterward decreased by 20.6 per cent to 58,211 in 1931.

The values for the actual and required number of workers and the actual and required number of kmh are given in the first four columns of Table 1. Trend curves for the values are presented in Fig. 3.

A similar reduction of 33 per cent in the number of kmh required to maintain a constant service could have been made by the two railroad companies which reported during the same eight-year period from 1923 to 1931. The reduction would have been from 134,131 kmh in 1923 to 90,540 kmh in 1931.

Work Period. The third result of continuously increasing productivity, viz., a constant quantity of product turned out by the same working force in a shorter work period, might have been brought about by the 50 manufacturing companies if the average length of the work week had been shortened from 51.2 hours in 1923 to 35.4 hours in 1931. The actual length of the work week had been shortened from 51.2 hours in 1923 to 39.2 hours in 1931.

Likewise a steady working force could have been maintained for the 51,787 workers employed by the two railroad companies if they had shortened the average length of the work week from 49.8 hours in 1923 to 33.6 hours in 1931.

A summary of the 1923–1931 comparisons for the 50 manufacturing companies follows:

	Per cent
Number of kmh Worked:	
Actual decrease	34.5
Decrease required to maintain constant production	31.0
Number of Workers:	
Actual decrease	14.2
Decrease required to maintain constant production in unvarying length of work period	31.0
Length of Work Period:	
Actual decrease	23.4
Decrease required to maintain constant production and constant working force	31.0

Optimum Operating Performance

At the request of The American Society of Mechanical Engineers transmitted through the American Engineering Council, the Bureau of the Census in the Census of Manufactures for 1929 obtained reports from four manufacturing industries on a basis permitting a kmh analysis of several factors of operation. The industries that reported are:

Blast-Furnace Operation
Machine-Tool Building
Petroleum Refining
Lumber and Timber-Product Manufacturing

The data for the following comparison have been taken by permission from the study and report of the Bureau of the Census, which report is in process of publication by the Government. The degree of coverage for the first three industries is 95 per cent. For lumber manufacturing it is only about 25 per cent, as only those concerns reporting products valued at $100,000 or more were requested to fill in the supplementary man-hour schedule; and further, of those that replied to the supplementary schedule a number showed that the inquiry was not understood, and in consequence their returns were excluded in the tabulations.

The Census report on the four industries is too extensive to review here, therefore comments are restricted to six items:

Physical Volume of Product
Selling Value of Product
Wages
Salaries
Optimum Length of Work Period
Optimum Size of Plant.

Physical Volume of Product. Values for this quantity were reported by three of the industries studied, the exception being machine tools. The data support the conclusion in our previous paper that there is a wide spread of physical volume of production per kmh among plants in the same line of manufacture.

Productivity of Blast Furnaces. The data for 86 blast furnaces are grouped according to number of tons of pig iron produced per 1000 hours of labor by wage earners. Attention is called to the final column, which gives the quantity of product per kmh for each of six groups of plants. The ratio of the lowest rate to the highest rate of productivity is 1:9.

Limits of groups, tons per kmh	Number of establishments in the group	Quantity of product, tons per kmh
Under 200	9	145
200 to 399	22	341
400 to 599	18	504
600 to 799	17	665
800 to 999	13	869
1000 and over	7	1313

Productivity of Petroleum Refineries. The rates of productivity of plants refining crude petroleum as revealed by the same method of analysis of returns from 306 refineries had a ratio of 1:224 from lowest to highest. The data are:

Limits of groups, barrels of crude petroleum refined per kmh	Number of establishments in the group	Quantity of product processed, barrels of crude petroleum per kmh
Under 1,000	9	633
1,000 to 2,499	59	2,008
2,500 to 4,999	97	3,734
5,000 to 9,999	72	5,810
10,000 to 24,999	49	12,709
25,000 to 49,999	13	29,972
50,000 to 99,999	4	56,570
100,000 and over	3	141,829

Productivity of Lumber and Timber-Product Manufacturing. The productivity rates as revealed by the same method of analysis of return from 305 concerns had a ratio of 1:13 from lowest to highest. The data are:

Limits of groups, M fbm per kmh	Number of establishments in the group	Quantity of product, M fbm per kmh
1 to 19	40	13
20 to 29	56	25
30 to 39	54	32
40 to 49	35	45
50 to 74	56	61
75 to 99	20	85
100 to 149	28	127
150 and over	16	173

Value of Products. The paper of 1928 showed wide differences in the selling value of product per kmh as turned out by different firms in the same industry and in different industries. The same situation is revealed in the data from the four industries included in this study. The limits are given in the following tabulation:

Industry	Lowest selling value of product per kmh	Highest selling value of product per kmh	Ratio of lowest to highest value
Blast-furnace operation	$2449	$24,087	1:10
Machine-tool building	918	10,673	1:11
Petroleum refining	4563	192,908	1:42
Lumber manufacturing	468	5,481	1:11

The figures for the four industries showing values of product per kmh by groups are now given.

Value of Product per Kmh

Limits of groups, average value of product per kmh	Number of establishments in the group	Value of product per kmh
Blast-Furnace Operation:		
Under $4,000	7	$2,449
$4,000 to $7,999	25	6,620
8,000 to 11,999	26	10,268
12,000 to 15,999	15	13,804
16,000 to 19,999	9	18,111
20,000 and over	4	24,087
Machine-Tool Building:		
Under $1,000	5	$ 918
$1,000 to $1,499	105	1,568
1,500 to 1,999	82	2,465
2,000 to 2,499	25	3,383
2,500 to 2,999	6	4,623
3,000 to 3,999	4	5,308
4,000 and over	4	10,673
Petroleum Refining:		
Under $5,000	15	$4,563
$5,000 to $7,499	35	6,218
7,500 to 9,999	60	8,671
10,000 to 14,999	88	12,276
15,000 to 24,999	52	17,364
25,000 to 49,999	43	29,539
50,000 to 99,999	9	70,975
100,000 and over	4	192,908

Lumber Manufacturing:		
Under $500	6	$ 468
$500 to $999	70	820
1,000 to 1,499	116	1,244
1,500 to 1,999	80	1,668
2,000 to 2,499	51	2,303
2,500 to 2,999	43	2,709
3,000 to 3,999	26	3,492
4,000 to 4,999	9	4,445
5,000 and over	4	5,481

Wages. The differences in wages paid in the four industries under investigation, as well as the range for each industry, are shown in the following tabulation:

Industry	Lowest wage rate per kmh	Highest wage rate per kmh	Ratio of lowest to highest
Blast-furnace operation	$198	$1,016	1:5
Machine-tool building	464	927	1:2
Petroleum refining	242	1,067	1:4
Lumber manufacturing	149	1,143	1:8

It will be noticed that the highest values are in substantial agreement for all industries, being respectively on an hourly rate basis: $1.02, $0.93, $1.07, and $1.14. The data for the four industries showing wages per kmh by groups are given in the following tabulation:

WAGES PER KMH

Limits of groups, average cost of labor per kmh	Number of establishments in the group	Wages per kmh	Hourly rate
Blast-Furnace Operation:			
Under $300	5	$198	$0.20
$300 to $399	8	355	0.36
400 to 499	15	446	0.45
500 to 599	31	551	0.55
600 to 699	14	636	0.64
700 to 799	9	738	0.74
800 and over	4	1016	1.02
Machine-Tool Building:			
Under $500	28	$464	$0.46
$500 to $599	55	552	0.55
600 to 699	90	654	0.65
700 to 799	39	737	0.74
800 to 899	15	844	0.84
900 and over	4	927	0.93
Petroleum Refining:			
Under $300	7	$242	$0.24
$300 to $399	19	393	0.39
400 to 499	44	469	0.47
500 to 599	109	547	0.55
600 to 699	70	631	0.63
700 to 799	36	745	0.75
800 to 899	18	826	0.83
900 and over	3	1087	1.09
Lumber Manufacturing:			
$100 to $199	5	$149	$0.15
200 to 299	57	263	0.26
300 to 399	84	351	0.35
400 to 499	68	454	0.45
500 to 599	71	552	0.55
600 to 699	72	644	0.64
700 to 799	28	739	0.74
800 to 899	15	856	0.86
900 and over	5	1143	1.14

Salaries. The cost of salaries paid to officers, executives, supervisors, and other salaried people can be taken as an indication of the cost of supervision. There are wide differences in this item in the various industries studied, the spread being:

Industry	Lowest salary rate per kmh	Highest salary rate per kmh	Ratio of lowest to highest
Blast-furnace operation	$32	$186	1:6
Machine-tool building	63	844	1:13
Petroleum refining	40	1056	1:26
Lumber manufacturing	18	339	1:18

The complete data on salaries for the four industries are given in the following tabulation:

SALARIES PER KMH

Limits of groups, average compensation of salaried persons per kmh	Number of establishments in the group	Salaries per kmh	Hourly rate
Blast-Furnace Operation:			
Under $50	15	$32	$0.03
$50 to $74	19	61	0.06
75 to 99	17	86	0.09
100 to 124	17	108	0.11
125 to 149	8	138	0.14
150 and over	10	186	0.19
Machine-Tool Building:			
Under $100	26	$63	$0.06
$100 to $199	78	143	0.14
200 to 299	51	246	0.25
300 to 399	32	304	0.30
400 to 499	16	431	0.43
500 to 599	14	527	0.53
600 and over	14	844	0.84
Petroleum Refining:			
Under $50	18	$40	$0.04
$50 to 99	46	76	0.08
100 to 199	110	147	0.15
200 to 299	68	224	0.22
300 to 399	28	338	0.34
400 to 499	14	470	0.47
500 to 749	16	593	0.59
750 and over	6	1056	1.06
Lumber Manufacturing:			
Under $25	24	$18	$0.02
$25 to $49	89	39	0.04
50 to 74	104	60	0.06
75 to 99	68	84	0.08
100 to 124	37	111	0.11
125 to 149	25	141	0.14
150 to 199	35	171	0.17
200 to 249	13	231	0.23
250 and over	10	339	0.34

Length of Work Period. A comparison of length of work year for the four industries studied is given in the following tabulation:

Industry	Shortest work year, in hours	Longest work year, in hours	Ratio of shortest to longest work year
Blast-furnace operation	1760	4340	1:2.5
Machine-tool building	1940	2970	1:1.5
Petroleum refining	1650	3460	1:2.1
Lumber manufacturing	1450	3000	1:2.1

The spread from shortest to longest is considerable in each industry. The longest for machine-tool building and lumber manufacturing is on the basis of 60 hours per week, for petroleum refining on the basis of 70 hours per week, and for blast-furnace operation on the basis of 84 hours per week. By way of comparison, the shortest are 40, 50, and 60 per cent of the maximum figures. The data for the four industries follow:

VARIATION IN LENGTH OF WORK PERIOD

Limits of groups, average length of work year in hours per worker	Number of establishments in the group	Length of work year in hours	Length of work week in hours
Blast-Furnace Operation:			
Under 2000	3	1760	33.8
2000 to 2249	3	2120	40.7
2250 to 2499	3	2400	46.1
2500 to 2859	16	2680	51.5
2860 to 3332	36	3070	59.0
3333 to 3999	18	3520	67.6
4000 and over	7	4340	83.4

Machine-Tool Building:			
Under 2000	12	1940	37.3
2000 to 2099	5	2090	40.1
2100 to 2249	9	2190	42.0
2250 to 2349	18	2310	44.5
2350 to 2499	64	2440	47.0
2500 to 2674	64	2560	49.1
2675 to 2859	47	2760	53.0
2860 and over	12	2970	57.0
Petroleum Refining:			
Under 2250	5	1650	31.7
2250 to 2349	13	2310	44.5
2350 to 2499	47	2450	47.0
2500 to 2674	50	2560	49.1
2675 to 2859	64	2810	54.0
2860 to 3079	94	2960	57.0
3080 to 3339	20	3160	60.8
3340 and over	13	3460	66.5
Lumber Manufacturing:			
Under 1667	15	1450	27.9
1667 to 1999	25	1910	36.7
2000 to 2099	24	2060	39.6
2100 to 2249	28	2160	41.5
2250 to 2349	51	2280	43.9
2350 to 2499	69	2420	46.5
2500 to 2674	73	2570	49.5
2675 to 2859	66	2780	53.5
2860 and over	54	3000	57.6

Optimum Size of Plants. In our paper of 1928 we presented a comparison on the kmh basis of the physical volume of production for the smallest and largest concerns in 53 industries. The criterion of size was the number of employees. That comparison brought out, among others, these relationships:

The smallest company has a higher rate of production than the largest in 35 industries

The smallest company has a lower rate of production than the largest company in 18 industries

The smallest company has the highest rate of production in 16 industries and a high rate in 5 industries

The smallest company has the lowest rate of production in 6 industries and a low rate in 16 industries.

These comparisons indicate that the optimum size of plant, from the productivity point of view—the one that produces most effectively—may not be the largest. Study of the data upon which this part of our paper is based showed that the most satisfactory unit of measurement to indicate the optimum plant is the number of kmh worked per year, and not the number of workers employed, and that the factors for any industry can be expressed as a range.

This optimum range is obtained by taking into consideration the kmh per year corresponding to the highest values of product, the addition made by manufacture, and the physical volume of product for each of a group of operating factors. Tables 2 to 5 present these data for Blast-Furnace Operation, Machine-Tool Building, Petroleum Refining, and Lumber and Timber-Product Manufacturing.

The relationship of wages to optimum operation is indicated by Tables 6 to 9. In general, the highest wage rate, measured in dollars per kmh, accompanies the highest kmh operating rate, and the lowest wage rate accompanies the lowest operating rate.

The relationship of supervision to optimum operation is indicated by Tables 10 to 13. In general, the highest salary rate per kmh accompanies the highest operating rate, and the lowest salary rate per kmh accompanies the lowest operating rate.

The relationship of length of work period to optimum operation is indicated in Tables 14 to 17. In general, the length of work week, for highest operating rate, reflects prevailing schedules, being, when arranged, about 44 hours for blast furnaces, machine tools, and lumber, and about 50 hours for petroleum refining.

TABLE 2 OPTIMUM SIZE OF PLANT—BLAST-FURNACE OPERATION

Factor per kmh	Range of factor	Value of products	Value added by manufacture	Quantity of products, tons	Kmh per year
Cost of fuel and electric energy	$6000 and over	$28,228	$8211	1514	273.1
Value added by manufacture	5000 and over	18,534	5287	984	346.4
Wage earners	0.400 to 0.449	22,060	5859	1229	393.6
Quantity of products	1000 tons and over	21,922	3393	1313	487.7
Value of products	$20,000 and over	20,811	4329	1357	499.4
Cost of materials	14,000 and over	20,822	3880	1366	512.1
Salaries	150 and over	14,421	2617	756	597.3
Prime cost	15,000 and over	20,672	3532	1137	611.5
Wages	800 and over	17,649	2753	1026	637.3

Dicussion

WILLIAM BAUM.[7] The authors, in their first paper on the subject in 1928, aroused favorable comment. They gave management a unified basis for evaluating manufacturing operation through the introduction of the "kilo man-hour," which unquestionably has great advantages over percentages and ratios heretofore used in the measurement of business efficiency. The new paper presents a wider scope in the application of the kmh to the measurement of operating performance, productivity, employment, and various cost elements. The data collected furnish a valuable basis for making comparisons with industries not covered by this new paper. The authors' unique work can be advantageously extended to other phases of managerial control, such as cost accounting and budgeting—not only to make comparisons with previous periods within a certain organization, but also to compare kmh results with other concerns in the same industry.

Direct labor costs expressed in money values per unit of product are meaningless when used for comparisons with previous periods. Variations do not reveal the causes and do not reflect true changes in operating efficiency unless allowance is made for fluctuations in wage rates. Direct labor costs in terms of kmh, on the other hand, give an accurate measure of operation and may be compared with similar figures of other concerns in the same industry. Such direct labor costs are independent of fluctuations of wages and may be broken down to costs by operations, jobs, orders, etc.

Another cost element which often lacks absolute definiteness is "indirect labor." This item is usually expressed in per cent of direct labor cost and therefore is subject to the same criticism. If direct labor wages fluctuate, the indirect labor percentage becomes meaningless. Likewise, if direct labor and indirect labor wages do not fluctuate in synchronism, the indirect labor percentage again is of no value. An absolute measure of indirect labor, however, is given by an expression which relates the indirect kmh to production.

There are other cost elements, such as clerical costs, supervision, selling, administration, etc., which lend themselves readily to similar treatment. Each cost element which has to do with labor in plant and office can be given an absolute measurement by the kmh method.

The present "standard cost system" advocated by progressive accountants is still based on standards expressed in money values per unit of production. The kmh system will some day find universal application in such cost systems. When that day arrives, standard costs will have a definite meaning. No corrections will have to be made for wage-rate fluctuations. A true picture of operating conditions and trends will be at the disposal of cost-controlling officers, leading to higher efficiency and reductions of costs.

The kmh system has been introduced in this organization to evaluate the individual effort of our employees. The standard time for a certain operation as found by time study is brought into relationship to the actual time spent on the job, and this relation expresses the effort of the worker. Each week the relative progress of each employee is followed up and controlled. No other method furnishes a more absolute basis for evaluating and controlling individual efforts.

It is not difficult to visualize revolutionary changes in the measurement of operation and costs. The Management Division of the A.S.M.E. is rendering industry and business a real service in giving the kmh system the publicity which it deserves and which reflects high credit upon its authors.

[7] Director of Personnel and Industrial Engineering, Realsilk Hosiery Mills, Inc., Indianapolis, Ind.

HAROLD V. COES.[8] The authors have demonstrated the value of kmh as an accurate evaluation of employment and as a means of comparing productivity. The reduction in kmh required indicates from studies made that productivity is independent of the phases of the business cycle. What is the significance of this with respect to total employment, particularly in basic industries? It would indicate a continuing but probably more gradual reduction in the kmh to produce society's needs for basic commodities in the stabilized industries. Where does this leave us with respect to labor released in these industries if the conclusions from the facts as presented are sound, and what may be done with the balance?

This study also indicates quite clearly the desirability, in fact the necessity, of reducing working hours per week for constant production, assuming a balance between consumption and production.

It seems, then, if purchasing power is to be maintained, particularly in that group whose annual compensation is $5000 and less comprising 80 per cent of our annual purchasing power, that we must quit thinking of wage and salary scales in terms of a horse-and-buggy age and base compensation on the reduced hours per week and consequently at a much higher hourly base rate.

What are the contributing causes to the wide spread in operating performance? The data pertaining to optimum size of plants and to relative operating efficiency as gaged by kmh seem to check with a study made of relative earnings of large and small industries by Prof. H. B. Summers, of Kansas State College, and reported in the May, 1932, issue of the *Quarterly Journal of Economics*. This study showed that in the nine industrial classifications he studied, comprising 1130 companies, the highest average rate of earnings was found in the smallest size group, including companies with investment below $2,000,000 in five of the nine classes.[9]

W. E. PARKER[10] AND JESS T. HOPKINS.[11] The break down made possible through the use of the kmh unit of measurement provides more specific and tangible basic units than do census figures for comparing costs and industries. This unit of measurement, making possible as it does optimum studies, should provide essential data for planning industrial production.

The kmh units of measurement show trends in employment and the effects of technological changes more accurately than do figures from any other published source and make possible a regular and frequent check of employment trends.

The kmh measurement can be applied effectively to determine seasonal factors in industry. Furthermore, productivity in terms of kmh units and labor stability units give to industry a calibration comparable to that provided by industrial management and engineering for the measurement of the effectiveness of the industrial worker or department.

The kmh system of recording essential data seems so basic and such an improvement over the archaic methods of census reports that its adoption as a common denominator for measurements of labor seems clearly indicated.

E. F. CURTIS.[12] For the past seven years the writer has been working on the same principle, extending its application to three

plants of different industrial operations, and has proved conclusively that its use in costing, estimating, and scheduling is efficient, accurate, and most valuable in controlling factory cost during periods of normal and abnormal operating capacities.

The only obstacle that, at the present time, hinders the extension of the general application of this theory is the time necessary to educate others in position to assist and the developments essential for the proper correlation of data.

ARTHUR HUNTINGTON.[13] The agitation for the short week and the split shifts of workers, which has been such a large part of our relief programs, makes this paper particularly valuable. In the face of the stand taken by union labor and by relief workers who are faced with apportioning the few jobs which are available, it would seem advisable that the paper be put in popular form and given wide circulation. Neither the labor leaders nor the relief workers are altogether satisfied with the position they have taken regarding the short week.

It has been stated that shorter hours and split payrolls savor very strongly of the assumption that our maximum living standard has been reached and that we must spread the work necessary to maintain that living standard as widely as possible. Last June the writer presented a paper before the American Society of Agricultural Engineers at Columbus, Ohio, in which it was pointed out that America must decide between:

(*a*) The efficient use of our machinery of production, and
(*b*) The better apportioning of the benefits of production.

There are many people who are advocating the throttling of production until it balances our antiquated machinery of distribution. The engineer has created our machinery of production; he must assume some responsibility toward the apportioning of the benefits of that which he has created. In other words, the engineer has arrived at the place where he must invade the realm which heretofore has been assigned to the business man. He must enter the field of economics.

Thinking labor men are wondering whether it is wise to assume that there is a minimum American standard of living; too many people regard such a minimum as the maximum. Some leaders, even in the labor group, are of the opinion that increased production should be crowded as long as we can find ways and means of apportioning the benefits—in other words, increase the standard of living. Basically this is a sound policy.

The first paper was a long step forward; this paper proves the value of the 1928 paper. It is hoped that this paper will reach well out into the commercial world.

GEORGE G. BERGER.[14] This paper is along the line of statistical treatment which is becoming so popular today despite the emphasis of modern science on more exact inductive methods. Statistical treatment is founded on the hopes that the plus quantities balance the minus quantities and that therefore the conclusions drawn are good bases for prediction purposes. The statistical method does not result in good controls except in cases where large tolerances are economically permissible.

There can be no doubt that costs and values of production on the basis of 1000 man-hours supply valuable comparisons. The writer likes this method of bringing together facts, but does not believe that we can disregard certain assumptions made. It is valuable to know that a plant does not produce as much per kmh as some other plant or that labor cost per kmh is higher or lower, but these comparisons only raise the question as to why this is so.

Some of the dangerous assumptions on which the comparisons made are based are as follows:

The effectiveness of the management is disregarded; in other words, by the statistical treatment it is assumed that the managements of the industries noted are representative and uniformly efficient. Also the paper does not bring out the effect of financial backing on raw material cost per kmh and on equipment policy which affect productivity per kmh. It is important to note, however, that equipment does not take the place of common sense in management, and occasionally we do find small concerns producing more economically.

The most dangerous assumption, however, is that actual wages paid are adequate economic wages. This assumption disregards the condition of one enterprise paying low wages and benefiting by the trade conditions which are due to the competitor and to other industries paying higher wages. In other words, the paper stresses a low labor cost per kmh for non-union labor and for low paying industries. This irresponsibility for buying power is perhaps the primary cause of our present state of affairs; it prevents any real comparisons of productivity or labor costs on the straight kmh basis.

Needless to say, industry is not paying adequate wages. In proof of this statement the writer wishes to submit a study of the responsibility for buying power in 16 groups of manufactures for the year 1929. This study shows three groups more than meeting their responsibility; two are nearly meeting their responsibility; the remaining groups are engaged in overcoming the advantages gained. The net result is a removal of $2,036,000,000 buying power by manufacturing industries in the year 1929.

From studies made on buying power, it was immediately apparent that wages bear a distinct relationship to the sales dollar or price, which could be expressed by formula. Applying this formula to the data in Tables 1 and 4 of the older paper, "A Basis for Evaluating Manufacturing Operation," the writer obtained economic wages per kmh which should be paid if industry is to share its responsibility for trading conditions.

Something is radically wrong when an industry pays $272 per kmh for labor charges and the worker is compelled to work 2.58 kilo man-hours in order to earn a living. One kilo man-hour is the same as 1000 men working one hour, or one man working 1000 hours. An ordinary working

[14] Consulting Industrial Engineer, New York, N. Y. Jun. A.S.M.E.

year of 268 days of 8 hours each would amount to 2.14 kilo man-hours. In other words, the worker is paid $272 for approximately half a year's work and is compelled to work considerably more than 8 hours a day in order to earn a living.

It seems to me that before we compare labor costs per kmh, or productivity per kmh which competitive labor costs are bound to influence, we must first determine what percentage of the sales dollar should go into wages and salaries in the specific case—i.e., distribute the responsibility of paying adequate wages.

TABLE 20

Industries	Wages per kmh	Economic wages per kmh
Automobiles	$683	$697
Manufactured ice	796	703
Explosives	437	695

Cast-iron pipe	372	...
Cotton fabrics	273	669
Leather shoes	272	680

M. W. La Fever.[15] Basically the kilo man-hour provides correct measurement of the trend of employment. The writer is interested in the worker as an individual as well as in the amount of real employment. Therefore, he feels that labor problems should be so developed for the public at large as to express the problem when possible in terms of men. For this reason, to discuss generally employment or unemployment in terms of man-hours leaves out the element of the individual, although it is the most impressive of all employment expressions. Further, when the term "worker" is used, it may mean one of two things: First, a person who is actually on the job; second, a person who is duly listed on a payroll and who under ordinary circumstances may or may not be working. Thus, the two possible meanings of the term "worker" seem to be used respectively in expressing quantity *A* and quantity *D*.

It seems to me that quantity *A*, "average number of workers employed," would be more distinctive and not so easily confused if the term were changed to read "average number of jobs furnished." It is obvious that the "average number of workers employed" is controlled by the number of jobs furnished from day to day, and consequently the suggested change would immediately cause one's mind to visualize the situation, while "the average number of workers employed" without further explanation immediately creates a desire to know exactly what is meant and just how such an average would be obtained. It appears that little change would be necessary to revise the entire discussion on this basis. Changes would only be necessary in units 3, 4, 5, and 6.

Unit 3 could be either "working force" or "job requirement unit." The trend of this unit would indicate an increase or a decrease in the number of jobs per 1000 hours of work in a year.

Unit 4 could be designated either as the "labor" or "job utilization" unit. The trend of this unit would indicate the influence of labor-saving facilities because it would show the available number of jobs used to complete a unit of product.

Unit 5 would be the "job performance unit." It would show the quantity of product output per job. It is obvious that in the course of a week, a month, or a year several workers could have been employed on a single job; but the trend of the unit would still indicate the effectiveness in the performance of the job.

Unit 6 would be either the "labor" or "job-time unit." The trend of this unit would indicate fluctuation in the length of the work period during which the average job was furnished.

[15] United States Department of Labor, Bureau of Labor Statistics, Washington, D. C.

The writer has avoided using the term "available jobs," because he can imagine a condition where jobs might be available, but because of a shortage in the labor market the jobs would not be filled. If such condition prevailed regularly, the term "average number of jobs furnished," as suggested, would equally apply. However, it seems difficult, at least at present, to imagine a shortage of labor.

The motive, as stated, is one to create in the mind of the reader a consciousness of the individual worker, and this is commonly associated when one speaks of a job. However, it will be noted that the use of an expression such as "jobs furnished" leaves the mind open to the element of labor turnover and tends to obviate the necessity of determining just what is contemplated by the word "worker."

There has been considerable discussion, pro and con, regarding the use of figures in the manner in which Table 1 has been compiled. Similar figures have been used recently by the Bureau of Labor Statistics to express the changes which have occurred in certain industries as a result of technological development. So far as is known, little criticism has come from the outside regarding such figures. However, they have been discussed among economists in the bureau. They point to the statement that, in 1830, more than a century ago, had there been no improvement in the method of carrying water in the city of London, half of the London population at that time would have been water carriers. The argument seems to be that to assume a constant production and to apply to that quantity a change of productivity does not take into consideration that portion of increase in productivity which has been made possible by the increase in production resulting from greater demand following decrease in the cost of producing and consequent lowering of consumer price.

There are probably instances where production has remained constant or so nearly so that this factor would be minimized, but, by and large, the factor of elasticity of demand is always working whether quantity production increases or remains constant. Hence, to assume a constant anywhere would be unreal.

No way of getting around this situation has been found, and it is felt that the least questionable method may be to confine the more general presentations to the changes in productivity.

In the same manner that the assumption of a constant production is open to question and criticism, the assumption of a constant working force or work week would also be open to question and criticism.

Statisticians, because they deal with facts more than with the theory of probability, are prone to avoid such assumptions, and consequently are constantly exerting such influence as they can to prevent the compilation of figures based on such assumptions. However, no better method has been found of depicting the probable trend in the immediate future than by the presentation of figures based on such assumptions.

The kmh method from the point of view of factory operation and management will furnish a more intensive analysis of factory operations and of factory efficiency than any method which has come under observation. Its application as a method of measuring statistical trends in employment and the elements of technological changes appears also to surpass any method yet proposed. However, labor and the public in general are interested in men as individuals and in the number for whom work is furnished by employers. Thus, in adapting it for lay thought we are at all times confronted by a demand for statistics expressed in terms of individual men, because it is the unit of which the public ordinarily thinks.

It seems also that there should be some definite discussion concerning the method or process of determining quantity *C*, "prod-

uct output." To elaborate on the construction of the trends of the various elements without a suggestion as to the method or process of determining "production" leaves a loophole for criticism among those acquainted with certain types of manufacturing but unacquainted with the possibilities of the kmh method.

The writer feels that it is possible to develop a measurement of production for any plant or any product even among the service industries, but he is often confronted, when discussing the method with others, by a question, for example, How would you measure production in a foundry, one floor of which is devoted to castings weighing tons and another floor to bench work, with perhaps a large amount of die casting on the side? Hence, if a hypothetical case suggesting a method of determining an adequate measurement of production were included, the whole presentation would be more convincing to the uninitiated. Diversified production seems to be the bugaboo which causes the average person to hesitate in indorsing the general application of the kmh method.

On the theory that things equal to the same thing are equal to each other, the writer has worked up a hypothetical case of determining the composite trend of productivity for several plants manufacturing unlike products. (See Table 21). At a given

moment it is assumed that in the broad sense progress has generally reached similar development in our industrial structure (although it probably is never so); hence, the average production per kmh in one industry should be comparable at the same time to the average kmh production in another. To date no one has suggested sufficient reasons to invalidate these assumptions. "Average employment" may be taken to mean either man-hours or full-time jobs; for purposes of theory it is immaterial, as its main function is to demonstrate the handling of plants of unlike size. It is assumed that production per kmh has been developed to start with in each case. The shoe plant was not added until the fourth year, and hence was assumed to be 100.7 per cent productive compared to the year of origin, because that appeared to be the stage of progress which the other five plants had reached. Notice the recessional productivity of the cement plant. Does this not involve the same principles used in compiling data for Table 1?

WALTER N. POLAKOV.[16] The value of the paper is not so much in the method as in the signification of the examples marked out. As far back as 1922 the writer said that "The time rate of man's work is the only measure of production which is of the same dimensionality . . . the scales may be as varied as are the activities under consideration themselves." There is nothing new in that idea, but its application brings to light new and illuminating data and relations. Studying the industrial data in their relation to the man-hour, the authors succeeded in presenting a bold picture, incomplete, to be sure, due to lack of suitable statistics, but believed to be indicative of the new trend.

The cry of today is for leadership out of the welter of fundamental contradictions in which our economic life finds itself. Yet the leadership is not forthcoming, and, it is feared, is due to the lack of full understanding that the old machine age is dead and a new power era is upon us.

Consider for a minute these staggering ratios of the lowest rate to the highest rate of productivity within an industry: Blast furnace, 1 to 9; lumber and timber, 1 to 13; petroleum, 1 to 224, or more especially consider the value of product per 1000 man-hours varying from $9918 to $192,908, and the conclusion that the old standard cannot fit the new relations is inescapable.

In the past we believed that there is a relation between the number of men employed and the volume of output. Today this notion is junked. In the past we believed that there is a relation between the investment and the value of the product. Today we know that for a few dollars' worth of competent counsel and perhaps a slight rearrangement in management, productivity may be doubled and trebled.

Mr. A. W. Mellon recently remarked that we have a "left-over" leadership of men who still think that today's problems are a continuation of the past and do not see that it is new. Perhaps Mr. Mellon can see that it is a new power era clearer than others, because in his own aluminum industry the power use increased in the decade 1919–1929 by 140.5 per cent, and correspondingly wages rose 123 per cent and the number of employees increased 86.1 per cent. Neither is the aluminum industry an exception in this direction. We have studied 40 industries. The trend throughout is unmistakable. Employment and wages have gone up as the use of power and advanced technology progressed during the past decade.

Now we have come to the point of curtailing production as the financial charges and overhead overtook the purchasing ca-

[16] Consulting Management Engineer, New York, N. Y.

pacity of the majority of our population. If we have increased productivity of labor per man-hour, does it mean that we must reduce the "man" component or the "hour" component? The answer seems clear, but the action was in the opposite direction, and we got the worst and the most ominous unemployment.

But reducing number of hours to 1400 per year per man will not establish the desired "balance" between the increased productive capacity and buying power unless the economic scissors—the divergence of prices and wages—is reduced and the scissors are closed.

G. S. RADFORD.[17] The authors' earlier paper on the kmh method impressed the writer with a profound respect not only for the kmh of intellectual effort that went into its creation, but also with its implied promise of future richly helpful and timely revelation. These impressions are bound to be accentuated by the authors' subsequent work as evidenced by this paper.

In fact, as events have transpired, there appears such a degree of fortuitous and fateful timeliness in their work as to make its rapid extension intensely practical, opportune, and necessary. They should be encouraged to extend the analysis as rapidly as possible and to give their interpretations of its implications, at least in general terms, for the more important or key industries.

JOS. A. PIACITELLI.[18] The authors have established eight units of measurement. One of the most significant of these, and perhaps the most difficult to apply correctly, is the "productivity unit." In following the productivity values through, the authors point out that the ratio of the lowest to the highest rate of productivity is 1 to 9 in blast-furnace operation, 1 to 13 in lumber manufacturing, and 1 to 224 in petroleum refineries. Now, before we can determine the degree of credibility in these cases, we should try to get behind the scenes and find out why these ratios exist.

The authors are not very clear in their expression "quantity of output." Can these ratios be due to the fact that the physical volume of the product is expressed in actual units when it would be more desirable to express it in "equivalent" units if a concern manufactures more than one product of similar substance? Are they due to variations in time of processing or the size of the production unit? The quantity of output is not always expressed in corrected equivalent or compound units which would place the various classes of products on the same basis of measurement.

About four years ago, shortly after the authors presented their first paper, the writer interested an executive in making an analysis of the productivity of one of his plants, month by month. In establishing the compound unit for this analysis approximately 150 products were first grouped into classes on the basis of the process involved, and then relative weights were assigned to each class on the basis of kilo man-hours and in terms of the most common class of product. For example, if class A, the most common class of product, is assigned the value of 1 and if it requires 0.6 as many man-hours to produce a ton of class B products as it does of class A, then class B will have a weight of 0.6, and so on. With the compound unit thus established, the amount produced each month is plotted on ratio paper along with the kilo man-hours required to produce them. In this way a month-to-month comparison is being made of the productivity of this plant.

It occurs to the writer that it would be wise to enlist the aid of the various A.S.M.E. professional divisions in establishing the compound unit of volume with respect to kilo man-hours for the various groups of products in each industry. With these kmh relationships for the various classes of products as a basis, it should not be a difficult matter to group them into a compound unit and make reasonable comparison of concerns in one industry. We must certainly be able to do this before we attempt to compare one industry with another.

The authors point out the effect of productivity on working periods, and if the results of their studies of the industries selected are representative of America's industrial structure, then the shorter work week is here by necessity and here to stay. The six-hour day and five-day week, wherever practicable, are not far off. We will either have that or continued unemployment difficulties.

L. W. WALLACE.[19] The writer is greatly interested in this paper, for it represents fundamental research and indicates an important method of making a more effective analysis of industrial operations. The authors' thinking is receiving wide study and application. It is interesting to know that Congress has instructed the Department of Labor to make a continuing study of technological employment. Something over a year ago the Secretary of Labor organized a committee to study the problem and advise the department as to the line of studies that would be the most beneficial. Its work disclosed that there was real need for a new approach to the analysis of industrial operations; hence the committee approved the Alford-Hannum method and included it in its report to the secretary. The report of the Committee on Technological Employment has been printed by the Government, and is recommended to the consideration of any one concerned with the broad problem it deals with, and as an evidence that the Alford-Hannum method is receiving consideration by governmental officials.

Mr. Eaton and Mr. Alford challenged the writer's statement relating to technological employment. The writer was thinking of one phase of the problem and they were thinking of another. If they will carefully read the report, they will get the full import of what the writer was saying and would then probably not disagree with the statement. This is another evidence of the need for the standardization of definitions. In this case there is need for a clear-cut definition of what is meant by technological employment. It is rather fully discussed in the report referred to.

AUTHORS' CLOSURE

The comments in the discussions are, in the main, so favorable to the paper that elicited them that little needs to be said by way of closure. However, a few additional comments are justified. They will be given in the order in which the occasion for them appears in the discussions.

Baum emphasizes the value of applying the kmh method to cost accounting, budgeting, and the analysis of direct and indirect labor costs. He says, "Each cost element which has to do with labor in plant and office can be given an absolute measurement by the kmh method;" and, referring to standard cost systems, "The kmh system will some day find universal application in such cost systems."

Curtis' discussion is along this same line when he says that he has "... proved conclusively that its use [kmh system] in costing, estimating, and scheduling is efficient, accurate, and most valuable in controlling factory cost during periods of normal and abnormal operating capacities."

The authors are conscious of these possibilities, have done some work in these fields, and in their next presentation intend to make a prominent feature of the application of kmh to cost accounting.

[17] Consulting Engineer, New Canaan, Conn. Mem. A.S.M.E.
[18] Consulting Engineer, New York, N. Y. Assoc-Mem. A.S.M.E.
[19] Executive Secretary, American Engineering Council, Washington, D. C. Mem. A.S.M.E.

Coes turns to the implications of the findings in the paper, pointing out certain indications. The " . . . gradual reduction in the kmh to produce society's needs for basic commodities in the stabilized industries;" " . . . the necessity of reducing working hours per week for constant production, assuming a balance between consumption and production;" and " . . . base compensation on the required hours per week and consequently at a much higher hourly base rate." Radford refers to the possibility of interpretation of the findings and hopes the authors will do this ". . . at least in general terms, for the more important or key industries." Polakov also directs his discussion to the significance of the examples.

The authors are in full sympathy with these comments, and have felt strongly the urge to offer explanation and interpretation of the findings brought forth by the kmh analysis. Hitherto, they have rigidly excluded all such comment, for the reason that they particularly wished to present their method of analysis and to show its possibilities. The data used and findings disclosed were incidental to this main purpose. They believe, however, that from now on more attention should be given to the findings, their implications and meanings, for the kmh method now seems to be established as one of the working tools of the engineer and industrialist.

Parker and Hopkins, La Fever, and Wallace give strong approval to the application of the kmh method to the analysis of employment and unemployment. The first two state, "The kmh units of measurement show trends in employment and the effects of technological changes more accurately than do figures from any other published source, and make possible a regular and frequent check on employment trends;" and " . . . a common denominator for measurements of labor seems clearly indicated." La Fever opens his discussion by saying, "Basically, the kilo man-hour provides correct measurement of the trends of employment." Wallace refers to the consideration being given to the kmh method in governmental circles, and points out that there is " . . . real need for a new approach to the analysis of industrial operations."

This generous recognition of the value of the kmh method in the study of employment and unemployment is especially gratifying to the authors. In spite of the tremendous amount of work done in studying all aspects of industrial labor, the need for a satisfactory analytic method had not been met. If the kmh method realizes its seeming possibilities in this field, we shall be richly repaid for the work involved in its development.

Huntington hopes " . . . that this paper will reach well out into the commercial world." It is too soon after its presentation to hazard a prediction as to whether this hope will be realized. However, the kmh paper of 1928 attracted far more attention among business men than among engineers.

Berger lists and objects to several assumptions which he says are in the kmh analysis: "The effectiveness of management is disregarded;" the " . . . effect of financial backing on raw material cost per kmh and on equipment policy which affect productivity per kmh" is not brought out; and "The most dangerous . . . is that actual wages paid are adequate economic wages."

These assumptions are Berger's and not the authors'. In the entire kmh disclosure there has been but one assumption. That is in the paper of 1928 and is: " . . . that on the average an hour of work in one industry, or in one plant, is the substantial equivalent in human effort (mental, manual, or combined) of an hour in another industry or plant."

Berger also includes a table of economic wages, taking his data from the 1928 paper. He does not give his formula whereby "economic wages" are calculated, and for that reason little can be said in reply. However, the creditability of the data in the 1928 paper is not high, as was plainly stated at that time. For this reason, alone, considerable doubt must be expressed as to the value of Berger's computed figures.

La Fever and Piacitelli point out the difficulty of expressing the "productivity unit" in physical quantities. This difficulty is real in some situations, particularly where products must be combined. However, the authors believe that skilful experimentation in any situation will yield a satisfactory solution of the problem.

La Fever suggests certain changes in the names and designation of the units involving the "worker." He prefers the term "job." The authors are grateful for this suggestion, which seems to be sound. When the terms in the paper were "coined," the authors were trying to give expression to new concepts in connection with employment, and were never entirely satisfied with their final selection.

La Fever objects to the setting up of a constant production factor in the analysis of rates of change. It is true that this constant is theoretical and not factual. However, the period of time to which it is applied is so short that surrounding production factors will have varied from simple rather than from complex causes, and its use gives a striking presentation of the rates of change of the associated factors. The kmh system is based upon a study of rates. If these rates are to be projected to indicate possible happenings, some bases of prediction must be selected.

La Fever presents in Table 21 a study of composite productivity. These composites he builds up from index numbers. The method he uses seems to have standing among statisticians. The authors have been unwilling in their work to apply mathematical processes to index numbers, considering the latter as expressions of relationships only, not as quantities. La Fever's study, therefore, while interesting, seems questionable because of the method used. However, his objective is highly commendable.

Progress in Materials Handling

REFLECTING general business conditions, activity in the material-handling field has been considerably restricted during the past year. This restriction has occurred in spite of the low prices of equipment and the evident savings possible with suitable material-handling facilities.

The sale of all kinds of machinery, of course, has been abnormally low, but the sales resistance to processing equipment is somewhat less than that to material-handling equipment. It is easier to see the need of a machine actually to make a product than of a piece of equipment to cut costs between machine operations. But often the lack of material-handling equipment more than sacrifices the savings made by an efficient processing machine. A double saving is possible, in many cases, when the installation of a new machine is accompanied by new material-handling facilities.

Savings Possible by Improved Handling

It is not necessary, however, to wait until new manufacturing machines are purchased to make improvements in material-handling methods. Many of the instances of substantial savings have occurred recently in plants that installed handling equipment without any change in processing machines aside, perhaps, from a new layout. In fact, there is scarcely a plant now operating at a loss, or at an extremely small margin of profit, that could not better its situation by improving its handling methods. Better handling may turn operating losses into profits. Even highly efficient plants make large savings by changes in material-handling methods. One large automotive plant, noted for its excellent handling facilities, at one time saved $275,000 in four months ($825,000 annually) by installing new handling equipment and changing the layout and methods at the beginning of its chassis-assembly line.

A conservative estimate of the savings possible by improvements in material-handling equipment ranges from 2 to 20 per cent of the total shop-labor payroll, direct and indirect. It is not impossible for the actual handling operations within a plant to total 60 per cent of the total work and the total labor cost, notably in plants that are concerned largely with simple processing of raw or semi-finished materials where packaging or repackaging constitutes a large part of the work. A plant of this kind, at present lacking in suitable material-handling equipment, can save as much as one-third of its labor cost by installing such equipment. One-third of 60 per cent is 20 per cent, the saving in total labor cost that probably can be brought about under such conditions. Higher savings are possible in cases where no attention has been paid previously to material-handling methods.

Progress Hampered by Two Factors

Material-handling progress is hampered from two sources—one within and one without industry. In both cases the obstruction is based on lack of knowledge and on unfortunate misconceptions.

Within industry the trouble arises in those managements controlled by officers or directors who originate from non-industrial fields. Banking, legal, commercial, and even political connections and obligations sometimes place enterprises under the influence of such groups. Plant administration is thus directed more along financial lines than along sound industrial and economic channels. The stock-market crash, the difficulties facing many mergers that got into trouble during the past two or three years, and the widespread readjustments of capital structure that occurred (partly through accounting measures and partly through actual reduction of stock values, but both acknowledging actual capital losses), all attest to this misdirection of emphasis. If the efforts and funds thus overconcentrated on financial matters had been expended, in part, on improving material-handling facilities in factories and shops, the profits made could have been permanent and not evaporative. Material-handling proposals meet too much sales resistance in the executive offices and board rooms for the general good of industry, and the resistance often is not based on good business judgment nor on a knowledge of the needs of the plant.

From without industry, the obstacles in the way of extensive use of material-handling equipment arise among those who are conscientiously laboring to solve the unemployment problem but in a field that unfortunately they know little about. It is not wise to pay much attention to agitation recommending a slowing up of technical and manufacturing progress in the effort to increase employment. Such agitation emanates from persons little informed on the fundamentals of industry and its possibilities of development.

Economics and Material Handling

In the first place, wealth in the economic sense comes only from the agricultural, extractive, and production activities of a nation or a group of people. Certain facilitating services, such as transportation, communication, finance, etc., add place, time, or "fluidity" utility, but are not creators of wealth. The correct distribution of wealth among those who produce it, or facilitate its production, gives purchasing power on which the ability to satisfy demand is based. There must be a balance between purchasing power and price so that each group of persons will be able to acquire goods and services sufficient to satisfy their reasonable needs and maintain or improve their standards of living. Anything that reduces the cost of making a product, and consequently its economic selling price, brings it within the purchasing power of wider groups of people. Material-handling equipment reduces such costs, and therefore fulfils an important economic function.

Even in those industries that ultimately may reach current saturation points—where the existing population of the nation or the world cannot absorb more without waste, because all needs are satisfied at prices practically within the reach of all—a further saving by cost reduction will place commodities on the market at lower selling prices, but with the same, or greater, total profits and greater percentage profits to the makers. Surely this is worthwhile, for why should we spend more time and labor on work than is necessary?

Material-handling equipment certainly tends to reduce the amount of human energy expended in the making of products. In this sense, of course, it cuts down employment. We could go in the opposite direction, however, as did the Canadian road builders who purposely reverted to pick-and-shovel work on a big job in 1932, and celebrated the increased employment of hand labor by burying a miniature steam shovel, the symbol to them of a technical progress that had brought about widespread unemployment. But one speaker, in commenting on this move,

---

Presented at the session of the Materials Handling Division, Tuesday morning, December 6, 1932, during the Annual Meeting, New York, N. Y., December 5 to 9, 1932, of The American Society of Mechanical Engineers.

Personnel of the Executive Committee of the Materials Handling Division for 1932: J. B. Webb, Chairman; M. W. Potts, Secretary; C. D. Bray, F. L. Eidmann, E. D. Smith, G. L. Morehead; Associates: R. H. McLain, G. E. Hagemann, F. D. Campbell.

pointed out the huge wastes that would follow a general adoption of such a plan, and the huge costs it would entail on the taxpayers. Quite properly he added, "Why didn't they use toothpicks on this job! Toothpicks would move even less earth than the shovels!"

It is not the job itself, as such, that is the pivotal factor, but the job *economically* done. The creation of wealth in the form of goods or services that can be distributed to everybody is the important factor in employment, not the mere employment itself. A foundry could engage a small army of men to carry pig iron by hand, unit by unit, from freight car to cupola; sand, bucket by bucket, to the mixing and molding machines; molten iron, ladle by ladle, from cupola to flask; but who would pay the exorbitant price for castings made under such methods? If we would not go back to plans like these because we have found ways cheaper and better than such antiquated methods, why not continue to go forward?

Herein lies the trouble: The need exists for some sort of control over technical developments so that plans can be made in advance to take care of the labor that will be displaced. Industry has social obligations to give useful employment to all who are qualified and desirous of employment in industry. A forecasting of the employment shifts that must follow imminent technical developments must be made. Perhaps strong trade associations can be formed to which advance notice of changes can be made, in confidence. Then, perhaps through a central federal employment bureau, with state and municipal branches, arrangements can be made to absorb the workers who probably will be displaced. Unemployment insurance may have to be provided to carry over those who cannot be readily readjusted. Extensive training facilities will be imperative not only to train men to fit the changes in occupation that they must undergo, but also to give all workers greater training to enable them to become more adaptable. Lack of such means at present is the cause of the "45-year-old man" problem in industry. The training courses must be conducted in part by industry and in part by universities and state, county, and city boards of education.

New developments will absorb some of those displaced by technical improvements and compelled to seek other employment. Others who are displaced will be absorbed by industries making the equipment that caused the displacement of labor. The increasing demands for service facilities, which multiply rapidly with the growing complexity of society, will provide employment perhaps for the remainder displaced. Service facilities include public works which may have to be increased or decreased to aid conditions. Furthermore, the workday has been gradually shortened in industry and further shortening of the workweek can be of assistance. Individually, the workers displaced from the factories may find employment in the service or distribution channels of these industries. The man losing his job in an oil refinery may open a gasoline station; the man laid off by an automobile factory may become a garage mechanic. The difficulty is not that technological progress causes unemployment, it's the *delay* in making the adjustment that really causes the unemployment and the resultant suffering.

Foreign Competition

There is another angle to the situation that is not often remembered. To a certain extent, nationalism does influence social developments. We necessarily are limited in the comprehensiveness of our undertakings because of the differences in climate, language, habits, customs, political background, and racial characteristics of the various countries. Each nation develops largely within itself because it cannot go outside and reconcile its political, social, and racial characteristics with those of other countries. There is usually no common basis of interchange of ideas, such as exists internally, that completely overcomes national barriers. However, technical progress can jump all barriers even though the products made through such progress cannot so readily surmount such obstacles. Hence, active, progressive industries within a nation push technical and industrial progress to the limit of their ability, to secure commercial and trade advantages and not be outstripped by other nations. Should we hamstring technical progress at home and therefore lose pace with what is going on abroad? Even friendly national competition would hardly countenance such a course. Should we deprive our people of the benefits of progress while those of other nations enjoy and profit by advances in science, invention, and the industrial arts? None would agree to this plan. Those who would put on the brakes in the interest of employment should realize that this step will have the directly opposite effect, and will throw our workers out of jobs while those of foreign nations will be the ones most benefited.

Material-Handling Equipment Does Not Have to Cause Unemployment

The foregoing analysis is presented to remove the misconception that material-handling equipment must cause unemployment. It naturally causes some *shifts* and readjustments in employment. It is "labor-saving equipment" in that it removes much of the drudgery from industrial work, and performs many tasks that would be impossible—certainly economically impossible—without it. But it is preeminently "cost-reducing equipment." Material-handling equipment manufacturers and users should clearly recognize the distinction and cooperate in efforts to stamp out the false, even though well-meaning, propaganda against the development and installation of such kinds of equipment. To clear up any existing misunderstanding on this point, the material-handling formula itself has been renamed the "cost-reduction equipment formula" or "economic equipment formula" and is no longer called the "labor-saving equipment formula."

The Material-Handling Formula

This formula, useful for productive-machine equipment as well as for material-handling devices, is not applied anywhere near to the extent that it should be by users and prospective users of material-handling equipment, who could discover worth-while savings from proposed new equipment through this medium. It is not employed as much as it should be by manufacturers of material-handling equipment, who could stimulate sales if they would train salesmen in its simple arithmetical calculations, and in the related cost-finding work applicable to clients' material-handling problems. The simple formulas, expanded in 1925 and refined in one or two subsequent studies, will yield all the results needed in most cases. In fact, when applied to material-handling equipment, they often point out savings of far greater extent than when applied to many productive-machine installations upon which some user was easily "sold," and to his benefit. Further developments in the formulas, suggested by Prof. Fairfield E. Raymond and H. L. Vorlander in their paper on "Economic Life of Equipment," presented before the Society in December, 1931, still await the cooperation of manufacturers and users of material-handling equipment who are asked to present concrete cases out of their own experience to Prof. Fairfield E. Raymond, Massachusetts Institute of Technology, Cambridge, Mass., for investigation and solution. Eventually, a series of simple formulas for various groups of cases will evolve from Professor Raymond's studies of such examples.

Sales Problems in the Industry

There are two troublesome problems facing installation of

better material-handling equipment and methods. The first lies partly within and partly without the industry and causes the second. A material-handling installation usually involves more than the selling and placement of a unit of equipment to do a certain piece of work. While many productive machine tools are standard and can be sold on the basis of performance as units, without a study of more than the particular operation that they are to do, a large percentage of material-handling installations, on the contrary, require an engineering survey to develop a system that will serve a number of operations—perhaps the entire manufacturing cycle—satisfactorily and economically. A personal, detailed investigation by a sales engineer, and sometimes considerable designing and calculation, are required before a proposal can be submitted and a price quoted. Prospective users have not hesitated to avail themselves gladly of such free services from a number of competing material-handling manufacturers, only one of whom could get the contract, with a profit sufficient to give him only a normal return on his venture. The losses to the other manufacturers, in engineering services and drawings, have had to be met at the expense of their own business development, or else have been spread over succeeding jobs secured, or equipment sold with little engineering service. A general regulation of services to the submitting of general proposals and prices, subject to engineering revision upon securing the contract, or to a charge for any actual engineering survey made for the prospective user prior to submitting bids, is required for the stabilization of the material-handling industry. Under present circumstances, the user cannot be blamed for adopting for his installation a number of ideas submitted in competing surveys and drawings, or for agreeing to have such surveys made, and then deciding not to make any installation, or to do the work himself.

The second problem is caused by certain "marginal producers" who unwisely introduce into the industry the same problem that is faced by other industries, namely, unwarranted price cutting, which is to be deplored because it is uneconomical in the end for both manufacturer and user.

New Equipment Developed

The reports received from manufacturers indicate that not as much new equipment was developed during the past year (September, 1931, to October, 1932) as was the case in previous years. This condition was to be expected on account of business conditions. Manufacturers of consumer products often could sustain business activity by introducing new products, but manufacturers of equipment for industrial use were not so fortunately situated.

Conveyors[1]

The Lamson Company lists three new devices developed since September, 1931. The first is a "Traylift," a conveyor designed primarily for handling trays of dishes vertically, either ascending or descending. It consists of a so-called Uni-strand vertical conveyor, and is motor-driven at the upper end, the final driving medium being a lower chain and sprockets. Devices are provided on this drive to protect the machine and operators in case of accident. The main carrying chain has arms at suitable intervals to provide a capacity of six to eight trays up and down per minute. The loads do not pass over either the upper or lower carrying sprockets, but are carried up to a predetermined level and, if they are not removed, the machine is automatically stopped. A similar arrangement is provided on the down-bound travel.

The second device is a "Trayvator," an elevator or lowering unit for the handling of trays. It consists of a reciprocating unit so arranged that the placing of the load, for instance at the bottom on the platform, will automatically start the machine and it will travel to the upper level and automatically stop and remain in this position until the load is removed. A similar arrangement is provided for down-bound travel. This unit may be made fully automatic, or entirely manually operated, or semi-automatic. The operating medium is an electric motor with suitable drive connections, while the raising and lowering element consists of an endless chain, thus insuring continuous motion in both the up and down directions. This unit may be built as an entirely self-contained device which may be installed quickly and effectively in locations where the service demands are not such as to require the use of the more elaborate continuous machine.

The third device is a "Selectoveyor," a conveyor that automatically selects commodities to insure their delivery to a predetermined station. This type of machine presupposes the use of a uniform-sized tray or box on which an indicating mechanism is mounted that may be sent by the operator to the predetermined delivery point. Upon its dispatch to the vertical conveyor, this indicating mechanism automatically sets another mechanism on the car, which, upon its arrival at the predetermined destination, automatically throws into operation a discharge station. This discharge station operates through a very small angle and, having no close clearances nor intermeshing arms, the box or tray is automatically discharged and the car upon its continued travel again resets the unloading station to the inoperative position. This machine provides for the utmost flexibility and may be applied to any number of floors in a building up to a present maximum of twenty. In connection with this machine, automatic loading of trays from a loading station outside the shaft containing the conveyor may be provided. Similarly, completely automatic safety devices are provided to insure the safety of the machine and operators in case of non-delivery of a tray or box, or of improper dispatch by an operator.

The Mathews Conveyor Company recently made two interesting installations of material-handling equipment. The first is that furnished for the Hastings Potato Growers Association's packing shed at Hastings, Florida. The system includes a belt conveyer, potato grader, vegetable washer, drier, etc. This is the first set-up used primarily for the washing of potatoes on a wholesale scale. The farmers' wagons and trucks back up to the platform and laborers dump the potatoes on to a conveyor, which carries them to the dirt and undersize eliminator. From there they are discharged to the receiver end of the washer and, after traveling through an impeller wash, they are discharged to the drier, which consists of a battery of blowers mounted over a rolling roll conveyor that automatically turns the potatoes over as they pass under the current of air. This action removes loose water from the potatoes, and from the point of location of the blowers to the discharge end of this unit the potatoes have ample time to dry before entering the grader. Fig. 1 shows the blowers in position, mounted over the top of the rolling roll conveyor. Picking out of imperfect potatoes is done alongside this rolling roll conveyor, pickers being stationed on each side of the unit. This installation has a capacity of 1100 bushels per hour. The present models have capacities ranging from 6 to 20 cars per day.

A most unusual application of heavy-duty roller conveyors, is that of a 90-deg twisted-spout conveyor furnished the Sharon Steel Hoop Company, Sharon, Pa. Fig. 2 shows the 90-deg twisted spout and vertical Y-sections of the heavy-duty roller conveyor.

[1] The data on new equipment were obtained through the kind assistance of representative men in the various fields, and by means of about 200 questionnaires mailed to individual manufacturers. Information on conveyors was collected under the direction of the following: Gravity conveyors, Frank E. Moore, president, and W. J. Ramsey, of the Mathews Conveyor Company; continuous conveyors, Jervis B. Webb, president, Jervis B. Webb Company.

Fig. 3 is a quarter-sectional view of the Mathews Type No. 100-B bearing and roller construction. This design has a continuous load rating of 8000 lb per roller. It is the largest of the line. The smallest has a continuous load rating of 150 lb per roller, and there are various sizes in between these two, having load ratings of 600 lb and 2000 lb per roller.

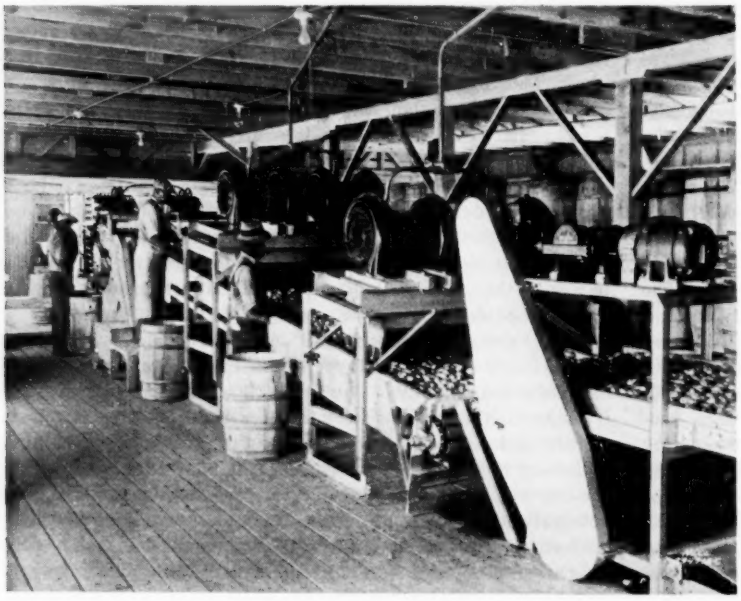

FIG. 1 BLOWER AND ROLLER-CONVEYOR SECTION OF A POTATO-WASHING INSTALLATION

The Standard Conveyor Company has developed rollers and bearings for conveyors, of which Fig. 4 shows one of the latest. In this design there is a heavily constructed ball bearing, protected both front and back, and using steel shields as retainers for the seal. The center of the inner shield is bent inward, forming a funnel shape to keep the grease from working out through and into the roller. The seal is a special but inexpensive grease which is forced through the end of the shaft. The shaft is crossdrilled to allow the grease to come in between the shaft and the inner ball race, then through the inner ball race to the chamber between the bearing and the outer shield. The rotation of the roller and outer part of the bearing carries a sufficient quantity of grease to the inside chamber, thus completely surrounding all working parts with an effective seal designed to eliminate wear. The time for replacing or flushing the bearing varies from 12 to 24 months. When the grease is replaced, any dirt or grit that may have accumulated around the outer edge of the steel shield is automatically flushed out. In addition to keeping out foreign matter, this type of seal also protects the bearing from rust. The hexagon-shaped shaft furnishes a positive lock for the inner ball race. Although this lock is particularly important when the bearing is not protected, it is also an important item where rollers are spinning idle after the commodities have passed over and the inner unit tends to slide around and would wear down the shaft.

A one-piece roller is also furnished in the lighter gages for use in handling light commodities. It is important to have free-running rollers and ones that are concentric so that the lightest commodity will start the rollers with the least possible resistance, because on long lines not enough pitch may be available to overcome high friction. These rollers are of one-piece construction and there are no inserts to get loose. Their rounded smooth ends adapt them for loading and unloading from the sides. The rollers are also used as idlers for belt conveyors.

The Sandvik Conveyor Manufacturing Company recently installed a steel-belt noodle cooker, of unique design, in the plant of the LaChoy Food Products Company, of Detroit, to produce high-quality chow mein noodles. A fabric-belt conveyor delivers the uncooked noodles to the steel belt (see Fig. 5). By the use of snub rollers, the steel belt dips down into a 20-ft long tank of hot vegetable oil, thence operating horizontally through the cooking oil and submerging the entire stratum of noodles, which have been uniformly deposited on the belt. The vegetable oil has a temperature range of 250 to 325 F. The steel belt is 24 in. wide and the approximate center distance between drive and take-up pulleys is 35 ft. Belt speed is variably controlled, ranging from 2 ft to 8 ft per min.

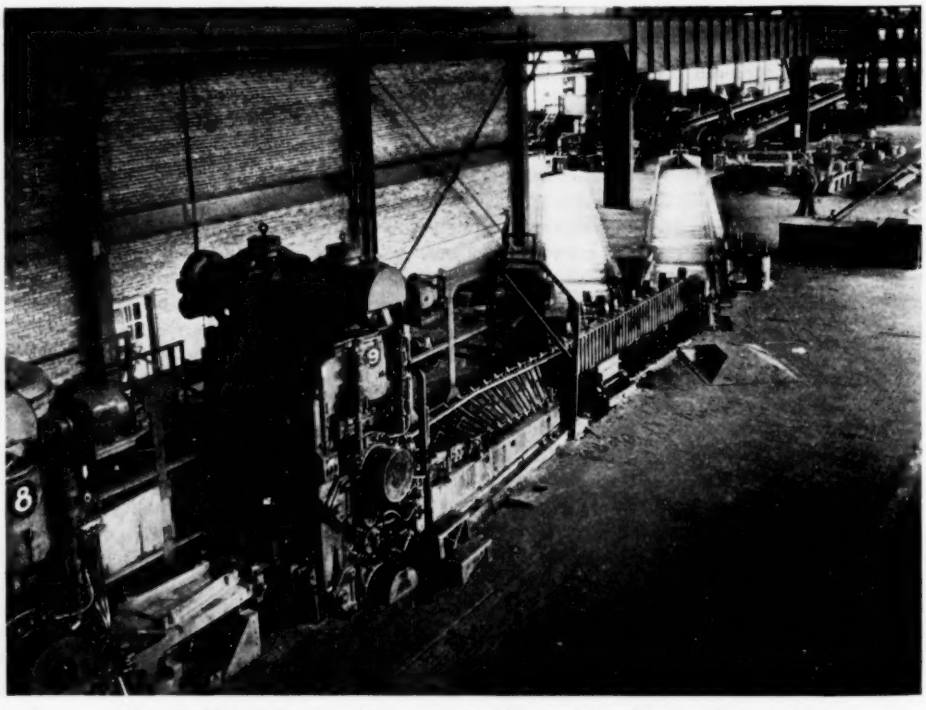

FIG. 2 NINETY-DEGREE TWISTED-SPOUT HEAVY-DUTY ROLLER CONVEYOR

At the unloading or discharge end, the steel belt operates on an incline, thus carrying the cooked noodles out of the tank, and thoroughly draining them of oil, which returns by gravity to the tank. The noodles are then automatically carried by belt conveyors to the point where they are packed in containers. The overhead traveling chain, to which rakes are attached at intervals, operates directly over and at the same speed as the steel belt. This chain, with the rakes, keeps the noodles in position on the steel belt while traveling through the hot oil and also up the incline at the discharge end of the unit.

Steel skirts are provided at each edge of the steel belt for the length of the tank, thereby forming a perfectly tight trough. This arrangement prevents any spillage of noodles into the tank and consequently the purity of the oil is not lowered and its period of usefulness is greatly increased. This feature is an attractive element of the equipment, because any product spilled into the tank would settle to the bottom and burn, thereby necessitating frequent cleaning of the tank and renewal of the cooking oil. The steel belt is kept clean at all times by automatic means provided for this purpose, thus removing any possibility of rancidity or taint to the product.

Previously noodles were cooked by intermittent overhead basket-type conveyors, and were hand-dipped into a kettle for cooking. The output per hour by the old method was 60 lb; it is now 250 lb. The saving in labor effected by the installation is 40 per cent, in oil used, 30 per cent, and in fuel consumption, 50 per cent.

A chip conveyor on the new "American" 100-hp, 22-in. lathe developed for testing metal-cutting carbides, handles 15 cu ft of chips per min, or more than 2 tons per hr. The chips are fed to the conveyor by a sloping bed and chip pan.

SPEED REDUCERS AND DRIVES[2]

The Palmer-Bee Company reports that, with many satisfactory speed reducers now available, the progress of development of the past year has dealt more particularly with refinements and improvements of design and construction rather than with the design of entirely new machines. Present conditions demand economy, both in first cost and operating cost. However, there exists a tendency on the part of both buyer and manufacturer to hold first cost so much in view that it completely overshadows operating cost. This trend can be, and probably has been, carried too far in many instances. True low cost can be described only in terms of cost per unit of capacity per year. In this item must be included first cost, maintenance charges, operating charges, and depreciation and obsolescence based on the useful life of the machine.

With these facts in mind, the company has carried on investigations of existing designs, and has developed new and desirable characteristics in its machines. Studies of tooth surface tension, zones of contact in worm and herringbone gears, and materials and their heat treatments, have made possible a new procedure in design which is based on the prevention of tooth pitting and inordinate wear, without recourse to special lubricants. The breaking value of the teeth is considered, but it is based on the fatigue limits of the materials used. From the breaking point of view, all of the company's H-series speed reducers will now safely carry 200 per cent of rated load and still be within safe allowable working stresses. Even these high values, while they protect the machines from failure through tooth rupture, are not sufficient without proper consideration of tooth wear. Stated simply, the contact pressure between the meshing teeth may be so great as to cause pitting of the contacting surfaces. This action rapidly leads to wear, and although the teeth will not break off, they will wear out. This wear may not cause immediate shutdown of the equipment, but it does materially lower the efficiency of the unit and will necessitate eventual shutdown for repairs. The company now rates its gears to give full and proper consideration to the contact pressure, based on the materials used in the gear and pinion, the zone factor existing between the gear and pinion, and the radius of curvature of the teeth.

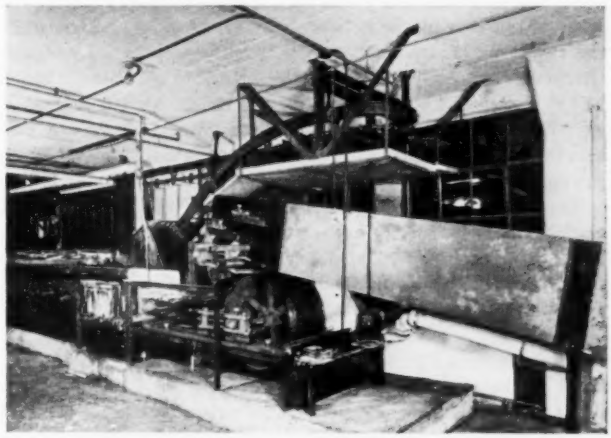

FIG. 5 STEEL-BELT NOODLE-COOKING UNIT

To a great extent, gear efficiency and life depend on the materials used for gears and pinions, and tooth form. They also depend upon the ratio between the two members, gear and pinion, and the number of teeth in the pinion. In its designs, the company no longer attempts to obtain the maximum possible ratio from a given number of gear steps, but first considers efficiency in determining the maximum ratio for one-, two-, or three-stage reduction.

Special attention has been given to the application of anti-

[2] Information collected by William E. Bee, president, Palmer-Bee Co.

friction bearings to speed reducers. In connection with bearing mounting, secondary stresses have been eliminated by getting away from constrained types of mounting. This plan has effected economies and given much better load factors in the bearings. The method of lubrication employed for either standard or special high-speed units has not been changed.

The Stephens-Adamson Manufacturing Company has developed a new type of variable-speed transmission known as the JFS transmission. Hardened steel disks are splined on two shafts. One is driven by the motor or other power source, while the other transmits the power to the machine to be driven. A series of rollers is placed between each of the disks and transmits the power by means of the traction between polished surfaces. Originally, this traction was set by means of set screws, which had to be tightened a trifle from time to time. This arrangement gave a constant pressure for all loads, light and heavy. A cam arrangement is now placed on each side of the machine to increase the pressure as the load is increased.

Some tests have recently been made on the latest type of machine with two disks on one shaft and three on the other. These tests indicate an efficiency ranging from 85 per cent to 95 per cent, with pressures ranging from almost 0 up to 300 lb, depending on the load transmitted. The speed ratio is changed by moving the rollers between the two shafts. The normal variation is from 2.3 to 1, past 1 to 1, and up to 1 to 2.3. The drive can be arranged to give a uniform range of about 5 to 1. When once set, the speed ratio remains constant until the position of the rollers has been changed to give a new output speed.

Mechanical Handling Systems, Inc., has designed an automatic load control for conveyor drive units, and the like, which can be used either as a means for stopping the conveyor in case of a jam, or as a device for synchronizing multiple-drive units when the conveyor is driven at more than one place. For this latter purpose it can be used in any equipment where it is necessary to synchronize the speed of multiple drives.

The device, Fig. 6, is used in combination with a variable-speed transmission, and, in accordance with a predetermined load variation, automatically speeds up or slows down the drive. This action is accomplished through a balancing arm installed

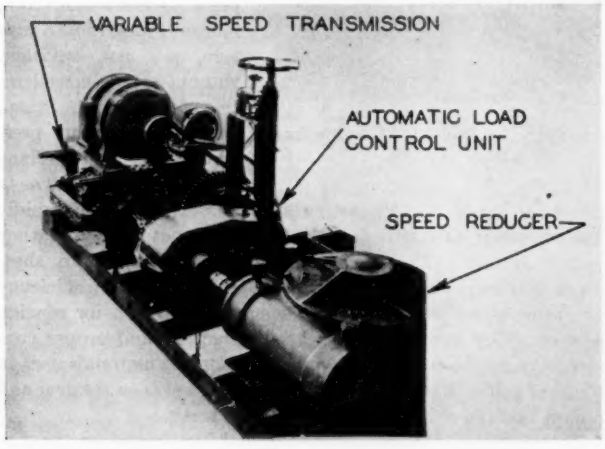

FIG. 6 LOAD CONTROL FOR CONVEYOR DRIVE UNITS

between the variable transmission and the reduction unit. This balancing arm is counterweighted to sustain the normal conveyor load. When this load varies up or down, the balancing arm reacts immediately upon the electrical remote control device that regulates the speed of the variable transmission. This arm is so sensitive that a fractional variation in load is measured at once and compensated for. When the control is used as a safety device, any dangerous increase in load imposed on the machine or conveyor, due to accidents or other reasons, will cause the balancing arm to operate a limit switch cutting off the power.

The Jervis B. Webb Company has introduced a new development in synchronous conveyor drives, described in a paper on "Application and Design of the Floating Drive for Conveyors," by N. H. Preble, engineer of the company, presented in December, 1931, and published by The American Society of Mechanical Engineers.

TRAMRAIL EQUIPMENT[3]

The 1932 developments reported by the Cleveland Tramrail Division of the Cleveland Crane & Engineering Company are as

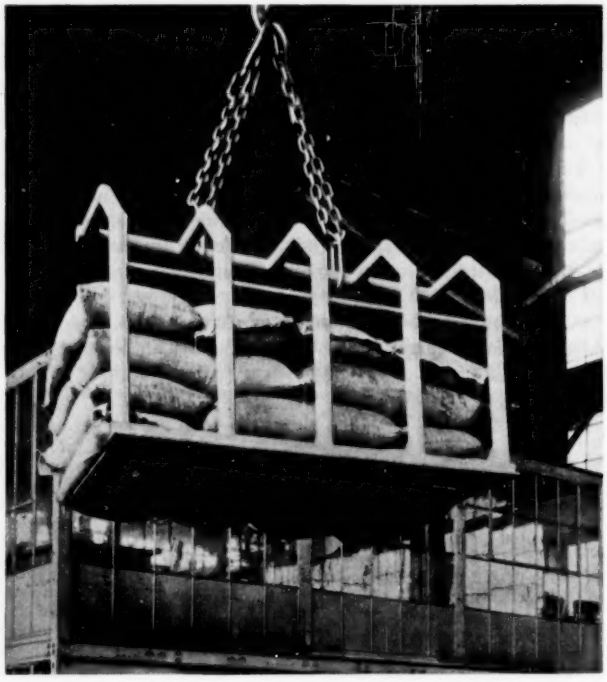

FIG. 7 GRAB FOR HANDLING BAGGED MATERIALS

follows: The arch-beam rail system was further developed by adding the Series 2400 arch beam, also called the 8-in. arch beam, comparable in all respects (except as to loading) with the original 10-in. Series 2500 beam. This 8-in. arch beam is designed for use as a self-supporting rail for handling of light loads where it is not practical or economical to suspend the regular rail from superstructure. The arch beam consists of a composite section. The lower portion is a high-carbon rail and the upper portion is scalloped, or arched, by slitting a Bethlehem I-beam, which is then welded to the lower high-carbon rail of the arch beam. New suspension fittings have made possible the further application of flexible suspension. The arch beam, being a self-supporting member on a longer span, is suspended on alloy-steel hanger rods, the upper ends of which are provided with a rounded head fitting in a cupped ceiling fitting, providing a ball-and-socket suspension. The lower portion of the hanger rod is threaded and fitted with a rounded nut that engages with a hardened-steel, inverted-concave washer, which is part of the coupling assembly, thus incorporating the ball-and-socket method of suspension in the

[3] Information collected by A. F. Anjeskey, sales manager, Cleveland Tramrail Division of the Cleveland Crane & Engineering Company.

lower fitting of the suspension system as well as in the upper fitting. This suspension, and the design of the couplings that join the various lengths of arch beam, requires less headroom than the conventional method of fittings attached to the upper flange of an overhead rail. Electrically welded steel sections have been substituted for castings, etc. in various parts of the tramrail systems, thus increasing their strength and effecting economies in manufacture.

The company has also designed a grab, Fig. 7, for the handling of bagged materials. This grab consists of a framework provided with tines at its lower end, which are inserted between the spaces usually formed when the edges of bags are piled close together. The grab is designed to handle approximately one ton of bagged material. In the case of sugar and similar heavy commodities, sixteen 100-lb bags can be placed on the grab, delivered to the storage point and deposited by withdrawing the grab. When later reclaimed from stock, the same unit load of 16 bags can be handled by reinserting the grab between the bag spaces. Tests have indicated that, even with bags in storage for a considerable length of time, the space between the bags is always large enough to permit reinserting the tines of the grab the full length of the bags. In using the grab, it is necessary to pile the bags in such a manner that they interlock, forming a unit of as many bags as the grab is capable of handling. This grab can be used also for handling any objects that, when piled close together, leave a space between them for the insertion of some modified form of the grab.

The Osborn Manufacturing Company, during the last year, through its Materials Handling Division, has developed, and is now in the process of testing, a new overhead tramrail line, to be known as the Osborn Tramrail Systems. It is complete in every way to fill the needs of overhead handling up to 6000 lb capacity, with either hand-operated or motor-propelled trolleys. The lift on the trolleys may consist either of chain block or electric hoist. These lifts can be furnished in either hook-on or built-in designs.

The new system has minimized headroom loss to an extreme. It has simplified erection by its very complete group of ceiling fittings, by jig drilling all rails at the factory, and by having the correct rail for all span conditions. It is built entirely of steel, with large factors of safety. Switches, turntables, and transfer bridges have safety equipment, and the electrical equipment meets the Underwriter's requirements, as well as the industrial codes of the various states. Standardization of rail widths has been accomplished by selecting a width that permits the system to tie up with other systems. The plant has been tooled up completely for mass production with precision methods, and is further continuing its research.

A New Principle in Bulk Handling[4]

During 1932, an American manufacturer, The Pneumatic Scale Corporation, Ltd., secured the patent and manufacturing rights to a conveyor that had been placed on the market successfully in England a few years before and of which several specially designed installations had been made in Europe and Africa. The principle of this conveyor was discovered by chance. Arnold Redler, the inventor of the equipment—the Redler conveyor—was a flour miller who had devised a seasoning method for flour in bulk, and reclaimed the flour by having the floor of the vertical-sided seasoning bin alive with chains.

When a careless night miller had loaded a bin from the back, leaving a space at the front with the chains bare, Mr. Redler halted the filling operation, got into the bin, stood on the chains, and ordered the unloading to start, so that he could observe the interaction of chain and flour at close range. Something seemed to be wrong, however. The chains were slowly moving under him, as usual, but unloading did not start. Puzzled, he kept pace with the live floor and stooped to see what was going on. Suddenly something bumped him from behind and he found himself between the end wall of the bin and an advancing slope of flour. He made a quick exit to safety, but the peculiar action that he had seen so impressed him that he turned his attention to a study of conveying, with the result that he became the manufacturer of a new kind of material-handling equipment.

The law discovered by Mr. Redler may be paraphrased briefly as follows: In bulk-material handling, if the boundary layers are

Fig. 8 An H-Type Horizontal and Vertical Conveyor for Bulk Materials

urged forward, the entire mass moves as a unit because the shearing strength of the material on itself is greater than the friction of the same material against the relatively smooth walls of the conveyor conduit. Applying this principle, Mr. Redler made a conveyor out of a square conduit, equipped with a longitudinally moving element having relatively light members sweeping all four sides. This turned out to be capable of conveying material *en masse* and quiescent at any angle in any plane. Later, he discovered that this conveying could be done with more finished design without complete four-side sweeping. The common shapes assumed by the transverse elements today are the "H," the "U," and the "L."

This equipment is now used to unload silos of foundry sand, vertically sided bins of hot, ground cocoa, 75-ft-high bins of flour, and for conveying and elevating cement, coal, cocoa, sugar, starch, bauxite, coffee, beans, ceramic clays, abrasive soap powder up to 20 per cent moisture, flaked breakfast foods, grains, bran, flour, semolina, rolled oats, and cookies. Inasmuch as there is almost no relative movement of one particle on another, the most fragile of these products is carried with practically no degradation.

In Fig. 8 is shown an H-type horizontal and vertical Redler

[4] Description prepared by Nixon W. Elmer, chief engineer, Redler Conveyor Division of the Pneumatic Scale Corporation, Ltd.

conveyor. The loading point is shown on the horizontal section and the unloading may be at any desired height and on any of three sides of the vertical leg, or, for that matter, on the horizontal portion. Partial discharge at any or all of these points is obtainable. In the horizontal portion, the H-element is laid on its side with the cable midway of the crosspiece of the H. The design of the transverse element is such that it automatically centers itself in the material, remaining out of contact with the casing. Under laboratory conditions, it has been possible to keep the transverse elements from ever touching the curved section at the bottom of the vertical while making the 90-deg change of direction. Friction at this point is negligible in commercial installations. In this case, one simple machine conveys both horizontally and vertically. The space occupied is small and no pit is required.

The first commercial installation of this conveyor made in the United States handles up to 330 bushels of uncleaned wheat per hour, over a distance of 340 ft, not quite in a straight line, and requires 2 hp for operation.

Where the material to be conveyed is of such a character as to corrode or chemically injure the cable, either a complete, flexible waterproof covering is molded over the cable or the cable itself is constructed of an 18-chrome, 8-nickel steel.

Fig. 10 Test Chart of the 5-In. Conveyor Shown in Fig. 8

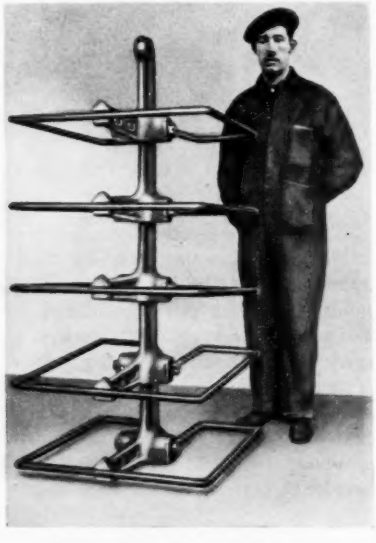

Fig. 9 Moving Element of a Conveyor Handling 400 Tons of Wheat per Hour

With this machine, when loading from a choked feed, an absolutely uniform delivery is obtained by putting a short sheet of steel between the two runs beneath the hopper opening. The upper run then acts as a measuring and feeding device for the lower run. This method assures a loose and uncompacted load on the carrying side, which is of importance with sticky substances.

Another installation of a pair of side-pull Duos serves 31 machines and occupies less than 6 in. of headroom, except at one spot between beams, and at the terminals, also between beams. This arrangement allows the release of the whole floor above for other purposes. The capacity of this small machine, $5^1/_2$ in. square, is 25,000 lb per hr. The material handled weighs 60 lb per cu ft.

Fig. 9 shows the moving element of a vertical Redler that handles 400 tons of wheat per hr at a speed of 40 ft per min. An interesting point here is that the outside dimensions of the flights shown are 30 in. × 30 in., whereas the casing through which these flights rise vertically is 36 in. × 36 in. The column of wheat carried up is 3 ft square, and the tiny grains of wheat do not fall backward through the 3-in. clearance on each side.

Another installation feeds coal from the bunkers of an English ship in the Australasian trade, first into the crusher, and then into the pulverizer. The second ship of this line is now being equipped with Redlers.

Fig. 10 shows the test chart of the 5-in. H-type Redler shown in Fig. 8. It represents a summary of a two-months' series of tests made under the direction of Professors Miller, Norton, and Wilkes of the Massachusetts Institute of Technology.

A test was run on this same machine to determine the breakage of friable rice anthracite in a 10-min closed-circuit run. During the $10^1/_2$ complete circuits of the horizontal and vertical H and the 45-deg chute from the outlet of the H to the inlet of the same machine, there was made only $^{50}/_{100}$ of 1 per cent of "fine" which would pass through a $^3/_{16}$-in. rectangular mesh in ten passages by gravity. Of these fines, 6 per cent would pass through a U. S. standard 60-mesh screen.

Because the internal pressure in the Redler conveyor is a function of the spacing of the cross-members rather than of the height lifted, the accuracy of this conveyor as a measuring device is unusually close. This fact has been demonstrated in cement, coking-coal, and cattle-feed blending, and similar service. The No. 1 measuring Redler conveyor measures accurately by the volumetric method from a plurality of hoppers, the measured amounts being carried to a single delivery point on the lower run of the conveyor. The No. 2 measuring Redler has a single inlet and the measuring is done into a plurality of outlets.

An English cement manufacturer was guaranteed accuracy to ½ of 1 per cent with one of these machines. In placing subsequent orders, this cement manufacturer said that his first machine had exceeded its guarantee of accuracy.

The capacities, with various weights of materials, of the different commercial sizes of Redler conveyors are shown on the chart in Fig. 11.

Horsepowers for driving this kind of a conveyor naturally are lower than those required by types of conveyors that disturb the material in transit, and thereby do work upon it. There is almost no internal friction in the material carried by the Redler method. The English and Swiss use empirical formulas which are reasonably satisfactory, but a general and logical one probably will be worked out shortly, based on the area involved, coefficient of friction, and the pressure due to the weight of material between flights, which latter seems to be a controlling factor. The arching action is controlled by this spacing, and the pressure against the sides of a vertical is independent of the total height. This fact means that the action here is similar to that of grain in a silo where the weight of the grain above the arch is transferred completely to the sides.

With material flowing quietly through a closed trough, there is no dust, and, because these conveyors habitually operate with a choke feed and can be pulled through a choked outlet, it is obvious that dust problems may be solved without dust collectors. This condition provides one reason why the Redler is the only elevator sanctioned unsprinkled for grain by the British Board of Underwriters.

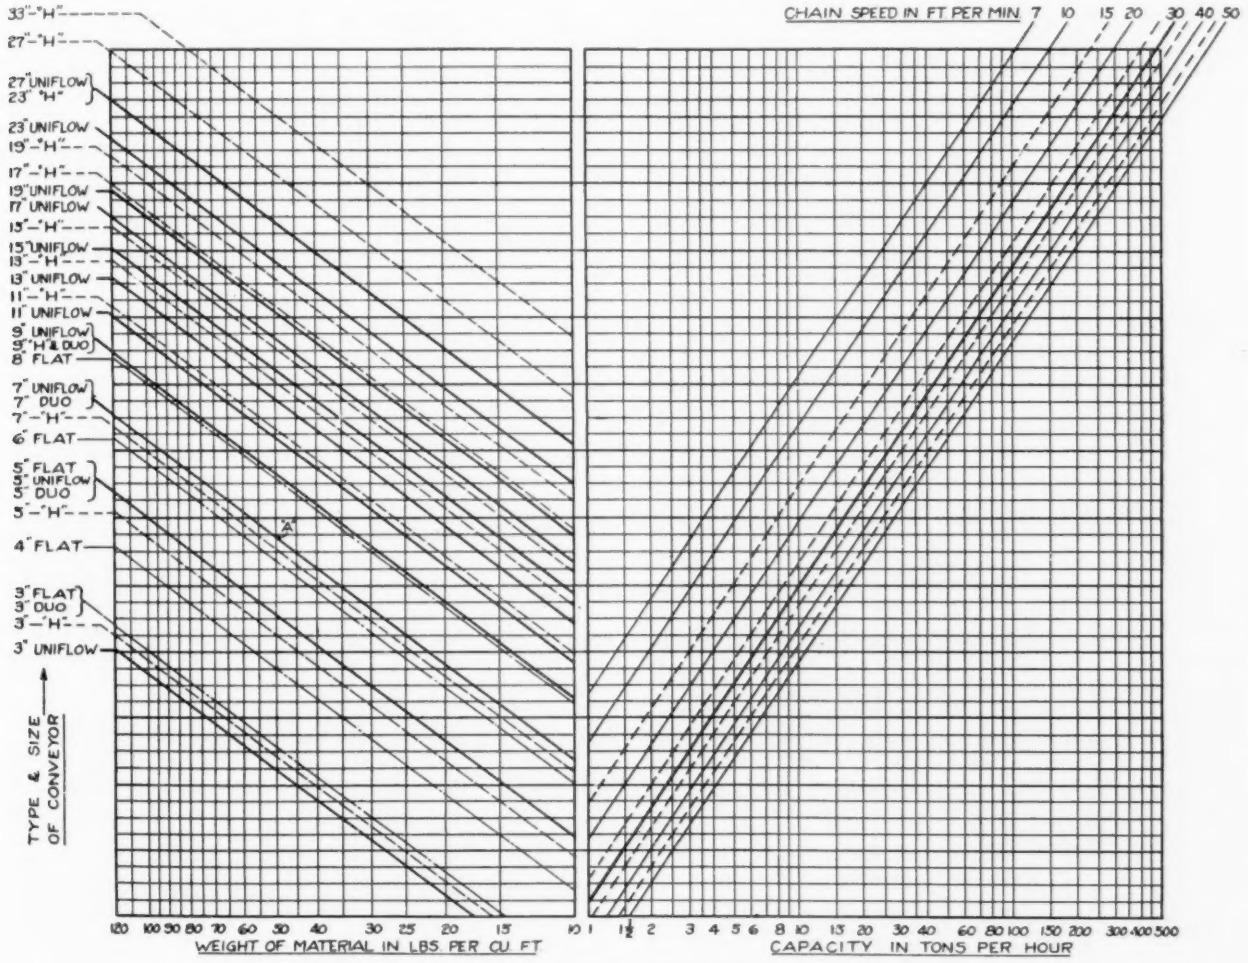

FIG. 11 CHART FOR DETERMINING THE CAPACITIES OF REDLER CONVEYORS

The field of prospective usefulness of this kind of conveyor ranges all the way from a 2-in. pipe conveying coal to, and ashes away from, a small domestic heater, to massive conveyors and elevators handling 600 tons per hr. Although this latter is the largest size built today, there is no indication that the limit of size is being approached. The principle appears to hold good irrespective of size. Other considerations, therefore, can be left to govern the size of the individual units best suited for the particular job.

SAND HANDLING AND POURING UNIT

The Modern Equipment Company has developed a sand-

conditioning unit that is portable, operates on overhead tracks and serves a series of hoppers. The unit includes screens, pug mill, aerator, and magnetic separator, also an automatic adjustable tempering device. It is adaptable to any capacity foundry (capacity per unit being 8 to 12 men) doing production or jobbing work, and operating either on a daily-pour or continuous-pour basis. It allows for the use of different kinds of sand on each floor, with various amounts of moisture if desired, can be used in foundries where many different metal compositions are poured, requires little electric power, and needs no floor pits. Molding increases through the use of this equipment have been more than 50 per cent. For example, on one hard iron ball job, production was increased from 180 to 308 molds; on a heavier job, from 16 to 36 molds, within the same period of time.

The molder makes his molds on his molding machine directly under the sand-hopper outlet, and places them on a gravity conveyor on which they roll down into the pouring zone. There the molds are poured by a pouring device operated on a pouring crane spanning the entire section. Each molder has two conveyors, the second one being used when the molds on the first one are being poured and shaken out.

The farther end of this roller conveyor is raised after pouring, so as to allow the molds to travel back to the shake-out end. The portable conditioning unit is then located directly in back of the hopper and the molds are lifted off the end of the conveyor and dumped directly into the vibrating shakeout. The castings are picked off the grate and put into a bucket operating on a monorail system. In the meantime, the sand drops through the shake-out and on a special shake-out belt which carries it into the bucket elevator. This bucket elevator, in turn, carries the sand to the top of the conditioning machine and discharges it on a belt operating over a magnetic pulley by means of which the metal drippings and small metal-shot particles are removed automatically. The sand then is screened through a fine-mesh vibrating screen and drops into the positive batch weigher.

The batch weigher is part of the adjustable automatic tempering system. It weighs off accurately a definite amount of sand, discharging this into a mixing unit and, at the same time, actuating the water apparatus and causing a discharge of water. The special mixer then thoroughly works and reworks the moistened sand, producing a well-bonded mixture. This sand is then conveyed by a flight elevator up to the aerating device where it is blended. Finally, it is discharged into the hopper by means of a high-speed belt.

Screening Equipment

The Dester Concentrator Company reports an important installation of its equipment in the new plant of the Mason City Brick & Tile Company, Mason City, Iowa. Twelve new Leahy heavy-duty vibrating screens were installed in this plant, in batteries of four. Each battery is in a unit including, in addition, a granulator, grinder, rotary drier, and accessory conveying equipment.

Pneumatic-Conveyor Systems

The Dust Recovering & Conveying Company made three installations during the past year that are of special interest to the material-handling field. The first is a high-vacuum suction-type pneumatic conveyor to unload crude arsenic. This material is poisonous and it is essential to observe special precautions in unloading it. It was decided to remodel several tank cars, load the material in bulk in these tank cars, and unload them by the use of a pneumatic system with a capacity of 4 tons per hr of crude arsenic, weighing from 135 to 150 lb per cu ft. There are four manholes on the top of the tank car, through which the nozzle and flexible hose are introduced, and the operator is not required to enter the tank car at all. Since the complete system is under suction, there is no leakage of material at any point, and the high-efficiency fabric filters remove over 99½ per cent of the dust from the conveying air before this air is exhausted to the atmosphere through the vacuum pump. The intake line is approximately 40 ft long, and a 15-hp motor actuates the filter system.

The second interesting installation is for the conveying of dicalcium phosphate from a loading platform to a mixing tank. This material is the base of a well-known tooth paste, and extreme care must be taken to prevent its contamination by any foreign substances whatever. The material is shipped in bags, and these are emptied into an intake hopper in a special room beside the unloading platform. The pneumatic-conveying pipe lines run from this intake hopper to a receiving station over the material storage bin. Two precautions are taken to insure absolute purity of the product. First, there is an atmospheric filter in the room in which the hopper is located. Secondly, all parts of the intake hopper, pipe line, receiving hopper, and discharge mechanism are of non-ferrous metals. The material, therefore, is conveyed by clean air, and is brought in contact only with rust-proof metals throughout the whole system. A capacity of 5 tons per hr is handled through this system over 75 ft of pipe line, with a 25-hp motor on the vacuum pump.

The third installation is a pneumatic conveyor to unload alum, lime, and soda ash from freight cars to storage bins. The receiving hopper is mounted in a tower over the storage bins so that the material is all conveyed first to the receiving station and is then distributed through gravity chutes to the various bins. The material also can be reclaimed from any storage bin and diverted to process through the same conveying system. There is a maximum length of about 120 ft from the intake nozzle in the car to the receiving station, and over this length of line more than 8 tons of these materials can be handled with a 50-hp motor on the vacuum pump. A 3½ in. pipe line is the only connection between the receiving hopper and the loading platform, and is carried for most of the distance outside the walls of the building.

During the past year the Kennedy Van Saun Manufacturing and Engineering Corporation has developed new equipment for pneumatically transporting material. This equipment can be installed for any capacity, distance, or elevation, is entirely automatic in its operation, has no motors nor feed screws, and is claimed to require no more air per ton at low capacity than at high capacity. It may be installed to deliver from the hopper of a bin or take the feed direct from a pulverizer. It is not sensitive to fineness, and can be used to handle flue dust or coal such as is used in stoker or hand-fired boilers.

Excavating Machinery

For general excavation work, a complete new series of revolving gasoline excavators has been developed by the Bucyrus-Erie Company. These machines, ranging in size from ½ to 2¼ cu yd., are available with gasoline, Diesel, or electric power, and may be equipped to suit various types of work, such as shovel, dragline, crane, clamshell, or drag-shovel operations.

For the contractor who needs a small, light shovel for county and state highway-department work, and for industrial concerns removing sand, gravel, earth, etc., the company has introduced a new ½-yd machine with maximum digging capacity per pound of weight, due to a new distribution of the weight of the equipment. It is available with gasoline, Diesel, or electric drive, and as a shovel, dragline, crane, clamshell, drag shovel, or skimmer scoop.

A line of heavy-duty, full-revolving shovels for ore and rock

digging in mines and quarries has been extended by the addition of three new units designed to bring about lower operating costs. The present line includes six electric shovels from $1^1/_2$-yd to 5-yd capacity each, suited to heavy digging.

For levee, drainage, and irrigation work and for certain other construction work, the company has developed specialized equipment for the speeding up of work and lowering of costs. This equipment includes the following three items: First, an improved type of electrically driven tower excavator has been provided, capable of handling a 10-yd bucket with a span of 800 ft between towers. Second, a new 1- to $2^1/_4$-yd dragline has been introduced, together with two similar machines having larger capacities but with the same low ground-bearing pressure, for work on soft terrain. Third, dragline booms have been introduced that are built of aluminum alloy and weigh only two-thirds as much as steel booms. These booms are applied to draglines up to 175 ft in length and permit the use of longer reaches with standard buckets or larger buckets at standard reaches.

A new series of dragline buckets has been introduced, designed to give maximum strength with minimum weight and intended for heavy, medium, or light work. These buckets are built in sizes from $1^1/_2$ to 8 cu yd. The arch is a one-piece annealed steel casting of great strength but light weight. The manganese-steel lip has renewable teeth inserted in bases cast in the lip and held by wedges. Replaceable runners and wearing plates protect the bottom of the bucket from damage.

A new Diesel-driven (Bucyrus-Monighan) walking dragline handling a 10-cu yd bucket with a 160-ft boom has been introduced. This equipment is especially adapted for such large irrigation and drainage work as is at present being done in the Mississippi River Valley.

For use in the open-pit coal-mining fields the company has introduced a new counterbalanced-hoist stripping shovel. This huge machine carries a dipper of 18-cu yd capacity. By means of the hoist counterbalance, this shovel is enabled to show an increase in operating speed, a decrease in power consumption, and lower overall cost per yard of material moved.

For industrial service, the Loadmaster has been redesigned and improved. This machine is a small, mobile, gasoline crane with a full-revolving boom, which can work in almost any place where an automobile can be driven. It is now offered with three makes of power units. The Model CT machine has 4500 lb lifting capacity, a hoisting speed of 47 ft per min, and a swinging speed of from 2.5 to 4 rpm. Standard booms are 10, 12, and 14 ft long. Special booms can be furnished. Clearances are 9 ft $^1/_2$ in. in height, and 6 ft $^1/_2$ in. in width.

For the railroad market, the company has developed and introduced a railway crane capable of handling a load of 200 tons at a radius of $17^1/_2$ ft. Among the features of this crane are: lower center of gravity, permitting high-speed transportation; strong construction; an unusual degree of accessibility; and wide clearance for lifting bulky objects.

Industrial Power-Driven Trucks and Tractors[5]

The Clark Tructractor Company has announced a new lifting and tiering truck, Fig. 12, that will pick up skidded or cleated loads with as low as 2 in. underclearance. It differs from the ordinary lift truck in that the load is carried on tapered steel fingers, with a standard length of 26 in., that touch the floor in the down position. Fingers tilt back slightly in the first 5 in. of rise, thus insuring balance for the load. Flexibility of operation is obtained by four-wheel steering with rear-wheel drive. The 2-ton model has a turning radius of 89 in., the 3-ton model, 98 in. Maximum lifting and carrying capacity are provided for by the powerful hydraulic lift, mounted over extra large (15 in. × 7 in.) rubber tires.

While the machine is capable of tiering to a height of 50 in., its low overall height, 77 in., makes it specially suitable for loading box cars. Special machines with greater tiering height to meet unusual conditions are built by the manufacturer on this same chassis.

The Elwell-Parker Electric Company has developed a complete line of tiering trucks fitted with true telescoping uprights on which the load carriage travels. Telescoping uprights are those which provide for a set of movable inside uprights sliding *within* a pair of fixed outside uprights. These trucks are intended to conserve floor space by utilizing all the cubical contents of storage areas. They are designed to pass low doorways, piping, and other overhead obstructions, and yet stack stored objects to the roof.

Tiering platform trucks of this general type are made for from 500 lb capacity with an overall width of truck of 30 in.

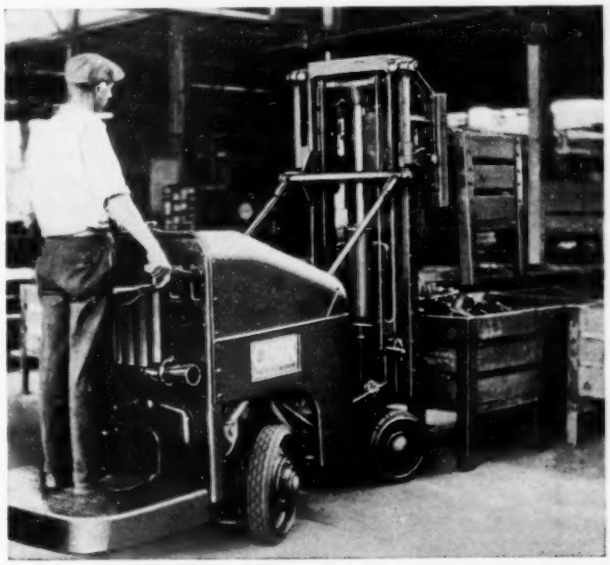

Fig. 12 Tiering and Lifting Truck for Cleated Loads

and a lift of 184 in. to a 10,000-lb capacity and a lift of 106 in. The intermediate sizes built have been the 4000-lb and 6000-lb. sizes (see Fig. 13). In fork-type trucks, those developed have been rated at 1000 lb, 3000 lb, and 6000 lb, with varying outreaches to the load center of gravity.

In addition to these machines, two special roll-on winch-type trucks have been developed to handle heavy cable reels; a special tilting-fork-type truck to handle cooker pallets of canned goods in food factories; and a special type of tilting-fork truck to carry bulky automobile bodies through a 7-ft high doorway, after passing which the body is stored on end.

There is also available a heavy-duty 10,000-lb combination fork-and-ram-type truck with motor-operated side-shifting device for handling mill plate and rod coils, and a combination crane-and-fork truck. (See Fig. 14.)

The development of accessories on electric trucks has advanced apace. Rubber pads have been placed on operator's platforms to reduce the vibration and add comfort to the operator. Wheel steer instead of either the vertical- or horizontal-type steer has been in greater demand on the lesser-capacity trucks. Ball-and-socket-type steering connections, pressure lubricated, have been made standard equipment, replacing the older pin-and-yoke, gravity-oiled steering connections.

[5] Data collected by S. W. Gibbs, assistant sales manager, The Yale & Towne Manufacturing Company, Philadelphia.

The higher types of battery, both alkaline and lead acid, have found greater favor and, with the gas-electric power unit, have required a redesign of most power unit compartments. In the redesign, greater attention has been necessary to provide more ventilation for the batteries, since the cells that are placed in the center of the high type demand better cooling facilities.

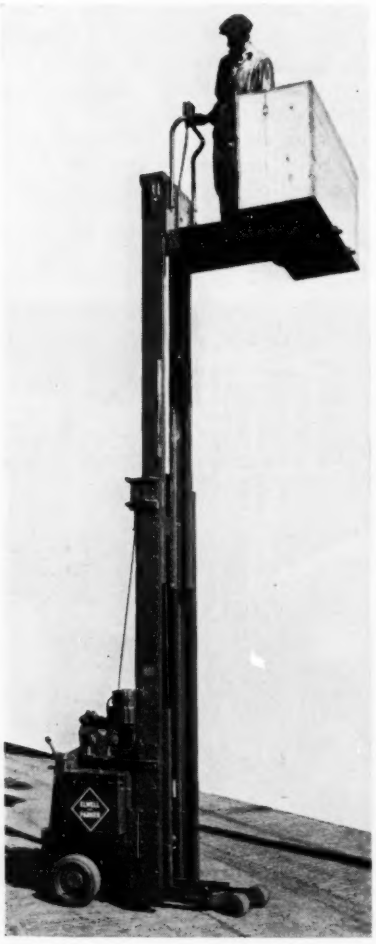

FIG. 13 TIERING PLATFORM TRUCK WITH TELESCOPING UPRIGHTS

Wider uses for the various kinds of equipment have been noticeable during the past year, since there has been insufficient work for the trucks to perform on the jobs for which they were purchased. Tiering trucks have been fitted with removable booms to serve as cranes, while slip-over platforms have been employed to permit landing skid loads on industrial trailers of the older types which do not provide the clearance necessary to permit the trail axle beneath the truck platform to be thrust under the load platform of the trailer.

The Mercury Manufacturing Company has added several designs of new units to its electric-lift-truck line. One of these new units is designated the "Little Giant" and is a small-sized, but powerful, truck of the standard "Type EL" line. The unusually light chassis weights and capacity ratings of the trucks of this classification enable them to operate where floor or elevator capacities are limited, and to negotiate narrow aisles and congested areas.

There are three modifications of the basic design—the low-lift, the high-lift, and the telescopic. The low-lift model has an overall length of $94^1/_8$ in., an overall width of 32 in., and an overall height of $46^5/_8$ in. It has a rated capacity of 3200 lb. The chassis, less battery, weighs 1850 lb.

The overall height of the high-lift model is 83 in., and the truck is capable of lifting the platform to a maximum height of $67^3/_4$ in. Trucks of the high-lift type have the same overall length and width dimensions and the same carrying capacity as those of the low-lift design. The chassis, without battery, weighs 2100 lb.

The telescopic model has an overall length of $96^1/_2$ in. and an overall width of 32 in. The overall height of the truck in its lowest position is 83 in. When raised to its ultimate height, the top of the platform is 112 in. above the ground. It has a lifting capacity of 3000 lb on the standard uprights and a capacity of 2000 lb on the telescopic members. The chassis, less battery, weighs 2400 lb.

Another development is a special adaptation of the standard "Type EL" fork truck to handle paper rolls of varying diameters and lengths and stack them three high without the employment of skids or supports of any kind. (See Fig. 15.) Mechanically, this unit is described briefly as follows: It has an overall length of 166 in., an overall height of 82 in., and an overall width of 46 in. It has a 50-in. wheel base and the turning radius is 138 in. The lifting forks are adjustable to handle rolls of paper varying in diameter from a minimum of 27 in. to a maximum of 40 in., with a maximum length of 6 ft. The truck lifts paper rolls weighing up to 4200 lb and tiers them to a height of 96 in. The truck, without battery, weighs 6000 lb.

Both of these new units have hydraulic-hoist systems, contactor-type controls, internal-expanding brakes in each drive wheel, semi-elliptic spring suspension of the frame, and efficient unit-gear-drive axle assembly, ball-bearing-mounted throughout.

The Terminal Engineering Company reports as probably its most outstanding development during the past year a crane with a boom that will give a lift of 26 ft from the ground to the hook. The chassis is a standard 60-in.-wheelbase crane chassis having two hoist units, one for the hook and one for topping the boom. The crane with normal-length boom has a capacity of 6100 lb two feet from the end of the chassis, and the long boom has a capacity of 1800 lb at the same overhung distance. The boom, however, is movable and also telescopic over a distance of 6 ft, so that different capacities are available with the different combinations of adjustment.

The long-boom crane was developed for working on one-story-building construction jobs, and has been used in particular for the erection of prison cells. One-story construction makes it impractical either to set up scaffolding for the steel-erection work or to put in overhead hoists on trolleys. The material for the high crane is supplied to it by electric lift trucks with separable large-area platform bodies. Last winter and spring

FIG. 14 COMBINATION CRANE-AND-FORK TYPE TRUCK

these four-wheel drive lift trucks operated over unpaved areas on building jobs without the use of chains on the wheels.

The high crane on prison-construction jobs was also used to install the ceiling plates, to raise all of the furnishings, and to hoist the concrete for the cell floors, instead of using a conveyor which would be at a disadvantage on account of the limited space available.

Additional lift trucks were used while the bricklaying was being done. Each of the seven cell blocks, three cells in height, was 320 ft long and 35 ft high, so that scaffolding would have

been expensive to erect, either around the whole area or in sections to be moved. Instead of building up and tearing down the scaffolding every four days, the contractor built a group of forty individual towers on four legs, complete with the necessary ledgers. These towers were counterbalanced with two tons of brick in the bottom and were moved from place to place by the electric lift trucks. Each tower was a complete scaffolding in itself, and a group of them, set at proper intervals with decks, provided a continuous scaffolding the length of the building.

These forty separate tower units on the outside, used with the electric trucks, replaced about 25,000 linear feet of scaffolding 30 ft high and the total saving on the bricklaying operation, which included supplying the masons with bricks by the same lift trucks, approximated $40,000. The scaffolding could be moved from one 320-ft section of wall to another in less than two hours' time.

The Yale & Towne Manufacturing Company has introduced as new models this year a line of rack-and-pinion tilting-fork trucks, in both the single and multi-lift, telescopic type. Another new development is a complete line of midget low-capacity trucks with models corresponding to the existing models in the higher capacity machines. These low-capacity midget trucks are rated up to 4000 lb maximum, and embody the advantages of small overall dimensions, lightness in weight, short turning radius, etc., necessary in this class of equipment.

Under the head of mechanical improvements during the past year, the company has perfected and now embodies in its equipment several features. One is a free-wheeling ratchet used on all high-lift trucks to guard against damage to the equipment when overrunning the travel or hitting an object when lowering the platform. Another is an interlocking four-speed control that prevents the application of power against the brake and necessitates the return of the control manually to neutral before reversing the direction of the truck. Wheel and bearing design has been improved with a view to permitting wheel dismantling or replacing without exposing or disturbing the bearing.

The chassis construction has been changed considerably, and wide use is made of form plates and alloy or heat-treated bar stock for the main frame, in place of the castings and shapes heretofore used. This change has been made to simplify the design, increase the strength, and provide a better distribution of load.

Hand Lift Trucks[6]

The improvements introduced by the Yale & Towne Manufacturing Company during the past year in hand lift-truck equipment have been in the development of added types rather than in any decided mechanical improvements. Included in this list of added types has been a U-frame hand-type single-stroke model with a pan for handling small reels. When lowered, the pan rests on the floor, the reels are rolled on to the pan and then the entire unit is then elevated. The second development has been in a hogshead or barrel truck, U-shaped, with the two sides of the U designed to fit the contour of the barrel. A third development has been in an extremely low platform truck for use in handling tinplate and similar commodities when these are shipped on low skid legs.

In the skid-platform field, which is accessory to lift trucks, a number of mechanical improvements have been made in the use of better structural sections, including channels and special shapes to provide more strength, and the use of both welding and stronger bolting to improve these members.

[6] Data supplied by S. W. Gibbs, Yale & Towne Manufacturing Co.

Floor Trucks[7]

The truck-caster manufacturers are cooperating with the Standardization Division of the Department of Commerce, through R. L. Lockwood, on a standardization program for plate casters. A preliminary meeting has been held and a second one is scheduled for an early date.

An outstanding improvement in the floor-truck field has been the adoption, by several makers, of rubber-tired wheels for casters and floor trucks. Improvements in design and construction of the tires and wheels have been very noticeable and a number of manufacturers have adopted the new easy-rolling rubber in the wheel tread. Wheels of this rubber require much less power to move than those made of any of the kinds of rubber formerly used. Under most floor conditions, except for the smoothest marble and new concrete, the rubber tire will run easier than a metal wheel of the same diameter under the same load.

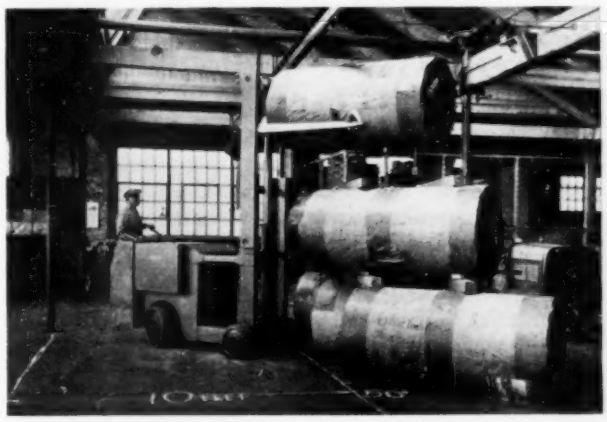

Fig. 15 Fork Truck for Handling and Stacking Paper Rolls

There also has been a more decided trend toward the use of roller bearings in floor-truck and caster wheels, particularly for the lighter and medium-duty equipment which generally has used plain bearings. Roller bearings usually have been standard units in heavier equipment.

Concerted action has been undertaken by the floor-truck and caster group to prepare and provide publicity on new equipment, new and outstanding installations, and improved handling methods. Most members of the industry feel that the importance of its equipment has not been brought to the fore as it should be, and that consequently the false impression is being created that this equipment is being supplanted by mechanical methods. As a matter of fact, floor trucks have been extensively employed in factories during the recent period of low production to carry on handling operations where mechanical equipment was shut down because of the low volume of output.

The Nutting Truck Company has announced a new all-steel platform truck, with frame and platform pressed from a single piece of heavy steel so that the edges form a channel shape. A steel angle welded into the frame forms the caster bar. The truck has the regular U-shaped handle, which is removable or can be fastened in place by set screws. These trucks are furnished in several sizes of standard platforms with a choice of two kinds of wheels.

Tires and Casters for Trucks[7]

The Nutting Truck Company has introduced three new

[7] Information furnished by J. F. Thomas, general sales manager, Nutting Truck Co.

types of tires made of "free-wheeling" rubber. The N type, for light and regular duty, has a 14-strand wire cable reinforcing the base, and is securely held between steel wheel disks which prevent it from jumping off or creeping. The RD type, for regular and heavy duty, is a demountable, wide-tread tire clamped between the halves of a split wheel. It has a hard-rubber base impregnated with cord fabric. The tire is made in sizes to fit any truck or caster. The RV type, for heavy and extra-heavy duty, is vulcanized to the wheel, and has an extra wide tread. Crosswise corrugations on the metal prevent loosening of the tire and consequent creeping. Advantages claimed for the "free-wheeling" rubber are: noiselessness, 60 per cent easier starting, 33 per cent less rolling effort, cushioning of loads to prevent breakage, elimination of creeping or jumping off, durability, low depreciation, and reduction of wear and tear on floors.

Divine Brothers Company during the year put on the market a new TonWate steel forged caster in both stationary and swivel types. The base of the caster attaches to the truck by bolts or screws on standard centers. The majority of the load in the swivel type is carried on a single ball which, acting as a flexible unit, distributes the remainder of the load to the vertically split, ball thrust bearing. A Dardelet self-locking safety set screw provides for adjustment in installation. Heat-treated forgings provide great strength without excess weight. Hyatt axle bearings, pressure lubricators on the oversize axles and swiveling mechanism, heavy-gage-steel hub guards for protection and cleanliness, and wide-faced, machined wheels are other features. Canvas-cushion wheels are provided where floor protection and quiet operation are desired.

Tests made for the Port of New York Authority, on June 20 and 21, and conducted at the New Haven Railway Express terminal of the Railway Express Agency in New York City, indicated the superiority of rubber tires over steel tires for use on trailers, and incidentally on industrial power-driven trucks and tractors and on floor trucks. The tests were conducted to demonstrate tires of the vulcanized-on type made of a new compound and produced by the B. F. Goodrich Company. Ball-bearing, swivel casters were mounted on the front of the truck and Hyatt roller-bearing wheels on the rear. Starting and rolling drawbar pulls on smooth and on rough floors, with casters parallel to and at right angles to the directior of pull, were run, pulling the trailer with different loads over different-sized obstructions. The pull to move the trailer over a length of hay wire was only one-sixth as much with rubber-tired wheels as with steel wheels. Tractors pulling trailers showed slightly less power consumption from batteries when the trailers were equipped with rubber tires. Increased resiliency was demonstrated by the new tires, for which the usual advantages of rubber tires, namely, reduced noise, wear, maintenance and breakage of objects carried, have been claimed.

Adherence to Tire Standards

The Division of Simplified Practice of the Bureau of Standards, in cooperation with makers and users of industrial truck tires, has issued its 1931 revision of the simplified-practice recommendation on widths of tires and nominal wheel diameters for 30 flat-base tires and 6 channel-base tires. Five tire manufacturers, in 1931, produced 48,459 tires, of which 77.3 per cent were of the recommended sizes. Nine truck manufacturers used 12,957 flat-base tires, of which 73 per cent were of the recommended sizes. Eventually, it is hoped to eliminate all the channel-base tires and 9 sizes of flat-base tires. Most non-standard sizes made now probably are required only for replacement purposes, except some oversize tires needed for trucks of higher capacities. Certain of these latter tires may be placed on the standard list.

Industrial Cars

The Koppel Industrial Car and Equipment Company has developed a larger size, automatic, air-operated, side-dump car of 50 cu yd capacity, along the lines of the 30-cu yd car that has been on the market for several years. This new car was specially designed for use in handling various kinds of metal, particularly waste materials in steel plants. Lower operating and maintenance costs, and lower initial investment, on the basis of cubical capacity, are claimed for the 50-cu yd car. The car will carry 140,000 lb, is 8 ft $7^5/_{16}$ in. in overall height, 10 ft $4^1/_2$ in. in overall width, and 46 ft in length overall over striking plates. It is 42 ft $2^1/_2$ in. long inside the body at the top, 9 ft 3 in. wide inside at the top, and 3 ft 7 in. deep. It weighs 80,300 lb and has a dumping angle of 45 deg. Dumping can be controlled from the locomotive or any car, safety devices protect against faulty manipulation, and the cars are universally accepted for movement in interchange service because they meet all A.R.A. and I.C.C. requirements.

Motor Trucks and Trailers

The General Motors Truck Company, to supplement its Model T-18 motor truck, which has a capacity of from $1^1/_2$ to 2 tons, has introduced a semi-trailer, Model TT-218, with a body capacity of from 600 to 800 cu ft, to carry from 3 to 5 tons. The working parts of the trailer are standard with the truck itself, for low-cost maintenance. A 42-in. stake-and-rack body, and a stake express body with a 2-ft reinforced tail gate are available. The supporting wheels at the front are raised or lowered by a steel cable and lever mechanism operated by a crank at the side. A dog locks the mechanism, for safety.

Tank Cars for Bulk Material

The General American Tank Car Corporation has introduced a standard railroad tank car for the handling of bulk materials in granular or powdered form. It is applicable for cement, clay, lime, sand, fertilizers, soda ash, sulphur, flour, and other products that require protection from the weather and from dust and contamination. Weights up to 70 tons of material can be transported.

The car is filled from hoppers or pipe lines through any of six 16-in.-diameter loading manways in the top, closed by dust-proof and water-proof covers. Loading time may be as little as 30 min. The car is unloaded through a hopper opening, $11^5/_8 \times 12$ in. in area, at the middle of the bottom. Unloading is done by two drag-chain conveyor systems within the car, one for each end. Slope sheets at the bottom of the car divert the material into the conveyor line, which runs in this trough along the bottom toward the central discharge hopper, then travels up and back toward the end of the car, above the material. The chain flights are 14 in. wide and travel at 10 ft per min, driven by a 1200-rpm motor through two high-ratio speed reducers, one for each conveyor. Clutch connections enable the operator to start or stop either conveyor independently of the other. A discharge rate of either 400 or 800 cu ft per hr is thus available, and the car is emptied completely. The total capacity is 1600 cu ft, and the car can be unloaded in from two to four hours, discharging to storage hoppers or onto a conveyor system passing beneath the track. Unloading is dustless. Power is obtained by cable from any convenient 220- or 440-volt line, or may be applied externally by means of a shaft provided for this purpose. Two bulkheads under the central dome house the driving mechanism and protect it from dust.

Savings indicated by tests are as follows: elimination of barreling, loading, unloading, and spillage in handling arsenic, $200 per 65-ton shipment; purchasing of quicklime in place of hydrated lime, where the former was too dangerous to handle

under previous methods, $1 per ton; elimination of packaging and the incident handling, $2 per ton; substituting some materials in bulk for less efficient ones in packages, as high as $1000 per month per car.

Handling on the Railroads

New methods of handling on railroads deserve special mention. A method for hauling freight containers in and out of the ends of covered cars has been developed by the Milwaukee Electric Railway and Light Company with the assistance of the Harnischfeger Corporation. Aluminum-alloy containers are used, mounted on skids moving on steel slides on the car floor. A Milwaukee electric hoist is mounted beneath the car, but the cable can be unreeved from the drum without power, because the hoist has a slip clutch for this purpose. The cable passes up through the car floor at the end, between two horizontal rollers, runs through a snatch block anchored there, and is pulled to the other end of the car where it is fastened to the container, which has arrived on a motor truck. Operation of the hoist moves the container into the car, which holds two containers. Power is obtained by hanging a pole over the overhead trolley wire, and the hoist is operated by any one of four push buttons at various points in the car. Unloading is done in a similar manner, because the motor truck has a snatch block back of the cab.

The National Malleable Steel Castings Company this year has adopted special containers, leased from the L. C. L. Corporation by the railroad, for receiving limestone, coke, dolomite, and similar material at its plant. The containers are loaded by grab bucket and crane at the shippers' yards, or by chutes from storage bins. They are carried on beams in gondola cars that hold 12 containers, or 60 tons. The car floors consist of screens, for drainage purposes. Open containers are used for stone, and closed containers for materials that must be protected from the weather. Eventually, it is hoped to carry clay and brick by this method. At the National Malleable plant, a crawler-tread crane is used to transport the containers from car to storage bin or other point of delivery.

An economy of about $12.50 per car, as well as a saving in time has been brought about by the new method. Under previous methods, it took six men from five to six hours to unload a car that can be emptied in 50 min under the new method. Demurrage on cars is obviated and, in addition, the cost of materials thus bought in bulk averages $1 per ton less than when bought in bags or barrels.

The Pennsylvania Railroad is experimenting with containers designed to transport face brick, hollow tile, firebrick, and similar products of the ceramics industry. Two types of face brick container have been tried out, a bottomless variety and a sectional variety. With the former, the bricks are stacked on skids which, when loaded, are stacked vertically (at present four high) so that a container can be lowered over the stack and fastened to the bottom skid by means of two beams swiveled from the sides of the container. The container is then hoisted by a crane into an open-top car.

The sectional container consists of a series of boxes or rectangular shells, each 16-in. high, to fit over steel skids or platforms mounted on legs with a clearance of 7 in. to permit the use of lift trucks. The box section in each case latches on the platform and the sections, when loaded, are stacked, usually four high, although any number up to five high is permissible. Cranes may be used to load the containers on cars, with lift trucks to do the intermediate handling, although hand loading is possible, due to the light weight of each section.

The data on the two kinds of containers experimented with are as follows:

Item	Bottomless container Small	Large	Sectional container
Length of base	4 ft 3 in.	7 ft 0 in.	6 ft 4 in.
Width of base	3 ft 6 in.	3 ft 6 in.	4 ft 3 in.
Height of container	7 ft 6 in.	7 ft 6 in.	6 ft 2 in.[1]
Skids per container	4	4	4
Bricks per skid	300	500[2]	600
Bricks per container	1,200	2,000	2,400
Containers per car	24	14	14
Bricks per car	28,800	28,000	33,600
Weight of container and contents, lb	2,000	3,350	.....

[1] This figure is approximate. Sections are 16 in. high, and four are used, which, with allowances for skid platform thicknesses and clearance under the legs of bottom skid, give a total height of about the amount stated.

[2] Figures in this column, from here down, have been estimated by calculation.

Coordinated Railway and Truck Service

The Chicago, North Shore & Milwaukee Railroad, as a new branch of its "ferry truck" service, is offering another facility to shippers in Chicago, Racine, and Milwaukee. Entire motor trucks and trailers, filled with merchandise, are now moved on specially constructed flat cars. The charge is 10 cents per 100 lb of merchandise, with a minimum load of 15,000 lb, for trucks and trailers up to a total of 23 ft in length, and the same rate for longer trucks but with a minimum load of 18,000 lb. Ramps at receiving and delivery points allow the trucks to be run on the freight cars and fastened. Loading and unloading are done by shippers or consignees, or their agents. The railroad, which has a main line 90 miles long, thus is counteracting competition from motor trucks on short hauls.

Seatrain Freight Service

Seatrain freight service was extended during 1932. The original service, with one vessel, has been in effect between New Orleans and Havana for three and one-half years, connecting the 2600 miles of Cuban railways with those of the United States. A car-ferry vessel, 427 ft 6 in. long, with a 62-ft beam, has provided the transportation. The vessel has three decks, all served by one large hatch amidships. Each deck has four rows of standard-gage track, and the superstructure deck also has tracks, giving a total trackage of about one mile, sufficient for 100 cars. A 110-ton crane picks up a cradle on which standard railroad freight cars are run, hoists the car and lowers it to the desired deck, where it is switched into position by a steam-driven car-hauling gear. The crane then picks up a car from the ship and hoists it to the dock on the return travel. From 15 to 20 cars per hr thus are loaded and unloaded. The cars, during the voyage, are secured by chocks and jacks. Two new vessels have been completed to start service between Hoboken, N. J., and Havana, late in 1932. On its trial run, one boat made a speed of 17.1 knots at 8800 hp, or $^3/_8$ knot faster than the designed speed, and thus will be probably the fastest freighter afloat. The New Orleans-Havana service to Cuba handles gondola cars of coke, tank cars of lard, cottonseed oil, gasoline, kerosene, lubricating oils, acids, etc., refrigerator cars of fruit and vegetables, box cars of unbagged grain, flat cars of lumber, etc. On return trips from Cuba, the gondola cars bring manganese ore, rock asphalt, scrap iron, and similar bulk materials for which economical transportation mediums formerly were lacking. Refrigerator cars bring back perishable commodities.

The advantages of the service are that materials are loaded in cars at the shippers' plants, moved over the railroad to the water front, hoisted on the Seatrain boat, hoisted off at the port of call, and moved over another railroad to the plant or warehouse of the consignee. In one year, the New Orleans service increased by $1,000,000 the sales of five Southern products in

Cuba. The one vessel, in three years, furnished over 40,000,000 ton-miles of transportation without incurring any damage claims.

Material-Handling Papers and Publications

A reduced amount of literature was produced during the year, due to the restricted number of technical meetings held and the concentration of attention throughout industry on problems of securing business rather than widespread improvements in plant equipment and operation. The quality of published items, however, was up to a good standard.

The Materials Handling Division, at its Annual Meeting in December, 1931, presented three papers in addition to its Progress Report: "Rustless Steel Conveyors—Their Availability, Application, and Use," by Nixon W. Elmer; "Improved Material-Handling Methods in a Container Plant," by H. N. Macdonald, and "Applications and Design of the Floating Drive for Conveyors," by N. H. Preble.

At the National Meeting in Detroit, held on May 4 and 5, 1932, in conjunction with the American Foundrymen's Association and the Materials Handling Institute, six papers were given: Three papers under the auspices of the Materials Handling Division were: "Maintenance of Materials Handling Foundry Equipment," by T. A. Bissell, associate editor, *Maintenance Engineering;* "Relative Wear of Metals by Abrasion," by C. R. Weiss, chief engineer, Link-Belt Co., Indianapolis, Ind.; "Management Policies and Practices in a Continuous Production Gray Iron Foundry," by W. G. Reichert, metallurgical engineer, Singer Manufacturing Co., Elizabethport, N. J. Three papers under the auspices of the American Foundrymen's Association were: "Tram-Rail for Materials Handling in the Foundry;" "Materials Handling Problems in the Foundry Department of the Western Electric Company;" "Materials Handling as Related to Miscellaneous Jobbing Foundries."

The Engineering Index lists and summarizes in *Mechanical Engineering* 85 articles on materials handling, from August, 1931, to June, 1932, inclusive, distributed as follows: cableways 2; chains 3; coal and ash handling 4; containers for shipment 1; conveyors 22; cranes 11; elevators 7; hoists 1; hooks 1; industrial trucks 2; materials handling 18; motor trucks 8; reducing gears 1; steam-power-plant handling methods 3; tractors 1.

One book of note, intended both for technical reference and college text use, appeared in the field: "Modern Materials Handling," by Simian J. Koshkin, assistant professor of machine design, Cornell University (John Wiley & Sons, Inc., 1932, $6). This is the first book of its kind to be published. Professor Koshkin has undertaken the preparation of another text on the subject of "Characteristic Modern Materials Handling Equipment" (types, applications, and design features), and has the active support of members of the Materials Handling Division in the securing of data for this volume.

The British Standards Institution, in April, 1932, brought out a revised edition of its 32-page pamphlet on "British Standard Specifications for Derrick Cranes."

Manufacturers' Committee of the Materials Handling Division

The Manufacturers Committee of the Materials Handling Division has been carrying on a number of activities, although efforts have been limited by the let-down in business during the current year. At the National Meeting of the Division in Detroit, in May, 1932, the committee held a session at which a number of reports were presented. The report on "Performance Standards of Locomotive and Crawler Type Cranes and Shovels" was submitted in final form by a committee consisting of F. A. Smythe, President, Thew Shovel Company, A. J. Fries, District Superintendent of Motive Power, New York Central Lines, Buffalo, New York, William Ogden, formerly of the Association of General Contractors, Washington, D. C., and J. C. Wheat, Industrial Brownhoist Corporation, Cleveland, Ohio. After approval by this committee, the Shovel and Crane Manufacturers' Association, and equipment manufacturers and interested users, it will be coordinated with pending safety codes of the Society. Copies are available on request. The report was accepted by the Manufacturers' meeting.

A committee on "Formulas for Figuring the Capacities of Containers" presented a summary of its survey of the field, which was accepted at the meeting and is being prepared for circulation to obtain comments and suggestions from manufacturers and users. The report was compiled by Chairman W. E. Farrell, president, Easton Car & Construction Co., assisted by H. E. Brendlin, of the Hayward Bucket Co., and M. J. Andrada, chief engineer, The Robins Conveying Belt Co.

The committee on "Nomenclature and Classification of Materials Handling Equipment," headed by Chairman George L. Morehead, vice-president, Link-Belt Co., and consisting of the following other members: L. J. Kline, general manager, Mercury Manufacturing Co., and S. Buckley, Shepard Niles Crane and Hoist Co., reported that its activities would have to be postponed until such time as funds could be raised to compile data for a manuscript to be published in book form on this subject. The work is too extensive to carry further than the planning stage at the present time.

A committee on publicity and the securing of material-handling data for publication in magazines, of which C. B. Crockett, of Crockett & Smith, Eastern Representatives of the Automatic Transportation Co., is chairman, presented a report prepared by M. W. Potts, Secretary of the Materials Handling Division, and covering the results of a survey of engineering colleges to see whether the mechanical-engineering departments or the local Students Branches would be willing to hold material-handling meetings, and desired speakers to be suggested for such meetings. Favorable replies were received in response to a majority of the 72 letters sent out. The Publicity Committee of the newly formed Materials Handling Institute is collecting lantern slides and motion picture films for such purposes and is cooperating in plans for such meetings.

A paper by J. C. Enders, Engineer, General Electric Co., on "The Need for Standardization in Material Handling Equipment," pointed out the expense and inconvenience to which users were put by the lack of standards for items such as conveyor chain, conveyor trolleys, gravity rollers, height of angle-iron sides on conveyors, and similar parts. M. W. Potts, Secretary of the Division, and engineer, Alvey-Ferguson Co., was appointed to set up a committee to study the situation and work out suggested standards for recommendation to manufacturers and users of equipment.

In December, 1931, the Material Handling Institute was formed as a trade and development association of manufacturers of material-handling equipment, to provide for activities that lay without the proper field of operation of other existing agencies serving the industry. A plan of cooperation has been established between this newly formed organization and the Materials Handling Division of the A.S.M.E., the first active step in the program being the joining of the two groups in meetings at Detroit in May where the convention of the Materials Handling Institute and the National Meeting of the Materials Handling Division were staged simultaneously.

MH-55-2

Rustless-Steel Conveyors—Their Availability, Application, and Use

By NIXON W. ELMER,[1] OAK PARK, ILL.

The paper covers corrosion-resistant metals for material-handling use, giving tables of relative corrosion resistance and costs under reasonably average conditions, particularly where food products are concerned. The various available materials are briefly described, and their good and bad features and qualities are developed. The types of conveyors for which these materials have been used are given, and the important and characteristic installation features of each are discussed.

FOR the purposes of this paper the word "rustless" will be interpreted in its broadest and non-technical sense as corrosion-resistant. From the point of view of the operator using the metal in his daily work it makes little difference whether the staining, corroding, or pitting is due to the formation of a sulphide of iron or an oxide of iron; what he is interested in is the deterioration of the equipment itself.

From an engineering standpoint it is almost as bad an economic error to make equipment better than is needed as to make it less good than is required. Therefore the first problem in design is to decide what degree of corrosion resistance is desirable or essential. Knowing the corroding agents and the working conditions, it is the duty of the engineer to find the cheapest suitable material to give the desired length of life.

Corrosion is undesirable, and in designing and making conveyors it is avoided, for two reasons, either of which may control: (1) Physical deterioration of the equipment itself. (2) Discoloration of and injury to the product conveyed. An example of the latter would be yellow rust stains on food products, making them unsalable.

All metal corrodes; some slowly under few reagents, others more rapidly with many reagents. The equipment to be discussed comes under the first class, the problem being to select the most suitable material (where the correct economic life is the object) to resist the corroding agent encountered in the given circumstances. If, for instance, the conveyor is to be used only two years, it would be poor engineering to make it good enough to last 20 years or to build it so cheaply that it wore out in less than the two years.

To start, let the materials generally available for conveyor use be arranged in the approximate order of their corrodibility, as follows: cast iron, malleable iron, hot-dipped steel, hot-dipped firebox steel, galvanized Armco or Toncan metal, Monel metal, 18-chrome–8-nickel steel, pure nickel, or block tin.

In the order of their cost, which is vital to the economic solution of the problem, these materials are as follows:

Material	Cost per 100 lb	Ratio
Malleable iron	$5.25	1.00
Cast iron	4.25	0.81
Hot-dipped galvanized steel	5.25	1.00
Hot-dipped galvanized firebox steel	5.75	1.10
Electro-galvanized Toncan and Armco	5.50	1.05
Hot-dipped tinned steel	9.25	1.76
Block tin	40.00	7.63
Monel metal, polished	53.00	10.10
18-chrome–8-nickel, polished	55.00	10.45
Nickel, polished	63.00	12.00

The engineer must so select and combine the materials that the best result will be obtained for the least money over the proper period of time.

In the comparative-cost table, which naturally changes with a changing metal market, malleable iron has been taken as a basis of comparison.

Cast iron of course lacks tensile strength, will not withstand shock, and rusts sufficiently to stain.

Malleable iron rusts enough to stain, but is stronger and not brittle.

Hot-dipped galvanized steel does not rust until the galvanizing has worn off or corroded off; thereafter it acts like any other plain steel.

Electro-galvanized Toncan or Armco has the slow rusting base of a pure wrought iron or copper-bearing steel, with a thin zinc coating which is not amalgamated with the iron at the surface by heat. The spread of rust from the spots exposed by wear is very much slower here than in the preceding case, although the exposure is quicker to occur. Inasmuch as this material is generally obtainable from stock only in sheets, no mention is made of it in hot-dipped form. Hot-dipped galvanized steel after fabrication is not practical for sheet-metal work.

Block tin is attractive in almost every way except physically. Perhaps its weakness and softness could be modified by the addition of minute quantities of metallic impurities.

Monel metal is expensive, but is easily worked, and where kept in use is itself stainless.

The 18-chrome–8-nickel, when properly made, under either the German or the English patents, and polished, is truly stainless for general uses, both as to itself and the products in contact with it. Nothing lower on the scale of chrome and nickel content will uniformly withstand fatty acids and fruit acids, and there is no need for going higher in the chrome-nickel content unless high-temperature oxidation or physical strength at elevated temperatures is involved.

Common salt is so widely distributed and aluminum is so readily dissolved in its presence that aluminum has not been mentioned in the table. However, the Aluminum Company's silicon alloy and the Major Metal Company's product show hopeful signs of progress in overcoming this defect.

Cadmium in the form of plate cannot be used either safely or legally in contact with food products, it having been declared poisonous by the Bureau of Animal Industry. This plate has, however, attractive properties, both as a rust preventive and as a lubricant, where there is no contact with food products.

---

[1] The author was engineer for the Link-Belt and Lamson companies from 1905 to the World War and consulting material handling engineer since.

Contributed by the Materials Handling Division and presented at the Annual Meeting, New York, N. Y., Nov. 30 to Dec. 4, 1931, of THE AMERICAN SOCIETY OF MECHANICAL ENGINEERS.

NOTE: Statements and opinions advanced in papers are to be understood as individual expressions of their authors, and not those of the Society.

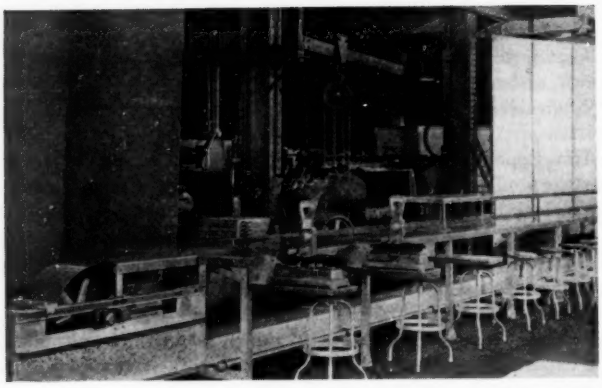

FIG. 3

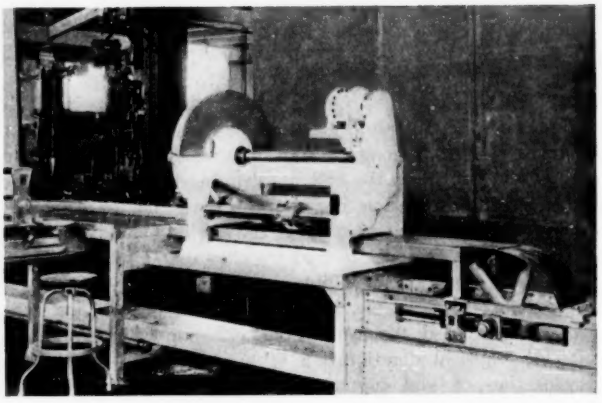

FIG. 4

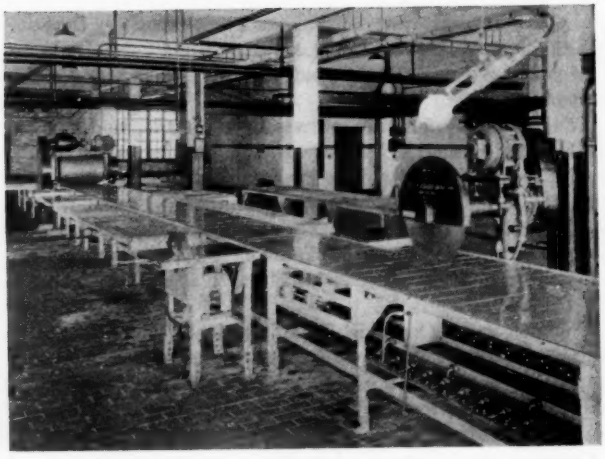

FIG. 5

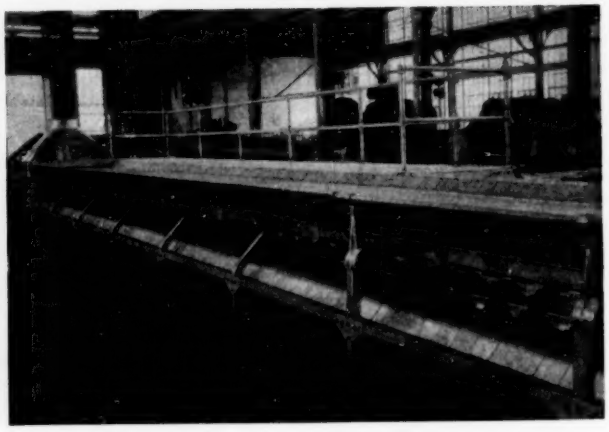

FIG. 6

With this outline of materials and their properties, consideration will be given to the types of conveyors for which these and similar materials may be used and are commercially available. These conveyors are as follows:

1 Steel belt conveyors:

(1) Woven wire: Woven of almost any material that is available in wire form.

(2) Doormat type: The choice is not as wide here, as the material must be available in both strip and wire form. The wearing qualities of this type are beyond expectation from a casual inspection of the design. The stretch is small, and all that is needed is good alignment and a good-sized, many-sided polygon for its pulleys.

(3) Swedish iron: This is an imported solid-steel conveyor belt that is not soluble in fruit or fatty acids, but which, when clean, will rust in clear water and air after the fashion of cast iron. (The author has used this conveyor with good success for trimming out cocoanut meats, for trimming fat and lean pork, and for conveying bacon from the slicing machine in front of the packers, as well as for the filling and cooling of canned lard.) The fundamental requirement here is, however, accuracy of alignment. This was particularly noticeable in the case of the cooling conveyor, Fig. 1, where the range in temperature was about 150 deg. and the speed was less than 1 ft. per min. (As the pulleys are practically uncrowned, it is necessary to have efficient scrapers on them.)

2 Apron and pan conveyors:

(1) A typical installation of a pork-cutting table is shown in Fig. 5. The frame is hot-dipped galvanized after fabrication and before assembly, and the flights are made of Monel, with rivets of the same material. As a matter of cleanliness, return rolls must be used to support the lower run. To minimize rust, malleable-iron chains are used, their size being determined by the amount of material and the area exposed to rust and wear, instead of by listed strength. The large knife in the foreground revolves in the same direction as the table and slightly faster, cutting in the groove between the two conveyors, which are kept in accurate alignment by V-shaped blocks on every flight and continuous V-shaped guides. The short right-hand conveyor is driven from the take-up of the main conveyor, and the shoulder is cut off by the knife and delivered over the end of the short conveyor. After the hams, shoulders, loins, and ribs are removed, the sides are flattened out under the heavy double roller shown at the left. The same motor drives the rolls and the conveyor, insuring synchronism.

(2) Fig. 6 shows the latest type of beef-viscera table. This is 5 ft. wide, so that the operators can stand on it, and is synchronized with the overhead chain carrying the carcasses. The moving part of the table passes through a continuous sterilizer on the return run at the take-up end. The flights are of $^1/_2$-in. firebox steel, with the edges planed, jigged, hot-dipped, and wiped. Neither zinc nor ordinary steel seems to be able to withstand the action of blood. It is the expectation of the designer of this table that, at the end of ten years, there will not be more than $^1/_4$-in. deterioration through rust of the $^1/_2$-in. hot-dipped galvanized firebox steel. The extremely heavy malleable-iron combination chain has the same life expectancy. The top-vent sterilizer is shown at the left. The overhead synchronized cattle chain brings the carcass in contact with the near side of the flight at the sterilizer, with the head projecting under the flights, but not touching the framework or stationary part of the conveyor, which is not subject to continuous sterilization. The operators ride the conveyor with the carcass and walk back on the platform shown on the far side. The overhead conveyor, with the carcass, turns away from the table near the middle of the picture, where the frame straightens up and the guard rail begins. The government inspectors operate from here on. Both runs are supported throughout on self-lubricating rollers and never touch any stationary part of the conveyor. The underlying patent on the sterilizing and synchronizing features has been dedicated to the public.

(3) A hog-viscera table is usually made of either 18-8 steel or Monel, with pans. There is a patent on trays and another on pans. The trays or pans are made 3 ft. wide and 3 in. deep on two strands of malleable-iron chain. Half of the pans are 30 in. long and half are 6 in. long, alternating. There are six double sets of K2 attachments under the long pans, with two pairs of plain links between. Only the center pairs of these attachments are riveted; the others merely support the loaded pan in the horizontal position.

3 Screw conveyors:

(1) These can be and have been made in both 18-8 steel and Monel. From the nature of the screw action the 18-8 is to be preferred, provided the purchaser will agree to accept the odd diameters that the manufacturers' standard equipment for rolling helical flights will turn out in this material.

4 Bucket elevators:

(1) Bucket elevators are made in these materials, but as the buckets are comparatively few in number and usually bolted in place, it is generally satisfactory to regalvanize or retin these when required, except in a few special cases, such as fancy table-salt and certain special cosmetic items.

(2) Any of these materials that are available in wire form may be used in the elevator type of self-cleaning screens which are standard for water intakes and sewage-disposal plants.

5 Various other forms of conveyors can be obtained in rust-resisting materials, such as scraper conveyors, gravity roller conveyors, etc., but it is so difficult to keep these types mechanically clean that there is less occasion to justify the added expense.

In conclusion, the author believes that future progress along these lines will be rapid as soon as the patent and licensing situation is straightened out on a tonnage production basis and the metallurgists learn to produce 18-8 steel from the chrome ore direct. Until something of this sort is accomplished, it will be economically impractical to make general use of 18-8 for rolled shapes and shafting, attractive as the idea is to the food-products manufacturing plant.

Discussion

S. Craig Alexander.[3] The author's statement on the order of cost, taken with the table on the first page, is likely to prove

[3] San Francisco, Calif.

misleading. Comparing, for example, Monel metal and the 18-chromium–8-nickel steel, it is not brought out that Monel metal weighs about 0.320 lb. per cu. in. against about 0.283 for the 18-8 steel, thus giving a percentage difference in weight in favor of the 18-8 steel of a little over 13 per cent. Taking two pieces of the same size and thickness, the Monel metal would weigh over 13 per cent more than the 18-8, thus affecting the cost to this extent were the two priced exactly the same per pound.

There would be no occasion for using a greater thickness of the 18-8 steel than of the Monel metal, because the elastic limit and modulus of elasticity are higher in the 18-8 steel than in the Monel metal, while the resistance to wear or the abrasion resistance of the chromium-nickel steel alloy similarly is superior to that of the nickel-copper alloy. If anything, the thickness of the design could be reduced with the 18-8 steel over the same design in Monel metal without sacrifice of safety and service.

Author's Closure

The two points brought out by Mr. Alexander and a third fact (that 18-8 is more expensive to work than Monel) were carefully considered, and the manufacturing costs of a concern which advertises its willingness to furnish either Monel or 18-8 at the same price were checked over a year's period before this table was passed.

This table is just as correct in the final analysis as in its more obvious interpretation

MH-55-3

Application and Design of the Floating Drive for Conveyors

By N. H. PREBLE,[1] DETROIT, MICH.

Increasing demand for longer conveyors and conveyors more heavily loaded per foot of length has brought about the necessity of using multiple drives on a single strand of conveyor chain in order to keep the weight and cost of chain and carrier units down to a reasonable point. To meet this requirement there has been developed a floating type of driving mechanism so arranged that two or more drives located at considerable distances from each other will automatically synchronize as to speed so as to maintain proper driving action at each drive point. The paper describes in detail the development of this design and its application to various types of conveyors, pointing out the advantages obtained through its use not only as a synchronizing means, but also in properly distributing the total load, in effecting smoother operation, in replacement of the standard form of shear pin, etc.

AS IS TRUE in most forms of engineering construction, the demand for industrial conveyors has tended during the last decade toward larger and larger units—units larger not only as to weight of material carried, but also as to length of line. This has been, perhaps, more especially true in the overhead trolley conveyor, a design particularly suitable as a transportation or processing medium. (See Fig. 1.) Due to the flexibility of layout which is possible with this conveyor, great length is entirely feasible, so far as layout and general conditions are concerned. Many other forms of conveyors, such as the slat conveyor, the belt conveyor, or any double-strand construction, can operate only in a straight line at right angles to the center line of chain pins. They may be curved up or down, but cannot be turned in a horizontal plane. Their length is then limited by the maximum length of the building within which they are installed. With the overhead conveyor, however, or with certain other types of single-chain construction, it is possible to curve the conveyor not only up or down, but also to one side or another, so that it may be run from one floor to the next, through bridges from one building to another, curving at will in either plane. (See Fig. 2.) It is therefore apparent that in the large plant or in a plant having a number of buildings located fairly close together there is practically no limit to the length of conveyor which may be laid out to transport material from one place to another within the building or grounds.

In view of the fact that the floating drive was originally designed particularly with a view to use on the overhead conveyor and its application is peculiarly suited to such a conveyor, a few brief comments in regard to the design of this equipment will perhaps be in order.

Essentially the overhead continuous power-driven trolley conveyor consists of some form of monorail track, usually an I-beam, although occasionally made up of two angles or a pair of rails of some other description. On this monorail track are operated 2-wheel or 4-wheel trolleys and ordinarily having anti-friction bearing in the wheels. These trolleys are attached to a conveyor chain at suitable intervals, and from the trolley or with lighter loads, from the chain at intermediate points between the trolleys, are suspended hooks, trays, or racks for carrying the material

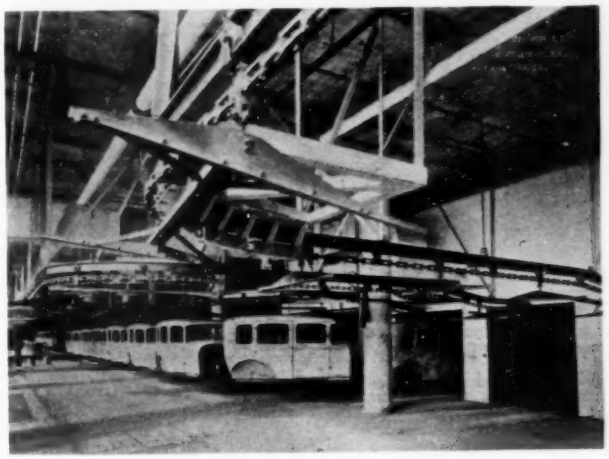

FIG. 1 TYPE OF OVERHEAD TROLLEY CONVEYOR

to be transported. The conveyor chain itself is of a flexible construction which can turn not only in the usual manner, but also can be bent in the plane of the pin center line. If the track is curved upward or down, the trolleys, being guided by the track, will rise or descend, guiding the chain in a line parallel to the track itself. Turns can be made in a horizontal plane, the conveyor chain in this case serving as the guiding medium and running against either a sprocket or a series of small rollers. Power is applied directly to the chain through a conventional type of driving sprocket or through a so-called caterpillar drive, which consists of a chain driven from a small-pitch sprocket and carrying dogs which engage with the conveyor chain and serve to propel it.

In laying out a conveyor of this type a typical calculation would be as shown in Table 1, where a conveyor is assumed having a total length of 4600 ft., with trolleys spaced at 2-ft. intervals, each trolley carrying a hook from which the loads of 80 lb. each is to be suspended. It is assumed that the line will be 80 per cent loaded and that there are no vertical lifts to be considered in figuring the power required; in other words, that any loads that are carried up an incline also run down the same distance, so that they will balance. The minimum radius of the horizontal turn, which is given as 24 in., will be determined by the clearance

[1] Chief Engineer, Jervis B. Webb Company. Mem. A.S.M.E. Mr. Preble was graduated from the University of Michigan in 1913 with the degree of Bachelor of Mechanical Engineering. He has been associated with the American Blower Corporation as research and design engineer, with particular reference to heating, ventilating, and air conditioning; with the Timken Detroit Axle Company as sales engineer; with Mechanical Handling Systems, Inc., as Vice-President and Chief Engineer. Now Chief Engineer, Jervis B. Webb Company. Mr. Preble served as Captain of Infantry with the A.E.F. in France, 1917 to 1919.

Contributed by the Materials Handling Division and presented at the Annual Meeting, New York, N. Y., Nov. 30 to Dec. 4, 1931, of THE AMERICAN SOCIETY OF MECHANICAL ENGINEERS.

NOTE: Statements and opinions advanced in papers are to be understood as individual expressions of their authors, and not those of the Society.

required between the loads as they pass around these horizontal turns. The minimum allowable vertical radius will depend upon layout conditions and should be kept as large as possible so as to reduce to a minimum the bending stresses imposed on the chain and the reactions of the chain on the trolley at the vertical bends. Usually a conveyor of this sort will be most efficient if

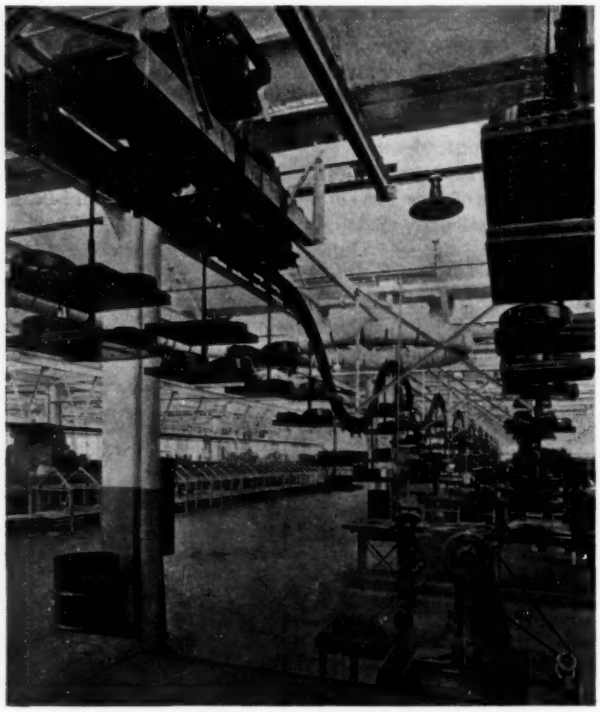

FIG. 2 OVERHEAD CONVEYOR OF SINGLE-CHAIN CONSTRUCTION THAT CAN CURVE UP OR DOWN

arranged with a variable-speed drive unit, so that the speed can be changed at will to meet varying production conditions. In this example it is assumed that the speed is to vary from a minimum of 10 ft. per min. to a maximum of 50 ft. per min. In order to determine the size of units involved, the first calculation must be as to the tension required in the chain at the drive to operate the conveyor, which will be a function of the total load moving plus the friction produced by the vertical and horizontal bends. The total load will consist of the weight of chain which, to start off with, will be assumed at 10 lb. per foot, plus the weight of trolleys, assumed at 12 lb. each, plus the weight of hooks calculated, knowing their design, together with the total live load carried. The total figures out to 232,300 lb. Assuming that the trolleys will have some form of anti-friction wheel, experience indicates that for the average layout the total friction will be approximately 5 per cent of the total weight of the moving load. The chain pull at the drive will then be approximately 11,600 lb. To determine this exactly, it would be necessary to examine the layout more carefully, calculating the known friction of the trolleys plus the friction at each turn, which is a direct function of the chain tension at the turn. In other words, the friction at each turn or bend will increase as the driving mechanism is approached and as the chain pull approaches its maximum. A 5 per cent figure, however, would be indicated by experience of average conditions. The horsepower required would then figure out to approximately 14 hp. to operate the line at its maximum speed of 50 ft. per min., which would involve the use of a somewhat larger motor to take care of frictional losses through the driving mechanism itself. If it is assumed that there will be used a caterpillar type of drive unit with a 30-in. power-drive sprocket, the torque on the head shaft would be 174,000 in-lb., requiring a shaft approximately $6^1/_2$ in. in diameter.

Examining these calculations it is immediately evident that with a conveyor of this length, carrying a heavy load, all of its component parts must be of very strong construction. The chain-pull requirement is over 11,000 lb., which means that the chain, in order to take care of the conditions which arise on the vertical bends, should have an ultimate strength of around 120,000 lb. The trolleys will have to be designed not only to carry the imposed load of 80 lb. plus 5 lb. for the hook, but also must be capable of withstanding the chain-pull reaction on the vertical bends. With a 2-ft. trolley spacing and vertical bends on 10-ft. radius, this reaction at points adjacent to the drive unit will run up to a figure somewhat over 2300 lb., so that instead of having a trolley which will merely carry the load, there must be one that will withstand momentarily this considerably heavier reaction. The track also will have to be designed at the curves to take such a reaction, and the horizontal turns will have to be braced progressively stronger as the drive unit is approached. The drive itself will have to be extremely massive in construction, for while the power requirements are relatively low, the torques involved are large, due to the slow speed at which the chain is traveling. Under actual conditions it probably would not be feasible, from an economic standpoint, to install a conveyor to meet these requirements. The cost would be excessively high, and there would be a dead weight equivalent to very nearly the total of the live weight or useful load.

It is at once apparent that if this conveyor can be split into four separate units, there can be effected some very considerable economies. If one were handling bulk material on a belt conveyor, it would be a simple matter, because such material can be

easily spilled from one section to another, but if one is handling a package, using the word "package" in the broad sense, it is quite essential that there be one continuous chain, to avoid the necessity of making a manual transfer or having extremely complicated automatic transfer devices. It is therefore desirable to have some form of driving medium which can be applied to the chain at more than one point.

Assume for the moment that such multiple units are available and analyze again this same conveyor. (See Table 2.) It found first of all that one can cut the size of the chain and use one of considerably lighter weight. The trolleys will not have to stand the extremely high reactions involved in the first example, so can also be reduced in weight. The hook load and live load will remain the same, but the total is immediately reduced to 190,000 lb. in place of the previous total of 230,000 lb. As the maximum chain pull will be considerably less than previously, it is safe to presume a friction load of 4 per cent in place of the 5 per cent due to decreased turn friction. A maximum total chain pull of 7600 lb., or a total horsepower under 14, is then indicated. If it is assumed that there will be used four drive units, the maximum chain pull at each unit, if they are evenly balanced, will be 1900 lb., and one can safely employ four 5-hp. motors. The chain being lighter, can be economically furnished in a shorter pitch, so that one can reduce the diameter of the caterpillar-drive sprocket. The torque required at the drive shaft, assuming a 20-in. pitch diameter sprocket, would be 19,000 in-lb., requiring a shaft of $2^{5}/_{16}$ in. in diameter. Specifications such as this would be quite usual practice in overhead trolley construction and would be met by the use of 4-in. I-beam track with a two-wheel ball-bearing trolley attached to a 4-in. pitch No. 458 forged chain, having an ultimate strength of 30,000 lb., giving a factor of safety of 15 to 1, based on the calculated maximum chain pull of 1900 lb. It also will be noted that the total live load is close to 150,000 lb., whereas the weight of the conveyor proper which must be moved is only 45,000 lb., or 1 lb. of conveyor to about $3^{1}/_{2}$ lb. of pay load.

It might be well to point out another factor which frequently enters into this problem of drive design and strength of units. Frequently one will have an existing conveyor which it is desired to extend. If multiple drives are used, this can be done without any change to the existing construction, whereas if one had to drive at only one point the added loads might make necessary new trolleys and chain.

In order to operate satisfactorily, the first essential of any multiple drive is that all driving points must be exactly synchronized with each other. If one drive should be running only a very small fraction of a revolution faster per minute, it will very quickly tend to pull the conveyor away from the other drives and assume the total load itself; a condition of synchronization of all separate driving points must be maintained exactly at all of the varying speeds, a problem which is somewhat more difficult to solve than would be the case if the conveyor was run only at a constant and fixed speed.

Under certain conditions a conveyor of this sort may loop back toward itself, and there will be several points where sections of the conveyor will be running parallel to each other and fairly close together. If such points occur, it is possible to drive by means of a single motor and variable-speed unit to a countershaft, and from this countershaft to the reduction gearing and final drive sprocket of the drive unit proper, thus securing exact synchronization of head-shaft speed. Such an arrangement has been used frequently and is fairly satisfactory so long as the pitch of the chain is the same throughout its length and a spot can be found where the necessary number of lines run adjacent to each other at reasonably close intervals and so located as to divide the conveyor as to length or load into approximately equal intervals. (See Fig. 3.) Such a condition is almost impossible except where the conveyor is confined to a single building or even to a single floor of one building. It also should be noted that such an arrangement does not allow for any compensation of load between the individual driving units to effect an equalization should the conveyor be of different lengths between the units or differently loaded.

If only a constant speed is required, satisfactory results can be obtained by the use of the ordinary form of synchronous alternating-current motor drive through a reduction gearing to a driving sprocket, fitted with a ratchet or one-way clutch. If one

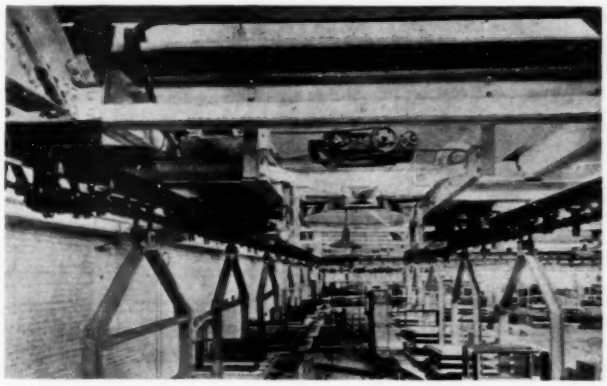

FIG. 3 SECTIONS THAT ARE PARALLEL MAY BE DRIVEN FROM ONE MOTOR

drive is getting more than the proper load, the motor will be slowed down automatically, whereas under an opposite condition, the chain will pull away from the drive unit through the ratchet mechanism and the motor will speed up. A number of installations of this type have been made and operated, but experience would indicate that a large number of separate drive units will be required for satisfactory results.

Various forms of electrical synchronization have been attempted with varying success. Most of them have, however, been rather complicated and expensive, and involve a considerable amount of excess wiring if the units are located at any distance from each other.

In order to overcome the disadvantages of other methods and to provide a simple and fully automatic synchronizing medium, the floating type of drive was developed and has been applied with entire success to overhead conveyors and also to other forms of conveyor construction. Fig. 4 shows a typical caterpillar drive mechanism consisting of a motor driving through a silent chain or V-belt to a variable-speed transmission. This variable-speed transmission may be of the belt type, as manufactured by the Reeves Pulley Company or the Llewellyn Manufacturing Company, or may be of the positive chain type, such as the P.I.V. unit manufactured by Link-Belt Company. Any of these three variable-speed transmissions operate by means of varying the position of the V-cones on which the belts or chain operate so as to change the ratio between the two shafts of the transmission, the change being effected by a screw mechanism operating on a pair of levers which push the V-cones closer together or pull them further apart as required. The range from the minimum ratio to the maximum between the two shafts is in an infinite number of steps. In other words, one can get as exact adjustment as required and not depend upon a limited number of steps as in the usual form of variable-speed motor. The variable-speed shaft of this transmission is connected through a chain or direct through a flexible coupling to some form of reduction gearing, and from the reduction gearing either direct or through separate gears to

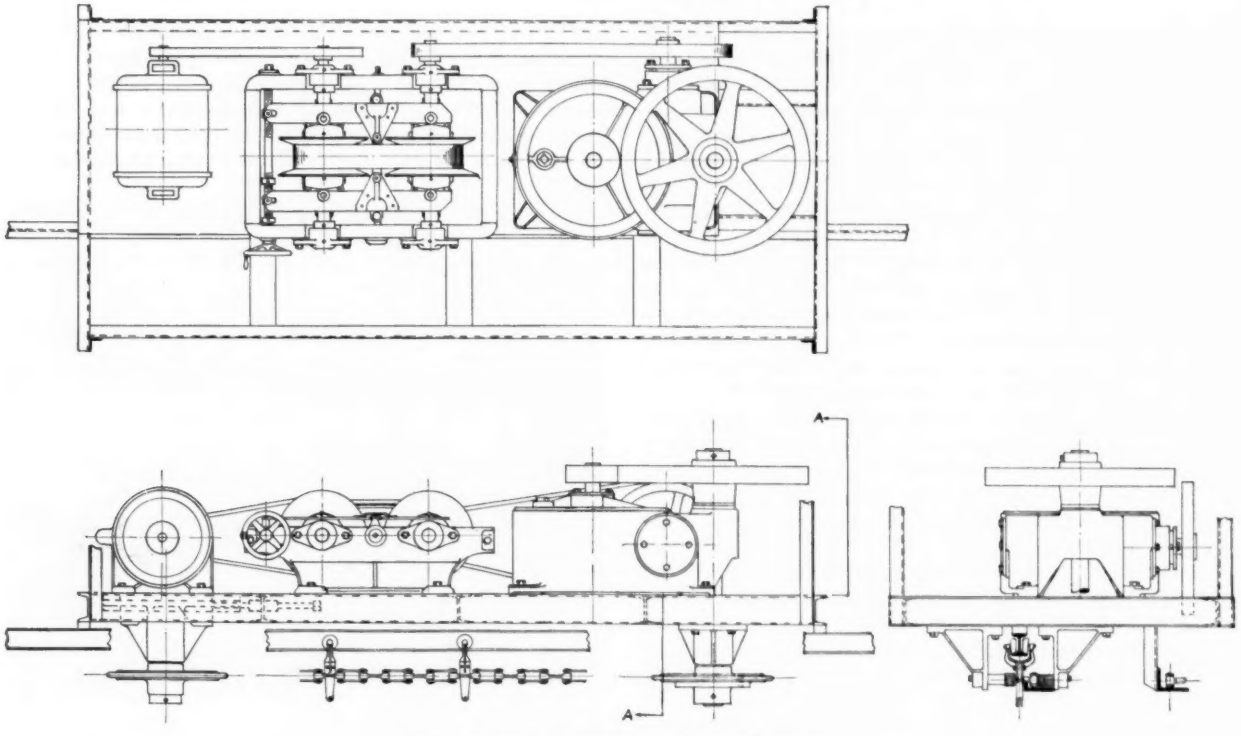

FIG. 4 TYPICAL CATERPILLAR-DRIVE MECHANISM

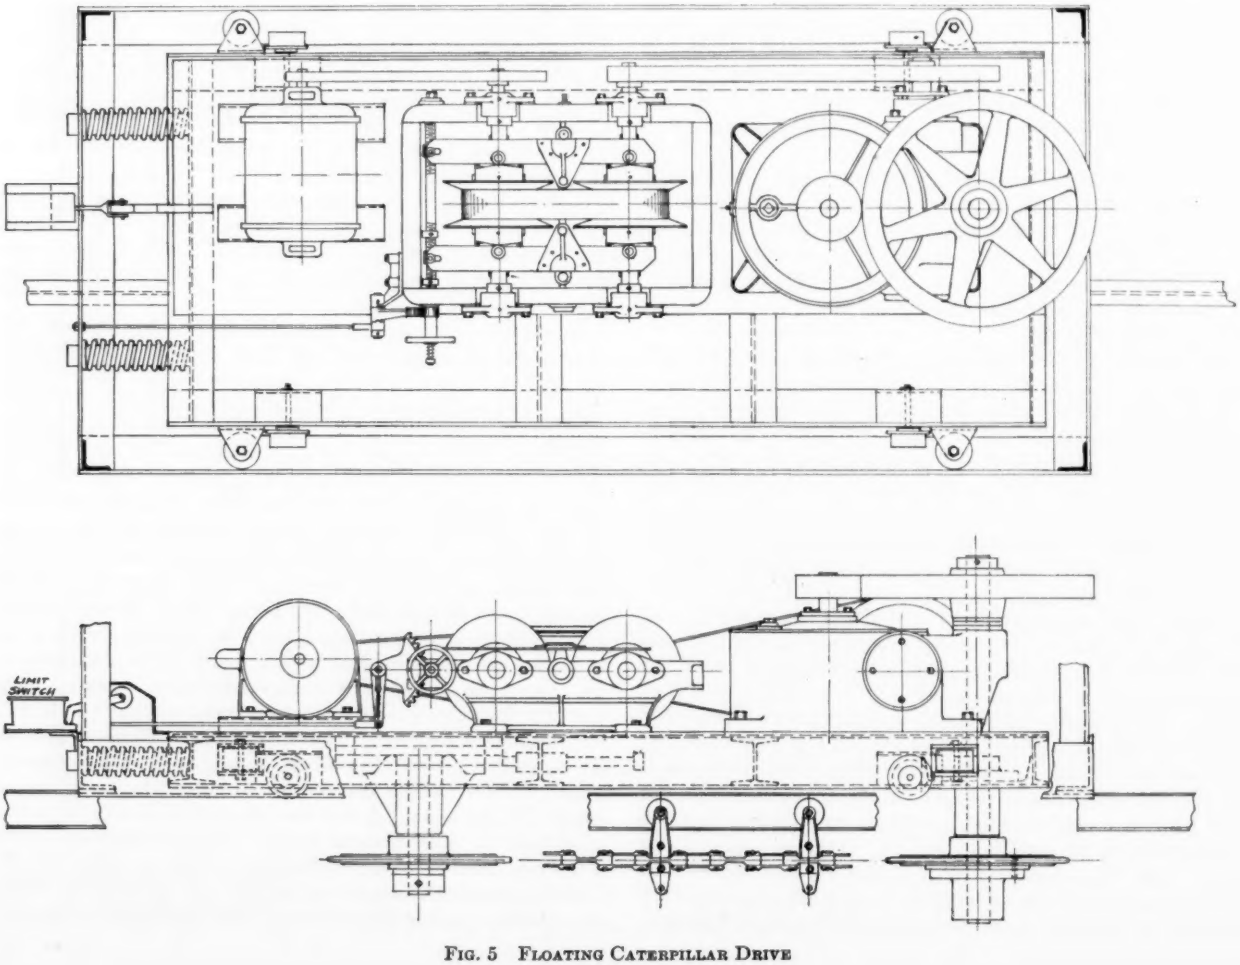

FIG. 5 FLOATING CATERPILLAR DRIVE

the driving head shaft. The entire mechanism is rigidly mounted on the same form of frame, the driving sprocket operating a caterpillar chain and the same frame carrying a take-up sprocket around which the caterpillar chain passes. The floating drive mechanism utilizes this unit frame and machinery units, exactly as indicated in the diagram of Fig. 4, mounted in a separate and fixed frame. (See Fig. 5.) The frame of the caterpillar drive proper is carried on rollers and guided within the secondary frame by means of vertical rollers. As the caterpillar chain operates in a direction parallel to the driven conveyor chain, the reaction of the drive effort on the conveyor chain will move the frame parallel to the conveyor, this movement being counteracted by a pair of coil springs attached to the fixed frame and bearing against the floating frame. The strength of these springs is adjusted properly to counterbalance the calculated chain tension at the individual drive.

It is at once apparent that if the chain tension or driving effort goes above the calculated figure, the coil springs will be compressed beyond their normal position, and conversely if the reaction is less than normal or calculated figure, the floating portion of the drive will be moved in the opposite direction by the springs. This tendency to movement is the operating medium of the speed control. The adjusting shaft of the variable-speed transmission is connected to the fixed frame through a series of gears and levers, so that if the drive moves back under excessive load, it will be automatically slowed down, or if it moves forward under less than normal load, it will be automatically speeded up. The result is that each drive will at all times adjust its speed to a certain chain pull, which will be determined by the strength and adjustment of the coil reaction springs. The detail of design of the connection between the fixed frame and the adjustment shaft of the speed transmission is so arranged as to allow for making the control more or less sensitive by variation in length of lever arms.

Exactly the same principle can be applied to a sprocket type of drive, the machinery framework in this case rotating around the head shaft under the influence of the torque of the shaft. This rotating tendency is again counteracted by means of a coil spring, the movement being used to vary the adjustment of the transmission.

This design will give in effect an exact synchronization regardless of motor speed or variation in motor speed and regardless of the location of the drives with respect to each other. It will further produce a synchronization or equalization of loads between the various units. If one section is carrying more chain than another or is more heavily loaded than another section, the various drives will adjust themselves to such variations and each will help out the other. Actual service tests on an installation of approximately 4000 ft. in length having three drives showed that the maximum in-put to any one of the three never exceeded 35 per cent of the total and the minimum was never less than 31 per cent of the total regardless of loading. The floating portion of the drive is further arranged in such a way that if for any reason the drive compresses the springs past a certain fixed point it will contact with a limit switch and shut off the current from the motor, thus acting as an automatic overload release to protect the conveyor and driving mechanism against any jam or snagging of the line, and taking the place of the usual form of shear or breaking pin. It shuts off the current without damage to any parts, and the unit can be restarted as soon as the line is clear, without the necessity of replacing broken pins, which is frequently the source of delay and annoyance.

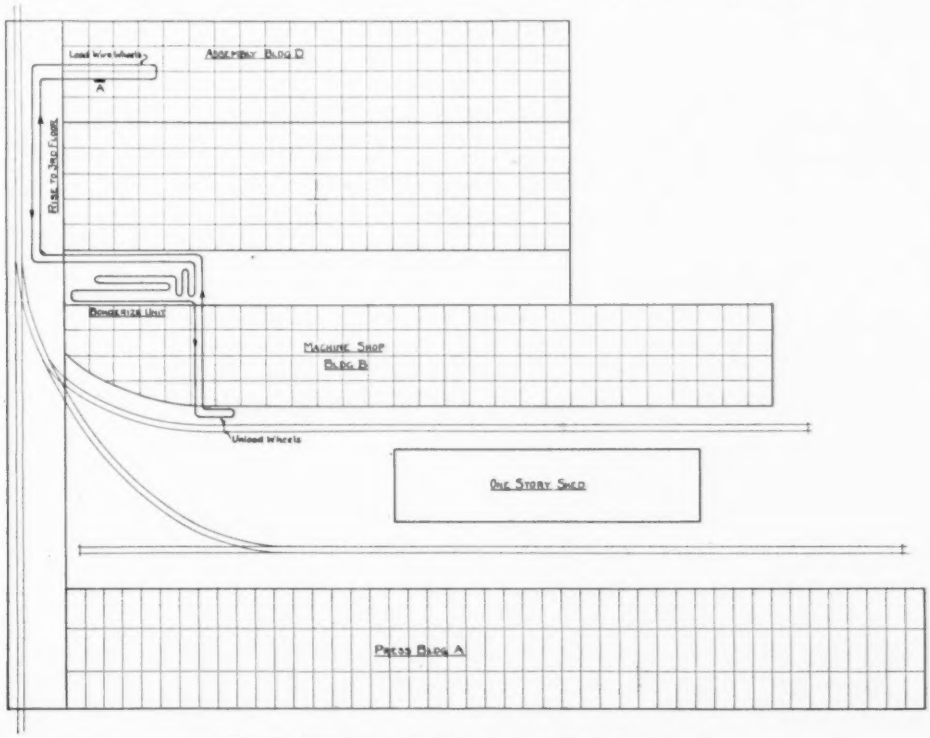

FIG. 6 OVERHEAD CONVEYOR AS AT FIRST INSTALLED

The various limit switches can easily be connected to a signal system so that at a central control point the drive that is shut off will immediately be indicated, and the place to look for trouble will be apparent.

It has been found by experience that a floating drive reduces the tendency of a conveyor to pulsate, the spring back-up of the driving frame smoothing out the power impulses, acting more or less in the nature of a shock absorber to take up sudden loads. A floating frame also will automatically care for variations in the

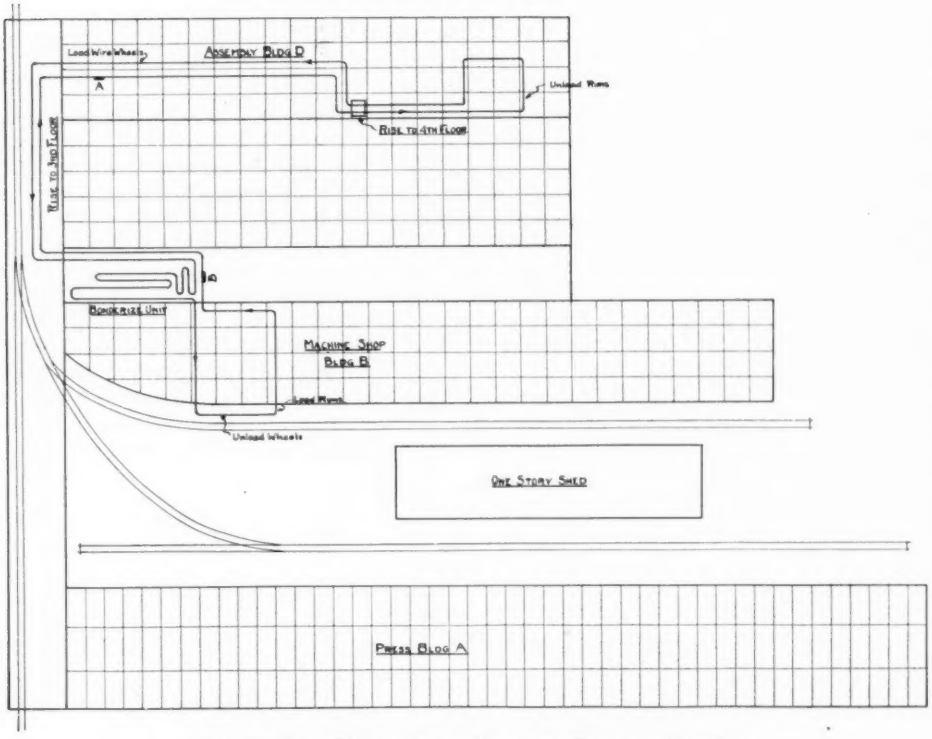

FIG. 7 FIRST EXTENSION OF CONVEYOR SHOWN IN FIG. 6

pitch of the chain in different sections, so that it is feasible to use a new section of chain with one which has been in use and has stretched or worn somewhat out of pitch.

It is not absolutely essential that the drives be located so as to each carry the same theoretical load, thus making it possible to put the driving mechanism at a point which may be most convenient.

A typical installation of an overhead conveyor with this type of drive is shown in Figs. 6, 7, and 8. Fig. 6 illustrates the original installation which was made to carry wire wheels through a bonderizing department, the wheels being loaded on the conveyor on the fourth floor, carried down through the bonderizing process, and then out to the shipping dock, where they were unloaded directly to cars for shipment. At a later date this same conveyor was extended to the layout as shown in Fig. 7, rims being loaded on the conveyor on the dock and carried up to the fourth floor, where the line was extended and the rims were taken to the assembly department. This increase in length, together with the added weight of the rims being carried from the shipping dock up to the fourth floor, imposed a load that was too severe for the original drive unit, chain, and trolleys. A second drive therefore was added, and both were mounted on floating frames. The conveyor was operated with entire satisfaction for a period of about six months under these conditions. At that time it became necessary for the user to bonderize another type of wheel, which was produced in another building, located some 250 ft. from the bonderizing unit. It was expensive to truck these wheels to the bonderizing unit and then bring them back to their starting point for enameling as would be necessary. In fact, it was almost physically impossible to do this by ordinary trucking without seriously interfering with production. The conveyor was therefore extended to the second building, running through a bridge between the two, and at the same time was further extended so as to pick up other parts produced in this building and carry

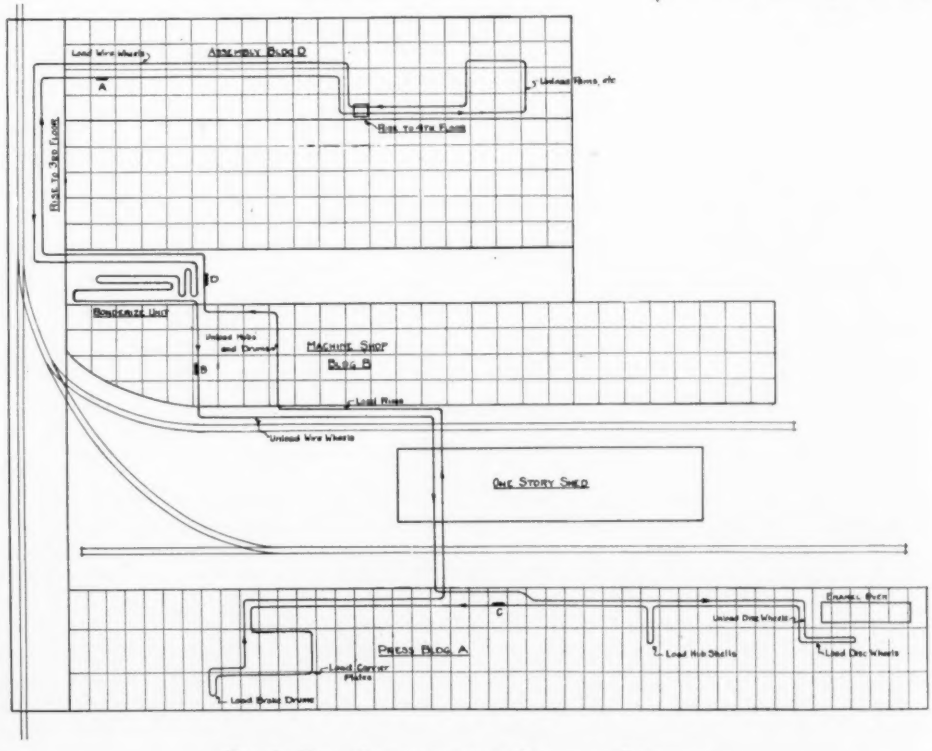

FIG. 8 FINAL INSTALLATION OF OVERHEAD CONVEYOR

them to other sections for machine operations or assembly. The final arrangement of the conveyor, as shown in Fig. 8, is approximately 5100 ft. long and employs four separate drive units, all of the floating type—a conveyor which would be practically impossible with a single driving mechanism, certainly

economically unwise even though physically possible from the engineering standpoint.

The discussion has been confined almost entirely to the application of this driving mechanism to the overhead type of conveyor. It is possible, however, to apply the same principle to any other conveyor construction. If one could conceive of a slat conveyor 10 miles or more long, there is no reason why a series of floating drives could not be so arranged, driving through caterpillar chains on both the load and return sides, as to make such an arrangement entirely practical from an engineering standpoint. In one particular case, applied to a single-strand motor assembly conveyor, there existed three separate conveyors of relatively short length, and due to changing manufacturing conditions, it was decided that it would be desirable to combine the existing conveyors to some additional material to make one long conveyor, the total load on which would be far beyond the capacity of the existing chain or driving mechanism. One of the existing drives was installed on the loading end of the new conveyor, this being fixed and operating at a certain speed as determined by the adjustment of the variable-speed transmission, and drives only the return strand plus a short section of the loads run. A second drive of the caterpillar type, the caterpillar mechanism only being mounted in a floating frame, was added to the load strand side of the conveyor just ahead of the horizontal turn. This floating caterpillar operating against two coil springs was connected by gearing to the adjusting shaft of the variable-speed transmission of a power unit, located in a pit alongside the booster, and thus synchronized with the fixed unit. The installation of this type of drive therefore made possible the utilization of considerable existing equipment of value, and as it was located immediately ahead of the horizontal turn, it materially reduced the wear of the chain operating around this turn.

The mechanism is extremely simple, requires no accurate adjustments, and involves no parts which can readily get out of repair. The maintenance problem is not complicated, and the results achieved in actual use have been satisfactory.

MSP-55-1

Progress in Machine-Shop Practice

ECONOMIC pressure, like unpalatable medicine, must be credited with some virtues, and not the least of these is the urge which it has put upon engineers responsible for design and fabrication, to bestir themselves to heroic efforts.

Despite budgets cut to unprecedented limits in so far as engineering activity is concerned, this motivating urge has produced some phenomenally productive machine tools and improvements in manufacturing technique which will tend, more than ever, to render obsolete the tools and methods which earned adequate profits as near back as 1929 and 1930.

The thought of those who earn their daily bread by the manufacturing arts, rising from the ashes of the high hopes of 1928 and 1929, is that an improved technique can still be produced which will earn a reasonable profit from a materially reduced volume of business. There is no complacency in this attitude; it is simply a case of the survival of the fittest; and the competition between methods and industries under this same economic pressure is, and will continue to be, more intense than ever.

Characteristically in line with former depressions, this one is prolific in hard thinking, and this in turn involves consideration of improved tools and methods which in other times would receive but scant attention.

As never before, the proponents of scientifically welded structures, die castings, precision forging machinery, improved machine tools, cold-heading equipment, and deep-drawing metal are being listened to with undivided attention.

Welded Structures

Despite the difficulties of the times under which we are working, a number of large concerns manufacturing welding equipment have carried a veritable torch of progress to the trade, and early in the year Mr. Everett Chapman, in his paper on "Welded Industrial Equipment With Reference to Machine Tools," quoted the case in a very able way.

While it is evident that welded structures cannot in every case replace castings with economic or engineering advantage, it is equally true that the use of these structures in the past has been hampered by lack of knowledge and some prejudice, and that with the availability of this knowledge, now resulting in a vastly increased usage, it may be safely said that during the next few years we will see a steadily increasing number of products produced in this way, with advantages to all concerned in lightness, cheapness, strength, and efficiency.

Concurrent with this development has also occurred a considerable improvement in the technique of cutting metals by the oxy-acetylene torch process.

One fairly large machine-tool manufacturing concern in particular has systematically combed its designs and substituted welded structures for castings in a great number of instances. To the uninitiated the results have been surprising to a degree in strength, saving in weight, efficiency, and grace. This firm has had many of its welded products in use for a long period of time, and their stability and permanence of accuracy are as outstanding as the other merits referred to.

The evidence is not lacking that, despite the conservative attitude of some designing engineers, the day is not far distant when welded structures for major units will be standard practice.

Die Casting

In many cases during the last few years the possible use of the die-casting method of fabrication has been hampered by the lack of definite information, or rather a formula which would give a quick and accurate method of computing costs. However, this information, under the economic pressure induced by the need for business, has now been made more generally available, and many concerns are looking to the die-casting method of fabrication to give them that margin between manufacturng cost and sales price which represents profit, and incidentally the inducement to continue to manufacture.

Accurate Forging Machinery

Concurrent with the development of more efficient machine tools and cutting elements, there has taken place a rapid increase in the quality of work turned out by up-to-date forging machinery, and in many cases work is now passed direct from the forging machine to the grinding machine without intermediate metal-removing operations. While the investment in such forging machinery is necessarily heavy, the results are economically attractive where work must be turned out in large quantities along mass production lines.

Improved Machine Tools

A questionnaire was addressed to the industry, the first three paragraphs of which read as follows:

1 What are the technical advances which have been made during the past 12 months in your specialties which are now ready for commercial presentation?

2 What advantages will be obtained from their use:
   (*a*) Decreased cost
   (*b*) Increased accuracy
   (*c*) Elimination of operations hitherto considered necessary
   (*d*) Specific commercial appeal.

3 On the resumption of normal production activity, do you look for an increased use of your product due to any of the reasons specified under headings *a*, *b*, *c*, and *d*?

And on the many replies received the following data are based.

Material-Handling Facilities

Without doubt, the most outstanding achievement in the attack on the idle or non-cutting time in the machine-tool cycle is the provision of automatic loading devices for individual machines or groups. While to date the majority of applications have been in connection with lathes and automatic grinding machines generally, there is not the slightest doubt that this type of equipment, which has been described in detail in the technical press during the year, will find many uses as an auxiliary to all types of machine tools that are used on high-production work.

When it is realized that the average machine tool is actually cutting metal only about 30 per cent of the total working hours, it will be appreciated how important this contribution is to the progress of the art.

Presented at the second session of the Machine Shop Practice Division on Tuesday afternoon, December 6, 1932, during the Annual Meeting, New York, N. Y., December 5 to 9, 1932, of The American Society of Mechanical Engineers.

Personnel of the Executive Committee of the Machine Shop Practice Division for 1932: F. C. Spencer, Chairman; R. E. W. Harrison, Secretary; W. J. Peets, Coleman Sellers 3d, and B. P. Graves.

Lathes

The outstanding technical advances made in lathes and automatic turning machines of all kinds during the present year include primarily an increased power input, higher operating speeds, additional anti-friction bearings, more universal automatic oiling, greater structural strength, the addition of automatic controls, and the use of more safety features—all in preparation for and in anticipation of the more universal use throughout the metal-working industry of the new cemented carbide cutting tool.

The specific advantages offered by these advances are:

(*a*) Decreased Cost. All of the improvements enumerated tend to increase the metal-cutting capacity of the machine tool, consequently to speed up production and decrease production costs.

(*b*) Increased Quality. The increased structural rigidity of the 1932 designs insures more constant alignments and diminution of chatter and vibration, resulting in higher quality of work produced.

(*c*) Reduction of Manual Operation. The addition of automatic mechanisms for controlling the machine's functions and of built-in measuring equipment and work gages eliminates many of the manual operations required by less modern designs, thus increasing the combined efficiency of the machine tool and operator.

(*d*) Specific Commercial Appeal. The specific commercial appeal of the modern improvements in machine tools is mainly that of a greater work return per dollar invested in equipment.

Precision Grinding Machines

The last year has been characterized more by a consolidation of the progress already gained than by the introduction of any radically new developments.

Automatic sizing, or in other words the provision of automatic compensation for the wear of the grinding wheel, continues to gain favor, and a number of interesting installations have been made in plants handling a mass-production program.

In the centerless grinding field the application of an increasing amount of horsepower to the grinding wheel continues, with resultant increase in rate of metal removal, and it may now be said that the precision grinding machine ranks high as a metal-removal tool for finishing operations.

Automatic gaging devices, which provide the operator with a quick and accurate means of sizing the work, are being used in greater numbers, and in some cases these gages are fitted with devices which automatically cause the grinding wheel to retract when the work is within the prescribed tolerance.

Screw Machines

In the screw-machine line one progressive manufacturer has announced the availability of a silent stock support which will prove of great assistance to screw-machine-parts manufacturers due to the fact that the excessive noise that is now caused by the stock rolling in the iron tubes will be practically eliminated by this new patented silent stock support.

Another improvement is a new nut-tapping attachment to be applied to screw machines which makes use of the bent tap, and this attachment lends itself to exceedingly high production, especially for brass nuts. Other types of nuts can be taken care of by making special adaptations of the attachment.

Another item of equal importance is the 30-speed countershaft for screw machines, which makes the screw machine a practical unit for either steel or brass work, and avoids the necessity of having the screw machine arranged for the standard speeds or high speeds, as the 30-speed countershaft machine will be suitable for either steel or brass work.

Drilling Machines

The last year has seen an extension of the progress in design which brought forth the continuous type of production drilling units of both hydraulic and mechanical construction.

One make of multi-spindle machine has a number of spindles operated by a hydraulic feed and a circular rotating hydraulic indexing table. Horizontal drilling heads at one or more of the stations are used according to the character of the job and the operations required.

Milling Machines

In the milling-machine field there has been released a new type of horizontal boring, drilling, and milling machine, which may be arranged with compound table. In general review, it may be said that there have been many contributions to the attack on idle or non-cutting time in the form of duplication of controls at the front and rear of machines, as well as the provision of more automatic features.

The planer-type milling machine continues to gain favor at the expense of the planing machine, and some remarkable economies have been reported by those companies that have had the courage to install this type of equipment.

There has been a general increase in the range of spindle speeds. One concern in particular now makes a practice of providing 32 spindle speeds ranging from 25 to 1800 rpm, and feeds from $^1/_2$ to 62 in. per min. This machine will aid in more efficient milling, as it adapts the machine to the latest cutting material, either tungsten or tantalum carbide, as well as being adapted to high-speed or carbon tools.

Die-Cutting and Engraving Machines

This type of machine, which is steadily gaining in favor, can now be said to represent the most up-to-date practice. High spindle speeds up to 4000 rpm are common, and permit the use of tungsten-carbide cutters.

Gear-Generating Machinery

The manufacturers of this type of equipment appear to have concentrated their activities on the provision of greater accuracy and facilities for testing the finished work.

The facilities for generating spiral bevel gears have been improved, and one manufacturer is in a position to cut hypoid pinions so that a right-hand one and a left-hand one will both operate equally well with one straight-tooth bevel wheel, an arrangement which, in many cases, is very desirable for reversible feed mechanisms.

This manufacturer has also completed a new method of cutting elliptic gears. This new method is a generating process, applicable not only to elliptic gears, but also to other kinds of non-circular gears.

Hobbed Integral Keys

One Middle West concern has succeeded in developing an integral key taper shaft end. These shafts are produced by the hobbing method, using a special hob in a special hobbing machine which has been developed for this purpose. The advantages of this construction over the present S.A.E. standard taper shaft, using a loosely fitting key, are evident.

In this construction is provided a conical section, or land, between the key, which conical section is practically impossible to produce accurately by any other method than hobbing. This gives the necessary seating surface, and in addition to this we

have the integral splines, which provide approximately three times the bearing we have at present by a single key. These splines cannot wabble or work loose as the present loose key does, and it is believed the whole construction provides a very superior drive to the present single loose-key construction.

The mating part to this piece, or hub, is very simply produced by reaming a taper hole as a first operation, and pulling through this hole a standard four- or six-spline broach. These two operations finish the boring of the hub, so that it is then ready to fit very accurately on the hob member.

This construction is particularly applicable to such places as the rear axles and drive shafts of automobiles, although it can be used wherever a severe reversible torsional action is likely to be experienced.

New Cemented Carbide for Cutting Steel

The new composition of cemented carbide for cutting steel permits increases in cutting speed as great as those that can be obtained with cemented tungsten carbide on cast iron and non-ferrous materials. Due to its new characteristics, among which is the elimination of practically all cratering action, or cupping out of the top surface of the tool, caused by the pressure and abrasion of the chip coming off the work, it is now possible to do many jobs formerly impossible with hard carbide tools, such as light finishing cuts on soft steel, where the cratering action was so destructive. The chips seem to slide off the surface of the tool easier, there is less tearing action, and a much improved finish is left on the work.

This is an entirely new development in hard-metal composition, being a mixture of several carbides held together with a binder, and embodying a rare metal carbide not previously used in this class of tools. It is manufactured by coating the cutting particles with a softer material which acts as a binder, mixing thoroughly to obtain a homogeneous and uniform mass, pressing together under enormous hydraulic pressure in a mold, and finally sintering at high temperature in an inert atmosphere in an electric furnace. This cementing process is similar to that employed in the manufacture of cemented tungsten carbide, as developed by Krupp, and produces a remarkably uniform and homogeneous product, free from porosity.

Developments in Drop-Forging Hammers

The steam drop hammer has for years borne the onus of being the least efficient tool in industry. It would be difficult to locate the source of its black reputation because there is nothing with which the efficiency of a hammer may be compared except the efficiency of another hammer, as industry has no operation comparable to drop forging.

It is admitted that steam drop-hammer operation has always been expensive in steam consumption and in maintenance, and that these two items of expense have boosted the machine-hour rate on steam drop hammers to an aggregate very much in excess of any machine requiring a like initial investment.

The efficiency of a steam drop hammer must be rated not merely on the amount of forging accomplished by a given amount of steam, but also on the number of actual operating hours in a given number of possible operating hours. The present-day demand for forgings with tolerances very much smaller than ever before has increased the importance of design which will give continued alignment and accuracy without down time for maintenance. Due to the expensive accessories of steam drop-hammer operation, such as the boiler plant and the billet-heating furnaces, down time is a large factor in multiplying forging costs.

After several years of scientific research and development, one company has put on the market a hammer which will produce more forgings with less steam, and will produce more forgings to any specified tolerance without down time for adjustment, than any steam hammer which preceded it.

This has been accomplished by developing a balanced design, based on laboratory results. The correct relation between ram weight, ram velocity, and anvil weight has been determined, so that a maximum of applied energy is absorbed by the forging, thus diminishing the number of blows necessary.

With the anvil weight determined, the other structural details are designed to give the utmost in rigidity and wear resistance. The frame-to-anvil connections are a combination of tongue and groove, step joint, and overlipping, and are rigid in all directions, with provision for maintaining the essential perfection of fit. The upper ends of the frames are restrained from relative motion by heavy interlocked tie plates.

The cylinder bore, ports, and valves are designed on the developed principles of hammer operation, replacing former standards based on steam-engine characteristics. Steam ports and passages are so designed that fluid flow is free and unimpeded, and no loss in pressure is caused by wire drawing.

Valve leakage has been practically eliminated, the throttle valve being self-seated by steam pressure, and the operating valve being a novel type of slide valve, with provision for adjustment for wear within limits of 0.001 in.

Energy consumption during idling has been materially reduced, and in case of compressed-air operation, the idling stroke can be entirely eliminated. Tests under laboratory conditions show a steam saving of no less than 20 per cent of what was until now considered normal, and there is evidence that the saving may reach 40 per cent.

Lubrication gaged to proper proportions is automatic, an oil reservoir and pump being built into the cylinder. The flow is through cored or drilled passages, with no external or screwed connections. Oil lies within the steam passages when the hammer is shut down, so that it is ready immediately to resume operation. Oil consumption is reduced at least 80 per cent.

Research has extended even to gaskets and packing, which as tested and determined to be most satisfactory, are furnished with the hammer.

OGP-55-1

Report on Oil-Engine Power Cost for 1931[1]

THIS report covers information on 119 oil-engine generating plants, with 330 engines, totaling 190,768 rated bhp. The previous report (1930) covered data on 94 plants, with 283 engines, totaling 161,583 rated bhp. Engines listed in the report are full-Diesel, vertical type, direct-connected to generators, unless otherwise noted in Tables III, IV, and V.

In previous years data were solicited from foreign plants, and the report for 1930 contains data for two plants located in Mexico. This year it was decided to limit the survey to the United States, and all data listed are for plants so located.

Plant Numbers. The system used in former reports of designating plants by numbers has been retained. Numbers identifying plants previously reported correspond to the same plants in this report.

Period Covered. All but four of the plants of this report submitted data for periods of exactly 12 months, which in most cases coincided with the calendar year of 1931. Of the four exceptions, one submitted data for 8 months, one for $7^1/_2$, one for slightly over 12, and one for an unstated period that was less than one year.

Output Represented. The total *net* output for the 119 plants in this report amounts to 333,066,644 kwhr.

Bases for Costs and Performances. Units costs referred to in this report were calculated on the basis of net kilowatt-hours. The net kilowatt-hour output is found by subtracting the power used for plant auxiliaries and station lights from the total gross output of the plant.

Figures given for power output per gallon of fuel oil and of lubricating oil were calculated on the basis of the gross outputs of the individual units and plants.

Load factors and capacity factors were calculated on the basis of the gross outputs.

Formulas defining running engine capacity factor, running plant capacity factor, annual plant load factor, and plant service factor are as follows:

$$\text{Running engine capacity factor, per cent} = \frac{\text{Engine output in gross kwhr} \times 100}{\text{Kw rating} \times \text{number of hours operated}}$$

$$\text{Running plant capacity factor, per cent} = \frac{\text{Plant output in gross kwhr} \times 100}{\text{Total rated kwhr of individual units}}$$

$$\text{Annual plant load factor, per cent (see below)} = \frac{\text{Plant output in gross kwhr} \times 100}{\text{Peak load in kw} \times \text{number of hours in period}}$$

$$\text{Plant service factor, per cent (see below)} = \frac{\text{Total rated kwhr of individual units} \times 100}{\text{Total installed kw} \times \text{number of hours in period}}$$

The expression "rated kwhr" refers to the kilowatt rating of an engine-generator set multiplied by the number of hours operated. For example, if a unit having a rating of 200 kw was operated 4000 hr, the rated kwhr equals 800,000, no matter what the actual output may have been. Thus the denominator of the expression for "Running plant capacity factor" and likewise the numerator for the "Plant service factor" are arrived at by totaling the rated kilowatt-hours of all plant units. In this report, the kilowatt rating of an engine-generator set is considered equal to: Rated bhp $\times$ 0.746 $\times$ 0.9. In this, 0.9 is the assumed generator efficiency.

In the strict sense of its definition, the annual plant load factor cannot be correctly applied to data covering any period other than one year. However, the committee extended the application of this to plants operated 8760 hr plus or minus 2 per cent, using the actual number of hours in the denominator in each case.

The formula for "Plant service factor" requires further explanation for special cases. The expression is an index of the actual number of hours of operation as compared to the total number of hours installed for operation. Therefore, when some units have been installed for longer periods than have others in the same plant, account must be taken of the fact in the calculation. For example, assume that a plant is reported for a twelve-month period, during which time one unit rated at 200 kw, installed before the start of the period, was operated 5000 hr. Six months after the start of the period, a unit rated at 300 kw was installed, and subsequently operated 2500 hr. The plant service factor in per cent is therefore:

$$\frac{200 \times 5000 + 300 \times 2500}{200 \times 8760 + 300 \times 4380} \times 100$$

Since the 300-kw unit was not installed during the entire 8760 hr, but only for 4380 hr, this adjustment must be made.

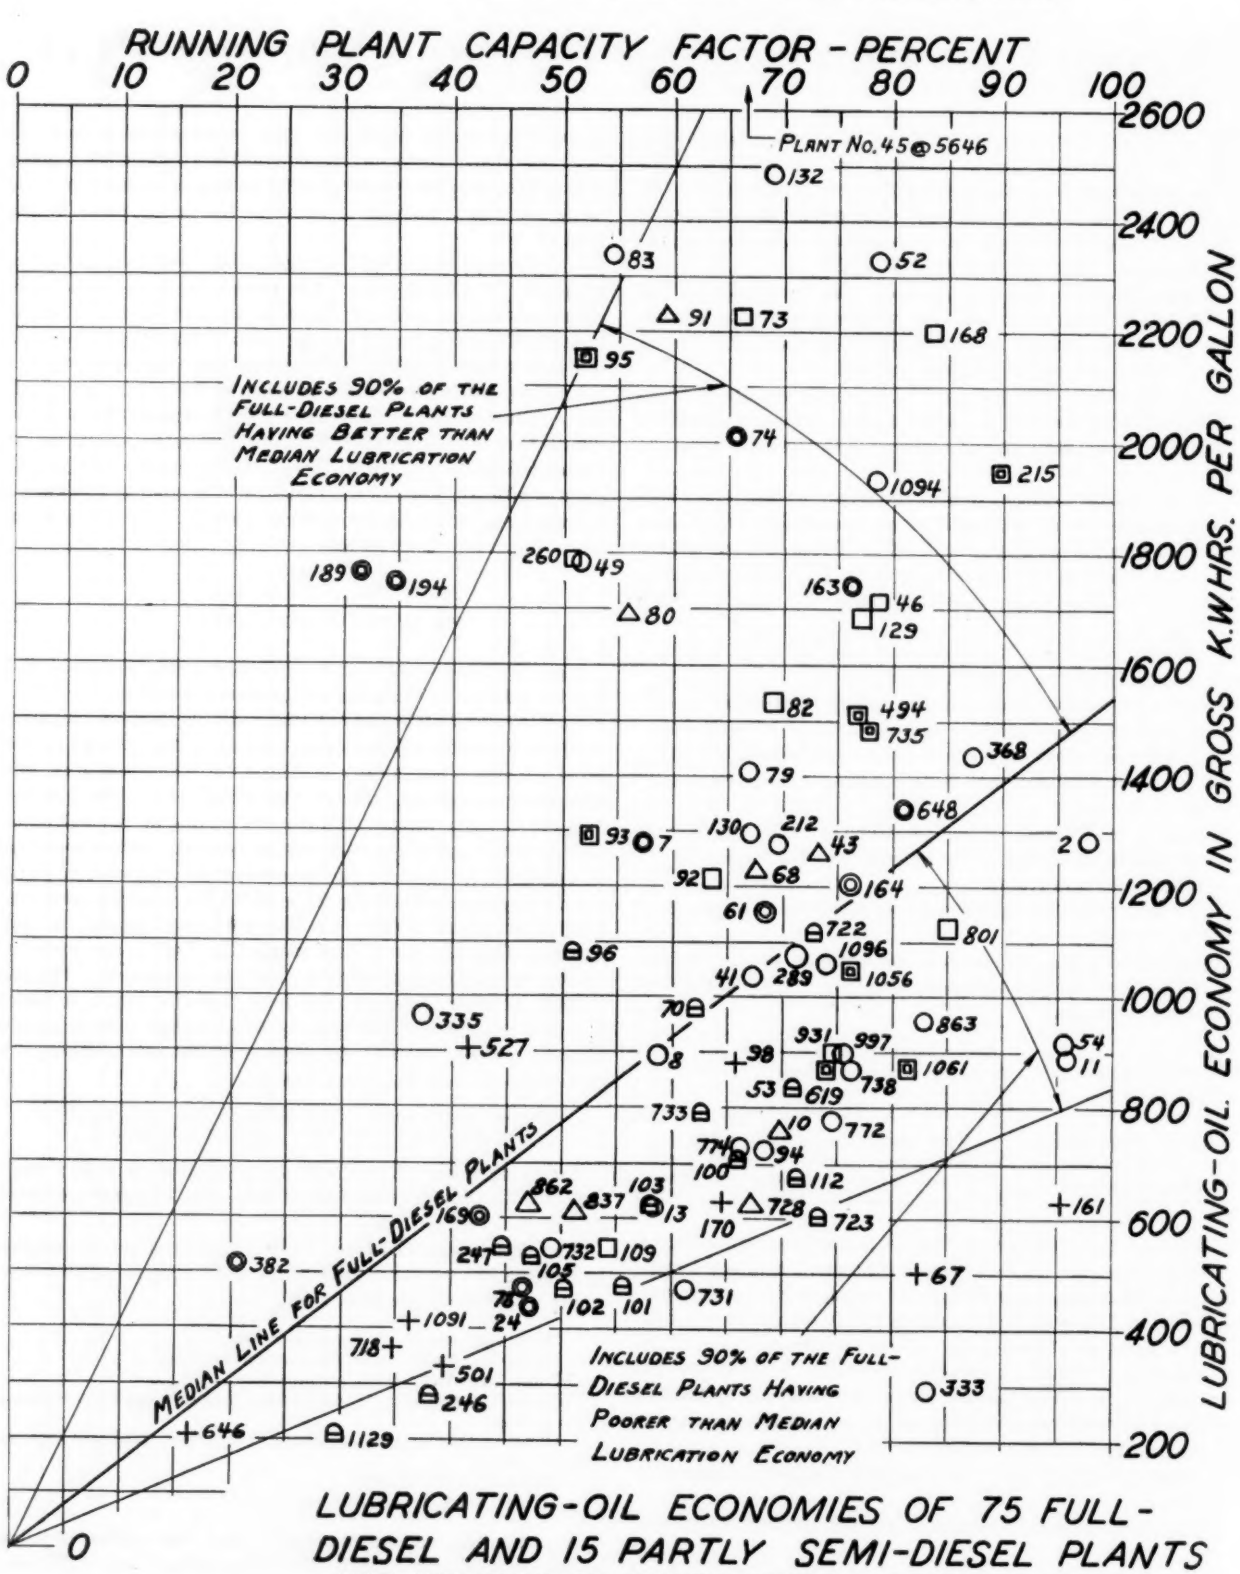
Fuel-Oil and Lubricating-Oil Data. Lubricating-oil economies of the 90 plants for which running capacity factors could be calculated are shown graphically in Fig. 1, in which the gross kilowatt-hour output per gallon of lubricating oil is plotted against running capacity factor. (Of the 119 plants, 29 did not report unit hours of operation, and running capacity factors could not be calculated for these.) Fuel-oil economies of the same 90 plants are shown graphically in Fig. 2, in which the gross kilowatt-hour output per gallon of fuel oil is likewise plotted against running capacity factor. The values plotted in Fig. 2 are corrected neither for the heat content of the fuel nor for altitude. The first of these possible corrections has been made for Fig. 3, in which the Btu consumption per gross kilowatt-hour is plotted against running capacity factor. In arriving at the values shown, the committee used the following formula:

$$\text{Higher heat content (Btu per gal)} = \frac{1180\,[40(\text{deg A.P.I.} - 10) + 18{,}650]}{\text{deg A.P.I.} + 131.5}$$

Inasmuch as not all of the 90 plants plotted on Figs. 1 and 2 reported the gravity of the fuel oil used, only 74 plants are shown in Fig. 3.

The type of the plant was judged to be that of the engines generating 95 per cent or more of the gross output. The following types of plants are illustrated:

Diesel four-stroke cycle, air injection
Diesel four-stroke cycle, mechanical injection
Diesel two-stroke cycle, air injection
Diesel two-stroke cycle, mechanical injection, separate scavenging
Diesel two-stroke cycle, mechanical injection, crankcase scavenging
Mixed-type full Diesel
Mixed Diesel and semi-Diesel.



A median line was drawn on each chart, the number of points above the line being equal to the number below—only full-Diesel plants being considered. High and low boundary lines were drawn to include all but 10 per cent of the full-Diesel plants on the high and low sides, respectively.

Unless it is otherwise noted in Table 4, plants received fuel oil in tank cars.

---

[1] Submitted by the Sub-Committee on Oil Engine Power Cost, Oil and Gas Power Division, A.S.M.E., Franz Eder, Chairman, Engineer, Robert W. Hunt Company, New York, N. Y.

Presented at the Fifth National Oil and Gas Power Meeting, Pennsylvania State College, State College, Pa., June 8 to 11, 1932, of THE AMERICAN SOCIETY OF MECHANICAL ENGINEERS. (Tables checked by H. E. Bethon.)

NOTES: Character of Plant
U - Private Power Company
P - Private Pumping Company
M - Municipal Power Plant
W - Municipal Pumping Plant
I - Industrial Power Plant
B - City Building Power Plant

Type of Load
C - Complete Power
B - Base Load
S - Standby
P - Peak Load
V - Type varied during period

Lettered Notes
a - Standby for last 8 months of period
b - Estimated by Operator
c - High plant use due to electric heaters for fuel and lubricating oil operated continuously.

TABLE II - COMPARATIVE COSTS - 1929, 1930 and 1931 REPORTS (Page 1)

NOTES:

INJECTION SYSTEM
- A - Air
- M - Mechanical

SCAVENGING SYSTEM (2 STROKE CYCLE ONLY)
- S - Separate (i.e., Pump or Blower)
- CC - Crank Case

LUBRICATING OIL TREATMENT
- CC - Continuous Centrifuging
- BC - "Batch" Centrifuging
- C - Chemically
- F - Filtering
- S - Settling

LETTERED NOTES
- a - No deduction made for Motor-driven scavenging blower
- b - Horizontal Engine
- c - November 5th
- d - Semi diesel
- e - Date of original installation; date of installation in this plant not known
- f - May 18th
- g - Includes first filling
- h - Date of original installation; installed in this plant in 1924
- i - Date of original installation; installed in this plant in 1930
- j - Date of original installation; installed in this plant in 1928
- k - November 9th
- l - Date of installation in this plant; date of original installation not known

NOTES:

INJECTION SYSTEM

A- Air
M- Mechanical

SCAVENGING SYSTEM (2 Stroke Cycle Only)

S- Separate (i.e., Pump or blower)

CC-Crank Case

HEAT UTILIZATION

N- not utilized

B- To heat building

F- To heat Fuel Oil

L- To heat Lubricating Oil (before purification)

BF-To heat Boiler Feed Water

T- Thawing Ice Cans

NATURE OF FUEL

API- American Petrolium Institute

"S.U.- Seconds Saybolt Universal
"S.F.- " " Furol

S- Sulphur

CC- Carbon by Conradson Method

BS & W- Bottom Sediment & Water

Asph.-Asphaltic Residue

LETTERED NOTES

a- No deduction made for motor-driven Scavenging Blower

b- Horizontal Engine

c- November 5th

d- Semi-Diesel Engine

e- Date of original installation; date installed in this plant unknown

f- May 18th

g- Date of original installation; installed in this plant in 1924

h- Increments over net output estimated by operator

i- Date of original installation; installed in this plant in 1930

j- Date of original installation; installed in this plant in 1928

k- November 9th

l- Date installed in this plant; date of original installation not known

NOTES:

INJECTION SYSTEM

A - Air

M - Mechanical

SCAVENGING SYSTEM (For 2-Stroke Cycle only)

S - Separate (i.e., Pump or Blower)

CC - Crank Case

PISTON COOLING

A - Air

O - Oil

W - Water

LETTERED NOTES

a - 60 Minute peak

b - Total maintenance labor; none included in attendance

c - Further expense on account of Sabotage in 1928

d - 24 average peak

e - 7 year overhaul for #1

f - Horizontal engine

g - November

h - attendant gives only part time to engine operation

i - Semi-diesel engine

j - Part of attendance is included in repair cost

k - Extra man part time only

l - Date of first installation; date installed in this plant unknown

m - May

n - Includes some new liners and pistons

o - Crank shaft failure

p - 35 Minute peak

r - Occasional

s - Installed in this plant in 1924

t - On overtime

u - Attendants have other duties - full charge is made against diesel plant, however

v - Installed in this plant in 1924

w - Installed in this plant in 1928

x - Date installed in this plant; date of original installation unknown

y - Estimated by operator

z - Runs part time unattended.

All fuel-oil and lubricating-oil costs include costs for the handling of oil from the cars to the tanks.

It is noteworthy that fuel-oil costs reported for plants Nos. 73 and 54 are considerably below anything previously reported—namely, 0.95 cent and 1.03 cents per gallon, respectively.

Cooling Water. The various water-cooling systems are indicated by the following symbols:

System A, raw water going to waste after one pass
System B, raw water recirculated after passing over cooling tower or spray pond
System C, soft water continuously recirculated, cooled by raw water going to waste after one pass through heat exchanger
System D, soft water continuously recirculated, cooled by raw water also recirculated after cooling by cooling tower or spray pond
System E, any of the foregoing systems with engine circulating water treated (added as a suffix).

NOTES:

a - Appraisal Value as of year Indicated

b - Estimated by Operator

Investment Costs. In this report the investment cost data collected for 1930, together with what new information has been obtained for 1931, are set forth in Table 6. Owing to the difficulty in obtaining reliable information on expenditures over past years and to the fact that such data may not reflect current costs, the committee has decided to omit this feature of the investigation in the future. The questionnaire for 1932 will therefore not contain a question on investment costs.

Enforced Shutdowns. No change is made in this report over previous issues in respect to enforced shutdowns. For the next investigation, however, the committee purposes to ask also for the number of hours each unit was unavailable for service on account of regular maintenance. In the past no definition of "enforced shutdowns" has been laid down; the committee now proposes to define an enforced shutdown as a stoppage caused by actual or imminent engine trouble. A prearranged shutdown for maintenance work is not considered an enforced shutdown. The duration of an enforced shutdown is the time required to correct the trouble that caused the shutdown.

Peak Loads. The peak loads presented in the report are the highest average loads sustained for 15 min, unless otherwise stated in Table 5.

Liner Wear. Liner wear figures presented in Table 5 are in each case the average of the wear in inches in all the cylinders of the engine, the wear in each cylinder being found by averaging two measurements—one taken parallel to the crankshaft and the other at 90 deg to the crankshaft, both taken at the point of greatest wear, which in most cases will be at the top of the piston ring travel.

The committee realizes that liner wear is a complicated subject worthy of a separate investigation, and therefore feels that it should not go into this question more intensively, because it wishes to maintain its concentration on its main purpose. Therefore, it will omit investigation of liner wear from the next year's report rather than slight the subject.

Supplies and Miscellaneous. Supplies in the meaning of this report are items used in the power-generating plant that are consumed in the operating process—namely, such items as waste, packing, wipers, gage glasses, gaskets, bolts, screws, nails, dynamo and motor brushes, cans for containing rags and waste, transformer oil, and hand oil cans. The term "miscellaneous" as used in this report refers to such items as expenditures for lighting, heating, and cleaning systems, fire-protection systems, janitor's supplies, ice water, meals and carfares, stationery, telephone and toilet service, care of streets, yards, and sidings.

Type of Load. The terms used for type of load are defined as follows:

Complete power: The plant is run regularly alone when needed, without assistance from any base-load or peak-load service
Base load: The plant is run at substantially full load whenever its capacity can be used, usually supplemented by a peak-load service. When full or nearly full capacity cannot be used, the plant is shut down
Peak load: The plant is run only when the load exceeds the capacity of the regular source of power
Standby: The plant is run only when the regular source of power is interrupted.

SUB-COMMITTEE ON OIL ENGINE POWER COST

E. B. Van Ness.

Progress in Oil and Gas Power

DURING the past year the spotlight in the oil-engine situation shifted to the fuel. The modern high-speed engines were found to be rather particular about their fuel and showed their dislike of certain fuels by knocking. This fact was made the subject of some searching investigations by several British and American oil companies. It was discovered that the suitability of a Diesel oil is largely determined by a previously unknown fuel characteristic, the ignitibility. The oil which ignites readily after a short ignition lag is the desirable fuel for Diesel engines. The customary lists of Diesel fuel-oil specifications never contained such an item as ignitibility; therefore they are now considered inadequate. The A.S.M.E. Committee for Diesel Fuel-Oil Specifications, in cooperation with S.A.E. and A.S.T.M. committees, is giving special attention to this phase of the fuel problem. Projected research is destined to find the best ways to determine the ignitibility of an oil and to express it in comparable units. The insight gained by recent investigations already has enabled several oil companies to bring distinctly superior Diesel oils on the market. Their high price prevents their more general use as yet, but further developments are impending.

The high-speed engines are not the only ones concerned with the fuel program. An important factor in retarding development of the large marine Diesel engine here is the fuel-price situation, which in the United States shows a differential of over 100 per cent in the prices of boiler fuel and Diesel fuel in favor of the former.

The development in the future of the large Diesel engine, stationary and marine, in this country appears to be contingent on active development of methods of utilizing boiler oil for Diesel engines; this is now in progress.

The field of the oil engine is now so diversified and includes so many types that each progresses more or less along its own line. General tendencies in design that could be noted have been the almost complete displacement of the air injection by mechanical injection, further increase of speed and reduction of weight for given piston displacement, a slight shift in trend in favor of the single-acting, two-stroke cycle, the preference for enclosed engines, the increased use of alloy steels, and growing dependence on specialty manufacturers for such parts as injection pumps and nozzles.

Stationary Engines

The five 7000-hp engines for the world's largest Diesel power plant have been completed by the Hooven, Owens, Rentschler Company; they have all undergone shop tests and will be erected in Vernon, Calif., during the winter. The engines are of the double-acting, two-cycle Hamilton-M.A.N. type, having eight cylinders 24 × 36 in., running at 167 rpm.

The world's largest Diesel engine unit of 22,500 bhp has been installed by Burmeister & Wain in the Copenhagen municipal electric plant to supply energy for the peak load. (See Fig. 1.) It is of the double-acting, two-cycle type, having eight 33-in. by 59-in. cylinders, uniflow scavenging, with piston-type exhaust valves in the heads, two rotary blowers driven from auxiliary shaft, and a hydraulic oscillation damper. The guaranties call for a fuel consumption of 0.55 lb per kwhr at 15,000 kw and 0.53 lb per kwhr at 12,500 kw. Another peak-load engine of 6900 hp was installed by M.A.N. in Minden, Germany. Several engines of 3000 to 4000 hp were installed for public utilities by the Busch-Sulzer Company in this country. The qualifications of the Diesel engine for peak-load service are more and more appreciated, and the attitude of the electric utilities has undergone a perceptible change in favor of the Diesel engine in the last two years. Two factors contributed to this change: First, the initial cost of Diesels went down considerably recently. The overall cost of a complete Diesel-generating station of moderate capacity, including land and building, may now safely be estimated at about $85 per installed kilowatt, as compared with $150 only a few years ago. This reduction, which is greater than the general drop of price in machinery during the same period, can be explained by the technological advances made in the design and construction of the large Diesel engines. The adoption of solid injection, the use of trunk pistons of progressively larger diameters, and the stepping up of the rotative speed are mainly responsible for the decreased cost per kilowatt. The 3000-hp installation of Busch-Sulzer Company in the Sterling plant of the Public Service Company of Colorado, running at

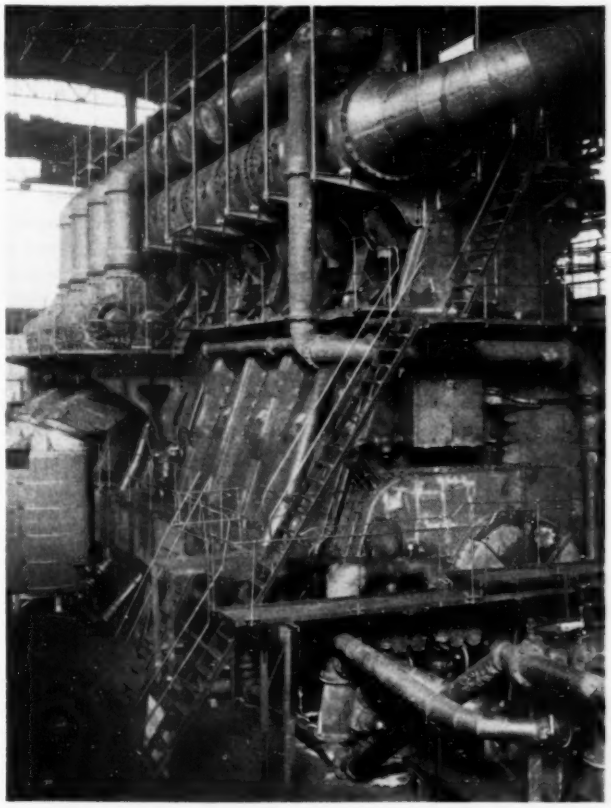

Fig. 1 World's Largest Diesel Engine, 22,500 Hp on a Single Shaft

(Being installed by Burmeister & Wain in the municipal electric plant in Copenhagen for peak-load service.)

Presented at the session of the Oil and Gas Power Division, Wednesday afternoon, December 7, 1932, during the Annual Meeting, New York, N. Y., December 5 to 9, 1932, of The American Society of Mechanical Engineers.

The report was prepared by Dr. P. H. Schweitzer, Associate Professor of Engineering Research, School of Engineering, The Pennsylvania State College, State College, Pa.

Personnel of the Executive Committee of the Oil and Gas Power Division for 1932: Louis R. Ford, Chairman; Edgar J. Kates, Secretary; Harte Cooke, L. M. Goldsmith, Lawrence B. Jackson, and Ralph Miller. Associates: L. H. Morrison and Arthur M. Tode.

240 rpm, and the four-unit plant, totaling 2760 hp, for the Commander Milling Company of Minneapolis by Fairbanks-Morse Company, running at 277 rpm, are cited as examples. The second factor is the increased amount of reliable information now available on the operating costs of Diesel engines. The A.S.M.E. Committee on Oil Engine Power Costs has collected and recently published an immense amount of carefully analyzed data, filling a long-felt need of the power producers. The study of that report is recommended to everybody interested in Diesel-power costs.

Marine Oil Engines[1]

The world-wide business depression reduced shipbuilding to the lowest level reached in half a century. Progress in marine Diesel engineering, as well as in all other phases of marine engineering, has been retarded, but this condition has also had the effect of emphasizing the inherent economic advantage of the Diesel engine. Between July, 1931, and July, 1932, the gross tonnage of all steamships decreased by 960,473, while the oil-engined ships increased in tonnage by 602,064. Motorships have been able to continue trading with reasonable earnings in a market that has necessitated laying up some 12,000,000 gross tons of steamers.

The outstanding marine Diesel installations of the year are found in the German naval vessel *Bremse*, the British passenger liner *Georgic*, and the Italian passenger liner *Neptunia*, each representing a different type of Diesel-engine installation. The *Bremse* is equipped with 26,000 bhp in the form of eight two-cycle, double-acting M.A.N. eight-cylinder engines, operating at 600 rpm, and connected to two propeller shafts through Vulcan gearing. The *Georgic* (27,000 gross tons) is driven by two B. & W. four-cycle, double-acting 10-cylinder Diesel engines, each developing 10,000 bhp and direct-connected to the propeller shafts. The *Neptunia* (20,000 gross tons) is fitted with four Sulzer two-cycle, single-acting Diesels direct-connected to four propeller shafts, developing a total of 18,000 bhp.

The success of the light-weight German naval engines is attested by the fact that a second and third sister ship of the cruiser *Deutschland* are being laid down, fitted with similar machinery, which consists of eight 7100-hp M.A.N. double-acting, two-cycle engines, with return-flow scavenging and rotary valves in the exhaust ports, each engine having nine 16.5 by 22.8-in. cylinders, totaling 56,000 hp, and the auxiliaries consisting of eight 250-kw Diesel-driven dynamos. The engines for these dynamos, built by Linke-Hoffman, are six-cylinder, single-acting, four-cycle, cross-head, solid-injection units running at 1000 rpm. They develop at that speed 375 to 400 bhp, and the weight per bhp, without the dynamos, is about the same as that of the main engines, i.e., 17.6 lb. The *Deutschland* machinery stood the acceptance tests excellently, the observed full-load fuel consumption being 0.385 lb per bhp-hr for the main engines, including scavenging, and 0.395 lb per bhp-hr for the auxiliaries.

Development of the marine Diesel engine along lines calculated to indicate the most suitable types of engines for various services has been carried out by Japan more systematically than in any other country. Japanese government departments concerned with the shipping industry have placed in service different types of Diesel-engine vessels specially designed to develop the possibilities and increase the national knowledge of marine Diesel engineering.

The United States has continued to lag behind the rest of the world in the development of large marine Diesel engines, but has made a creditable showing with small engines. A recent Department of Commerce report shows that in the past 10 years the number of Diesel-driven vessels increased from 95 to 3458.

[1] Largely from report by Louis R. Ford.

In regard to construction, the welded-steel frame constitutes the most noteworthy innovation that has originated in the last year or so from numerous sources. The result obtained in the way of weight reduction is little short of miraculous. The engines of the *Bremse* weigh only 14 lb per bhp, while both M.A.N. and Sulzer are developing engines of 2000 bhp per cylinder at 265 rpm and weighing around 22 lb per bhp.[2] Although such engines are not yet built for commercial purposes, the fact that engines are constructed of the power mentioned, with about one-tenth of the weight that a few years ago was called normal, opens immense possibilities.

A somewhat similar development approved by commercial practice is the "hydrogen brazing" of engine parts, primarily cylinder heads, introduced by the German A.E.G. Instead of a casting, several simple forgings are made and united in a very effective manner by the new method.

Torsional vibrations, old well-known trouble makers for long multicylinder engines, are now well in hand. Vibration dampers of the hydraulic types are finding extended use. Supercharging is gaining, and also the exhaust-gas utilization, which permits very attractive economy on board. It may be mentioned that in the contract for the engines of the motorship *Berganger*, a vessel now approaching completion in Denmark, it is stipulated that the fuel consumption shall not exceed 0.35 lb per bhp-hr.

Automotive Diesel Engines

In appearance and construction the giant Diesels have little in common with the Diesel engines used in trucks and buses, of which now about 3500 are in operation in Germany alone. The General Omnibus Company in London is gradually replacing its gasoline engines with Diesels. In America at least four makes of trucks are now offered with Diesel-engine drive, and during the last year quite a number of Diesel-equipped American tractors have been shipped to many parts of the world. The saving in fuel costs claimed with Diesel-engined vehicles is as high as 70 to 80 per cent, while in spite of views expressed to the contrary, in acceleration and flexibility the Diesel truck excels the gasoline truck of equal power, as has been evidenced by Professor Langer's systematic tests and the favorable experiences of American fleet operators with Cummins Diesel-equipped trucks, one of which holds a non-stop record of 13,500 miles (December, 1931). The majority of the automotive Diesel engines are around 80 hp, but now demand is being expressed for more powerful engines. The top speed of 2000 rpm is today no more exceptional, and the engine weights approximate those of gasoline engines. The automotive industry begins to take the Diesel very seriously, and experimentation is going on behind closed doors in many plants.

While in large Diesels the direct-injection and undivided combustion chamber is sovereign, in automotive engines there is a fight among the various systems. At this time the two-chamber principle seems to be ahead of its rival, as is exemplified by such recently developed successful types as the new Mercedes-Benz, Linke-Hoffmann, Oberhaensli, Dorman-Ricardo, and Ganz-Jendrassik engines.

The open combustion chamber seems to hold its best in opposed-piston engines of the Junkers type and its various modifications, like the German Michel engine, which has a common combustion space for a Y-shaped cylinder and was subjected to successful tests recently. Distinct from this is the crankless Michell engine, being developed in this country, which also has opposed pistons.

The economy and performance of the automotive Diesel is no more questioned. Where it fights its battle is on the plane of knock, smoke, odor, and ease of starting. All of these are

[2] Several companies are now prepared to build 40,000-hp engines.

more or less related to the problem of ignition lag, and here the cooperation of the engine designer with the pump specialist and the fuel technologist is bound to give the answer.

Aircraft Oil Engines

During the last year several new types have been reported as having been developed or as being developed, but little progress is noticed in the actual use of the Diesel engine in the air. We know of a 720-hp Junkers engine in line service between Berlin and Amsterdam, having 120 hours in the air behind.

A notable development is the Guiberson radial air-cooled Diesel, somewhat along the Packard line, while several other American aero-engine manufacturers experiment with spark-ignition, solid-injection engines.

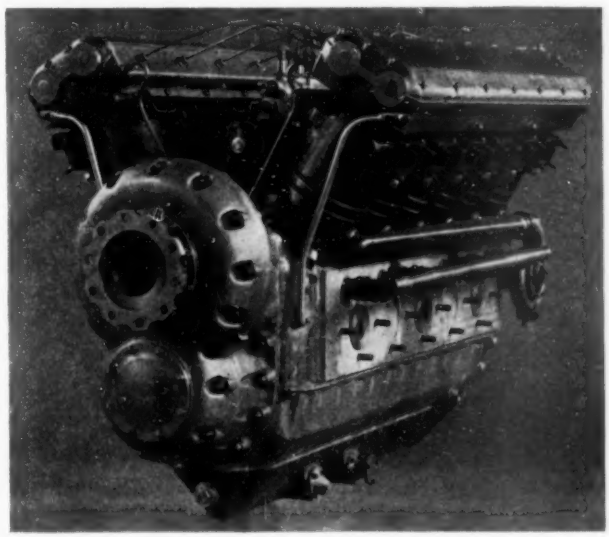

Fig. 2 Daimler-Benz 750-Hp Aviation Diesel Engine

Abroad, the Daimler-Benz Company is ready to announce the completion of a 750-hp aviation engine. It is a water-cooled 12-cylinder V-engine, 6.5 in. bore, 8.3 in. stroke, with two overhead camshafts and two inlet and exhaust valves for each cylinder. Split roller bearings are used for the crankshaft and Bosch pumps for the injection of the fuel. The whole engine weighs 2100 lb. It develops 700 hp at 1675 rpm and 750 hp at 1720 rpm crank speed, which is reduced with spur gears by 1:1.5:1.2, so that the maximum propeller speed is under 1000 rpm. The observed fuel consumption is 0.366 lb per bhp-hr at 1508 rpm and 518 hp and 0.42 lb per bhp-hr at 1753 rpm and 792 hp, which is the peak output with slightly visible smoke. (See Fig. 2.)

Very unlike to this is a 1000-hp, 7-cylinder airship engine on the test floor of the M.A.N. Company. While the Daimler-Benz engine follows gasoline-engine lines, making liberal use of the light alloys, the M.A.N. development, a supercharged double-acting, two-cycle job, is almost exclusively out of steel, with through anchor bolts along the line of their welded battleship engines.

According to unauthorized information, the engine that ran over 70 hours already develops a peak output of 1200 hp at 1000 rpm, and its total weight is below 4.4 lb per bhp. It is expected that it will add much to the fire safety of the new German zeppelins.

Development of aviation Diesel engines is also reported from England, France, and Italy, but if any outstanding success was attained, they have succeeded in keeping it secret. Yet there is little doubt that injection engines will displace carburetor engines in the air before long.

Locomotive Engines

It is exceptionally unfortunate that just when railroads had convinced themselves that the Diesel locomotive is the only logical switching locomotive, they do not have the money to buy them. As an exception 37 Diesel locomotives have been installed for operation in the freight yards on the west side of New York City by the New York Central. In spite of lack of orders, several engine builders are at work developing locomotives, and some of them are known to be successful, technically speaking.

While main-line Diesel locomotives still seem to be some distance off, a very promising application is that to the railcar. In the last years more and more branch-line passenger traffic has been lost to the railroads. To ease this situation the railroads frequently have gone into the bus-operating business themselves. Recently it became apparent that the railroads need not go off the rail to meet bus competition, if they apply the light-weight, high-speed principle to their equipment. What can be done is shown impressively by the Budd-Michelin 40-passenger railcar, one of which was put into regular service recently by the Pennsylvania Railroad in Philadelphia. Its weight is 14,000 lb, instead of the 175,000 lb usual for rail coaches of similar size of or 90,000-lb, the weight of the average railcar in branch-line operation. It is a one-man-operated unit, instead of having the crew of four required for steam equipment. The unusual weight reduction is attained by the use of pneumatic tires, a thin welded-steel-sheet construction, and a light 90-hp Diesel engine of the Junkers opposed-piston type. The operating expense of such a railcar, including wages, fuel, repairs, supplies, interest, and depreciation, is calculated as 20.5 cents per train-mile, compared with 26 cents for motorbus, 55 cents for the orthodox railcar, and $1.02 for steam trains. Of course, any good automotive Diesel engine is fit for railcar service, which fact is apt to furnish incentive for such development.

Research

Mention has already been made of the recent Diesel fuel research. Investigations by Le Mesurier and Stansfield, of the Anglo-Persian Oil Company, and Boerlage and Broeze, of the Royal Dutch Shell Company, increased our knowledge of fuel and combustion considerably. Neumann's theoretical work and Pope and Murdock's experimental work also have contributed to it. The point is now reached that fuels can be evaluated on a firm basis and steps can be taken to control their ignition in the engine. "Dope" for Diesel fuels is an imminent possibility.

National Advisory Committee for Aeronautics

The National Advisory Committee for Aeronautics attacked a number of problems during the year. A most outstanding result of their high-speed photographic research relates to fuel vaporization. Contrary to prevalent opinion, Rothrock found that the vaporization of the fuel is extremely fast and practically complete before ignition occurs in the engine. Pressure waves and injection phenomena received much attention as also did combustion analysis. The engine research of the committee was divided between the quiescent and the turbulent engine, both being investigated methodically.

Pennsylvania State College

Pennsylvania State College completed its investigation on spray dispersion. The information made available, complemented by Holfelder's data, answers most questions, theoretical and practical, in regard to the dispersion of oil sprays. Liquid turbulence was found to be the primary and air friction the contributory cause for spray dispersion.

The Massachusetts Institute of Technology obtained interesting results with a fuel-injection spark-ignition engine.

In the Dresden Technische Hochschule, Schmidt conducted a valuable investigation on the temperature fluctuations at various points of the combustion space. Haenlein and Holfelder obtained interesting data on fuel sprays. In Hannover, Neumann and Klüsener investigated the charging and scavenging process. Injection pumps and nozzles received the attention of several investigators in England and Germany.

Gas Engines

Two-cycle gas engines again made their appearance, but of much improved fuel economy. M.A.N. is applying its reverse scavenging principle to the gas engine, obtaining four-cycle economy with much reduced first costs.

Clark Brothers Company developed the "injection gas engine," in which the gas is introduced by a pump after the exhaust ports are covered by the piston, and thermal efficiencies exceeding those of four-cycle engines are obtained.

Business Outlook

The present economic crisis did not spare the oil and gas power industry, although it probably did not hit it more than other machinery industries. Even if the immediate future is rather uncertain, the distant future is distinctly bright for the survivors. The triumph of the Diesel engine may duplicate that of the electric motor, as the field is beginning to be ready for it. The Diesel Engine Manufacturers Association elected Mr. H. Birchard Taylor for president, and a broadening of its activities is being contemplated.

OGP-55-3

Improving Operation and Overall Economy of Diesel-Engine-Driven Generating Stations

These Conditions May Be Attained Through the Use of Selected Boiler Fuel Oils and More Intelligent Supervision

By H. W. STALNAKER,[1] OSCEOLA, IOWA

The majority of Diesel plants are operating far below par, and if real economical operation is to be obtained, better supervision is necessary. The larger plants can afford to retain engineers capable of producing results. Small plants could engage supervising engineering companies on a percentage of the net savings. If boiler fuel oil could be proved to operate more economically, it should be used.

WHEN we look back over the 1930–1931 operating-cost records of even the most modern Diesel-engine-driven generating stations, as compiled by the A.S.M.E. Diesel Cost Committee, there can be but little doubt of the vital necessity for cheaper Diesel fuel oils and more efficient operating methods. Indeed, unless some such changes are made in the very near future, the Diesel-engine manufacturers are going to find some of the most fertile fields closed to the use of Diesel engines. It is quite obvious that prospective customers of Diesel engines must be shown authentic operating-cost records of plants in their locality to substantiate the estimated operating costs as compiled by the manufacturers' sales organizations. In the Eastern part of the United States, where the so-called good Diesel fuel oil costs 5.5 to 6 cents per gallon and where the on-the-switchboard cost per kwhr is well above 1 cent, can these authentic records be obtained? The three largest and most modern Diesel plants in the East are all municipal owned. Their generating costs are 8.20 mills, 10.29 mills, and 13.86 mills. None of these generating costs are in line with what it costs to generate 1 kwhr in the modern central-station steam plant; neither are they in line with what it costs to generate 1 kwhr in a modern Diesel plant where the cost of fuel oil is more reasonable. Such generating costs, when fixed charges and distribution costs are added, are prohibitive. For the latter reason many of the larger electrical utility companies, particularly in the East, refuse even to consider the operation of Diesel engines except for standby service.

This paper is intended to show that Diesel-plant operation can be improved and that the present more-or-less closed fields for Diesel-engine installation can be opened up. While the paper contains many positive statements of a highly controversial nature, they reflect actual experience of the author while in the employ of one of the large electrical utility companies and while using the heaviest of boiler fuel oils as Diesel fuel.

The two chief reasons for high generating costs in Diesel-driven generating stations are the high cost of so-called good Diesel fuel and the employment of unskilled supervisors, the latter usually having been recommended by Diesel-engine builders. To unskilled supervision can also be attributed low thermal efficiency, high maintenance costs, and high fixed charges—the latter on account of the necessity for installing standby generating capacity to take care of service in case of mechanical failures.

In the Eastern part of the United States Diesel fuel oil that will meet the specifications of the Diesel-engine manufacturers costs about 40 cents per 1,000,000 Btu, while the best qualities of steam coal cost but 8 cents per 1,000,000 Btu. In other words, the Diesel operator must pay about five times as much for fuel as the steam plant pays. Then consider what the difference in thermal efficiency is between steam and Diesel plants.

A few years ago about 30,000 Btu was required to produce 1 kwhr in the central-station steam plants, and the Diesel plant of even small size required but 12,000 Btu for the same work. However, today the modern central-station steam plant of even medium size requires but 15,000 Btu, and in some cases even less. On the other hand, the Diesel plant of even the largest size remains at 12,000 Btu per kwhr in even the most efficiently operated plants. In other words, while the efficiency of the steam plant has been increased by more than 100 per cent, the Diesel has remained at a standstill. In view of these facts it begins to look as though it will be but a short time until the steam plant will have surpassed the Diesel in thermal efficiency, just as it already in many cases has surpassed it in overall economy. Such being the case, it is quite obvious that a centrally located steam plant of, say, 25,000 kwhr capacity can supply electrical energy to two or more small cities far cheaper than it can be produced in Diesel-driven municipal-owned plants operating at the present high generating cost per kwhr.

Even in view of these startling facts the Diesel manufacturers are very reluctant to turn to the cheaper boiler fuels as a possible means of bettering conditions. They still seem to think that they can still further reduce overall generating costs by lower initial cost per horsepower and lower labor costs by practically automatic operation. Again referring to fuel oil, the Diesel manufacturers are even unable to agree on any one standard specification, but rather each Diesel manufacturer has his own specification and insists that his engines be operated on fuel of such characteristics, otherwise they wash their hands of any

[1] Consulting Diesel Engineer. H. W. Stalnaker was born in Charleston, W. Va. He served apprenticeship as machinist, and took home-study courses in mechanical and chemical engineering. During the World War he was assistant superintendent, Poison Gas Division, Rollin Chemical Corporation, and was sent to England to join the staff of the Hedworth Barium Company, Newcastle-on-Tyne, as plant-betterment engineer. Returning to the United States in 1921, he joined the Laurie Coal Company in West Virginia as chief engineer. In 1923 he was appointed chief engineer and superintendent of power of a string of Diesel properties operated by the Haytien Corporation of America, Port au Prince, Haiti. While in the West Indies he also acted as consulting engineer for several smaller companies. He returned to the United States in 1930, and has since been associated with the Gulf and Great Lakes Pipe Line Companies.

Presented at the Fifth National Meeting of the Oil and Gas Power Division of THE AMERICAN SOCIETY OF MECHANICAL ENGINEERS, State College, Pa., June 8–11, 1932.

NOTE: Statements and opinions advanced in papers are to be understood as individual expressions of their authors, and not those of the Society.

troubles that may develop. Such conditions of course go a long way toward keeping up the prices of the light Diesel fuel oils. The oil companies complain that such specifications compel them to store large quantities of many different-quality fuel oils and that this, added to the refinery costs, is what keeps up the prices. Whether this is true is of course open to argument, but nevertheless it is a good alibi, and the Diesel manufacturers would better conditions quite a little if they would get together and decide on one specification for light-duty medium to high-speed Diesels and still another for the heavy-duty slow-speed engines. So far but one manufacturer of Diesel engines has shown any inclination toward very broad specifications. His specification is, "Our engines will operate on any commercial fuel oil or crude produced in the United States or Mexico." It is very clear that such broad specifications if adopted by the rest of the Diesel industry would go a long way toward lowering the cost per Btu. In other words, the manufacturers of Diesel engines have built an engine and expect the oil companies to produce a fuel to operate it with. Why not the other way around? Build an engine with an injection system that will operate efficiently on the fuel oils that the oil companies at present produce. However, there are quite a few slow-speed heavy-duty engines that will handle the heavier fuel oils with but few changes, all of a minor nature. However, as I have previously mentioned, these same manufacturers are slow to take advantage of the cheaper fuel oils.

Take the residual fuel oils from the low-pressure stills: These residues are all pumped to the same storage tanks, and the resulting mixture is marketed as Bunker C. This fuel, which is almost a drug on the market, due to the ever-increasing use of pulverized coal in the large steam stations, can be purchased for about one-half of what the lighter fuel oils sell for. Bunker C, when properly prepared by passing it through a centrifuge and when heated to give the desired viscosity, makes a very suitable fuel for slow-speed heavy-duty air- or mechanical-injection Diesel engines. That such engines will operate efficiently, with 100 per cent reliability, and with very low overall generating costs, can probably best be shown by a comparison of plants operating on such fuel oils with plants operating on the best qualities of so-called good Diesel fuel oil.

Five of the plants used for comparison are taken from the yearly A.S.M.E. Cost Committee Report for 1930–1931, and two plant records are from plants operated by a large electric utility company in the West Indies. The author was connected with the latter for quite a few years. These records are given in Table 1.

TABLE 1

A.S.M.E. plant	Kwhr generated	Kwhr per gal fuel	Generating cost, mills	Fixed charges, mills	Total cost, mills	Maintenance hp per year, dollars	Fuel cost per gal, cents	Load factor, per cent
Municipal-owned plants operating on best quality 24 to 36 B Diesel fuel oils								
45	7,000,000	10.25	8.20	7.50	15.70	1.65	5.19	69.50
52	7,000,000	10.75	10.30	9.10	19.40	0.89	5.70	75.20
82	8,000,000	11.13	13.86	11.75	25.61	2.74	5.70	65.00
Municipal-owned plant operating on 11 to 14 B boiler fuel oil, 18,150 Btu per lb								
73	8,500,000	10.26	4.59	7.50	11.69	0.17	1.30	64.00
Privately owned utility plants operating on 12 to 20 B boiler fuel oil								
92	10,500,000	9.66	4.08	5.82	9.90	0.54	2.09	65.00
1*	5,500,000	11.88	7.66	5.60	13.26	1.50	6.00	72.65
2*	530,000	11.00	7.29	6.22	13.51	0.17	5.19	74.50

* Operated by a large electrical utility company in the West Indies. Maintenance charge in plant 1 is estimated at $1.50 per hp per year over a five-year period. Actual costs are well within this limit. Analysis of fuel oil as supplied to plants in the West Indies by the Shell Oil Company is: Baumé gravity, at 80 F, 15.1; flash point, Cleveland, 270 F; fire point, 310 F; water and sediment, A.S.T.M. D-96-30, 0.70 per cent; viscosity, Saybolt Universal at 100 F, 6054 sec; ash, 0.10 per cent; carbon residue, Conradson, A.S.T.M. D-189-30, 10.88 per cent sulphur, 2.04 per cent.

The engines represented in the comparison in Table 1 are: McIntosh-Seymour, De La Vergne, Nordberg, and Busch-Sulzer; speed range, 125 rpm to 360 rpm. However, with the 360-rpm engine the piston speed is 1200 fpm, and the operation on boiler fuel oil is very unsatisfactory; the liner and piston-ring wear is more than double that of the slower speed engines. From all indications the maintenance costs per horsepower per year will be in excess of $3 over a five-year period (in other words, liners will have to be replaced or rebored every $2^1/_2$ years).

Plants 52 and 82 are each at the present time installing additional 3000-hp units, although their annual plant-load factors are but 34 per cent. What is going to happen to the fixed charges in these plants when this installation work is finished? (Plant 82 has been finished.)

As to reliability, the only shutdown was one of two hours' duration in plant 52, which is one of the light-fuel plants. None of the plants operating on boiler fuel oil reported any shutdowns. It would seem from this that 100 per cent reliability can be expected, even when operating on the heaviest of boiler fuel oils.

From the foregoing comparison it looks as though the heavy boiler fuel oil plants have the best of it when it comes to maintenance. However, the author does not wish to be quoted as saying that maintenance with boiler fuel will be less than with light Diesel fuel oils. Rather, the opposite will be the case. When operating on light fuel oil, engines of the type used in the plants taken for comparison should be maintained for $1 to $1.25 per hp per year, depending of course on operating conditions and type of supervision. On the other hand, the same engines operated on boiler fuel oil will show a maintenance charge of very close to $1.50 per hp per year, and then only when the operating force does all maintenance work and a capable Diesel man is employed as supervisor.

Of course in either case much depends on what the machine-shop facilities are. There are many very large savings that can be made through having adequate machine-shop facilities; 500 per cent on fuel-pump plungers, valve, and valve-cage repairs, bushings, and many other small parts is not uncommon, while savings on bearings, regrooving of piston-ring slots, making of special tools, etc. will be but slightly less. A lathe, drill press, tool-post grinder, shaper, and portable grinder will cost but little when the many advantages and savings are taken into consideration.

Continuing along the same lines, of the larger plants operating in the East, the A.S.M.E. Cost Committee plant 45 is by far the most efficiently operated of any shown in the 1930–1931 report, and it also has the lowest generating cost. However, even in view of this being the most efficient plant, there are still some very attractive savings that can be made in two ways; one through increased thermal efficiency (report shows plant to be far below manufacturer's guarantee) and another through the use of cheap boiler fuel oil. The author would like to point out that the actual kwhr generated is not the true load on the engine shaft. Motor-generator sets are used for excitation, and when this is deducted, the actual effective load will be more like 7,000,000 kwhr, and this still leaves some 91,500 kwhr for power and lights used in production. Still another thing to point out is that this plant uses a 35 B gas oil which weighs but 7.065 lb per gal. Another thing is that these engines are of the four-cycle air-injection type and operate at a slow speed. Engines of such type will not as a rule operate satisfactorily and give their guaranteed thermal efficiency on such light fuel oils. The injection period of time is much longer than with engines operating at higher speeds, and the loss of high-pressure air during injection is quite large. Fuel pumps also give lots of trouble due to the very light fuel cutting the plungers, and the packing must be kept very tight to prevent leakage. However, on the other hand, if an engineer with sufficient Diesel experience is employed as supervisor, he can, by use of an indicator, set the

injection valve so that good thermal efficiency can be obtained. But how many plants employ such a type of engineer? In any case it is necessary to watch the fuel-valve settings very closely, as a very small change in setting will often make as much as 10 per cent difference in fuel consumption. Employment of inexperienced engineers can usually be traced to the Diesel manufacturer. Quoting one of the manufacturers of high-grade engines, "A Diesel plant is so simple that a week or two of training will make a good attendant of any man with average intelligence and mechanically inclined." They fail, however, to say anything about supervision. They also go on to say that plants can be operated on 24-hour basis with but two men. Such conditions are largely responsible for high maintenance and generating costs.

Analysis of power costs in plant 45 is given in Table 2. Column 1 shows actual costs; 2, possible costs with expert supervision; 3, possible generating costs with expert supervision and using boiler fuel oil. Maintenance costs in the estimated part of the analysis are based on $1 per hp per year with light fuel oil and $1.50 per hp per year when using boiler fuel. Estimated efficiencies are based on 0.43 lb of 18,500 Btu fuel per hp-hr at 75 per cent running plant-load factor (manufacturer's guarantee). A 100 per cent perfect combustion cannot of course be obtained with boiler fuel oil (using manufacturer's guarantee for comparison); due allowance has been made. A different distribution of production supplies and miscellaneous expense has also been made in the estimated analysis, so that it will be more in accordance with "Classifications of accounts for electrical utilities." (See Table 2.)

TABLE 2 PLANT 45, A.S.M.E. DIESEL COST COMMITTEE REPORT, 1930–1931

	(1) Actual cost	(2) If efficiently operated	(3) Possible with heavy boiler fuel oil
Kwhr generated	7,492,325		
Kwhr used in station:			
Lights and power	91,500		
Motor-generator sets	492,325		
Actual load on engine, kw	7,000,000	7,000,000	7,000,000
Actual load on engine, hp	10,290,000	10,290,000	10,290,000
Fuel oil used, gal	676,475	620,567	579,480
Fuel oil used, lb	4,779,296	4,384,305	4,659,598
Actual kw per gal fuel	10.348	11.280	12.080
Lb fuel per kw	0.682	0.626	0.665
Lb fuel per hp	0.459	0.425	0.452
Lubricating oil used, gal	1,245	1,245	1,245
Kw per gal lubricating oil	5,540	5,540	5,540
Btu per kwhr	13,056	11,965	12,290
Thermal efficiency, per cent	26.150	28.540	27.780
Running plant-load factor per cent	69.500	69.500	69.500
Weight of fuel per gal, lb	7.065	7.065	8.044
Btu per lb of fuel	19,000+	19,000+	18,500
Btu per gal of fuel	135,000	135,000	144,000
Fuel oil cost, cents per gal	5.190	5.190	3.000
Costs:			
Labor per cent supervision	$12,228.05	$12,228.05	$12,228.05
Fuel oil, including handling	35,760.05	32,207.43	17,384.40
Maintenance of engines	6,977.60	4,250.00	6,375.00
Other plant maintenance	690.85	350.00	350.00
Miscellaneous supplies and expense	69.80	350.00	350.00
Lubricating oil	621.75	621.75	621.75
All other expense	none	100.00	100.00
Total operation and maintenance	$56,348.10	$50,107.23	$37,409.20
Total cost in mills per kw	8.05	7.16	5.34

The savings that can be made in many of the present Diesel-generating stations are very attractive. However, within the next two or three years, or perhaps even much sooner, they will be not only attractive, but a necessity. Taxes on imported crudes will raise the price of fuel. And we all realize that but a short time will see at least a partial application of the Diesel engine in the automotive and airplane industries. In fact, airplane and truck engines are already in commercial production. What is going to happen to the prices of the so-called good Diesel fuel oil which is the type of fuel that must be used in these light high-speed engines? It is not unreasonable to suppose that the fuel consumption of these engines will amount to several hundred million gallons per month. Boiler fuel oil will, however, be even more of a drug on the market than it is now unless a market can be opened up for it.

Before making any attempt to burn boiler fuel oil in Diesel engines—providing the engine is of a type that will handle the boiler fuel oil efficiently—the following provisions should be made:

Of prime importance is the supervision of the plant. A capable Diesel engineer should be employed of a little higher caliber than usually found in the average Diesel plant. He should have at least a high-school education and preferably a technical education. He should have a record of being able to obtain the highest possible efficiencies when operating Diesel engines on the lighter fuel oils. In other words, he should be able to make the engines live up to the manufacturer's guarantee or better. Any engineer that operates a Diesel plant and gets but 11 kwhr per gal of fuel when he should get 12 certainly should not be trusted to operate a plant on boiler fuel. He should also be a first-class machinist and able to do all maintenance and repair work, regardless of its nature. Unless a man with such characteristics is employed, it will usually be found that the heavy-fuel project is a failure even before the first car of heavy fuel oil arrives at the plant.

It is very important that a Diesel engine have plenty of excess air for any type of fuel oil. However, it is far more important that it have a very large excess when it is to operate on boiler fuel oil. Of course, the amount of excess air is to a great extent regulated by the factory air-inlet valve settings. However, in many cases air filters are installed, and often they are too small or perhaps not kept clean. Or perhaps new timing gears have been installed, and the air-inlet valve settings are not the same as the original setting. Or, again, it may be that the original factory setting was not correct. (It is the present practice of many manufacturers to ship engines without running them.) In two-cycle engines the scavenging pressure may have to be increased or the exhaust ports may be fouled with carbon. There are many factors that may have a large effect on the amount of air drawn into the cylinder.

The compression of the engine should be raised to not less than 525 lb per sq in. (by inserting shims under the foot of the connecting rod). Two-piece piston rings should be installed in the third and fourth grooves of the piston to prevent the corrosive exhaust gases (caused by sulphur in boiler fuel) from blowing by into the crankcase. In no case should two-piece piston rings be installed in the top two grooves as they will cause very rapid wear (stepping) of the lands on the piston.

A pyrometer should be installed. (This is very important with solid-injection-type engines.) An indicator must be provided. It is usually unnecessary, however, to provide an indicator motion, since the fuel-valve settings will be much more clearly shown on an out-of-phase or hand-drawn card. However, if the engine does not perform as well or better on the heavy fuel than it did on the lighter fuel oils, then an indicator motion should be installed and phase cards taken to locate the trouble. Sometimes it is necessary to provide burner plates or spray nozzles with slightly larger holes (usually only on mechanical-injection-type engines). It also may be necessary to respace the atomizer disks. Of course, none of this can be done to any set rule, but must be determined from the indicator cards taken after the engine is in operation on the heavy fuel oil.

Next we come to the necessity of cleaning and heating the boiler fuel oil. Nearly all of the commercial fuel oils reach the same viscosity around 200 to 225 F, and by raising the temperature of the boiler fuel, light fuel-oil viscosity can be duplicated. In nearly all of the heavy-duty slow-speed engines the best

operating viscosity is usually between 50 to 75 sec Saybolt, and nearly all of the commercial boiler fuel oils will reach this viscosity well below 200 F. However, even much higher temperatures are well below the flash and carbonization points. The best operating temperature for any engine can be found by actual operation. Separate fuel tanks or accurately calibrated meters must be provided for each engine and the fuel consumption checked each 24 hours. Any change in rate of consumption should immediately be investigated. It is well to remember that the products of poor combustion are very abrasive, and they are even more so with boiler fuel than with the lighter fuel oils, and that poor combustion is responsible for rapid cylinder-liner and piston-ring wear.

A very efficient and very simple type of heater is one that uses a part of the exhaust gases, and it can be made in the plant at small cost. A 15 to 20 ft length of 4-in. black wrought-iron pipe is fitted with a stuffing box at each end bored to take a 2-in. standard-pipe-size copper pipe. One end of the copper pipe is connected to the exhaust header with a gate valve in between, and the other end, after it passes through the 4-in. black pipe (or the jacket of the heater), is continued on outside the building. Two pipe connections are welded to the heater jacket, one on each end. One connection is for the fuel supply, and the other, or outlet, is to be connected to the fuel-injection pump through a Cuno or Hesselman jacketed strainer. Light fuel oil will have to be used for starting and stopping the engine. Not only does the light fuel oil make starting easier, but it clears the cylinders of all corrosive gases that would otherwise remain from combustion of sulphur in the heavy fuel oil. The light-fuel connection should be made in two places, one for normal operation and one for emergency operation. The normal connection is made to the jacket of the heater at the same point as the heavy fuel connection. The emergency connection is to be made up close to the engine injection pump. In normal operation, when the engine is to be shut down, the heat-control valve is closed, and the light fuel oil is turned on and the heavy fuel turned off. The engine is then operated until all of the heavy fuel oil in the heater has been replaced by the lighter fuel. When the engine is again to be started up, the heavy fuel oil is turned on and the heat control valve opened. By the time all of the light fuel oil in the heater is replaced by heavy fuel oil, the temperature of the heavy fuel will be high enough for efficient operation. The other light-fuel-oil connection is to be used only when the engine is to be shut down quickly, as in case of mechanical or other troubles. To prevent gas binding of the fuel pump, a vent must also be provided just as close to the suction side of the fuel pump as possible. This vent is to be run back to the fuel-supply tank up over the top on the outside. The usual operating temperature is 180 to 200 F.

Hot-water-heating systems are also used for heating heavy fuel oil in some installations. However, they are much more expensive, both in operation and in first cost. Also, since the temperature of the hot water is always constant, such a heating system is not very satisfactory where there are large and sudden changes of load; whereas with the exhaust-gas heater, the rise and fall of the load will cause a rise and fall of the exhaust-gas temperature and make the operation of the exhaust-gas heater almost automatic. In either case, all pipes carrying heavy fuel oil should be slightly larger than with light fuel oils, and all pipes carrying hot oil, exhaust gases, or hot water should be insulated. Of particular importance is the insulating of the fuel piping from the engine injection pump to the engine-fuel valve. It is very important that the temperature of the fuel at the fuel valve be but little below the temperature reached in the heater.

The heavy fuel oil should be passed through a centrifuge, although some plants operate with only a heating, settling, and filtering system. The latter system operates very satisfactorily, but the overall maintenance cost will probably be slightly higher. In either case, it is very necessary that the heat required for cleaning the fuel be obtained from the jacket water or exhaust gases, or as in most cases a combination of the two. This is for economical reasons.

It is well to remember that where engines of such type as are capable of operating on boiler fuel are to be operated on boiler fuel oil, it will be necessary for them to operate on such commercial fuel as is available if advantage is to be taken of the present very favorable market prices. Such specifications as are specified must be very broad. A fuel that the author has in mind and that he has used in McIntosh-Seymour, De La Vergne, and M.A.N. engines, and found very satisfactory, is: Baumé gravity, 12 to 16; asphaltum residue, not to exceed 15 per cent; Conradson carbon, not to exceed 8 per cent; sulphur, not to exceed 3 per cent; bottom settlings and water, not to exceed 1 per cent; viscosity and flash-point, flash-point to be above the temperature at which the viscosity reaches 50 sec Saybolt Universal.

The majority of commercial fuel oils in the East will be well within these limits. However, in order that my meaning might be perfectly clear, I would like to say that three distinctly separate fuel-oil specifications should be able to take care of the Diesel-engine industry: 1, a fuel oil for slow-speed to medium-speed heavy-duty full-Diesel-type; 2, a fuel oil for any type engine, with exception of automotive and airplane types; 3, a fuel oil for automotive, airplane, and other engines of like characteristics (the third fuel would probably be very much like the second specification, with the exception that it should be a filtered or centrifuged fuel).

In conclusion, the author would like to suggest this: If real economical operation is to be obtained in Diesel-generating plants, the majority of which are now operating way below par, then better supervision of operation is necessary. The plants of fair size can afford to employ the services of engineers capable of producing the desired results. However, on the other hand, there are many small plants that cannot (even if there were enough good Diesel men to go around). It would seem that this is a very good field for "supervisory engineering companies" to investigate, with a view of profit to themselves, operating on a percentage of the net savings made in each case. Or probably even better still would it be for the manufacturers of Diesel equipment to retain supervisory control over the smaller plants until such time as the operating force can show that they are capable of economical and reliable operation. With "supervisory" control, whether by private engineering firms, consulting engineers, or Diesel manufacturers, there would be no question of what kind of fuel oil to use or if new cylinder liners should be installed or the old ones rebored; such items would take care of themselves. If boiler fuel oil could be shown to operate more economically in the particular locality, then it is certain that boiler fuel would be the one used, just as is the case with large electrical utility companies and pipe-line companies operating long strings of stations. The Diesel-engine manufacturers, with their branch offices in all of the larger cities, should easily be able to operate such a service, and not only better the entire Diesel industry, but show a profit to themselves. Of course, however, it would be necessary for them to employ engineers of a different caliber than the usual factory erection engineers. These should be men of the same caliber as the master mechanics of the large pipe-line companies or men such as the superintendents of Diesel power for the large electrical utility companies; in other words, men that are capable of looking at the overall cost per hp-hr or kwhr, and not just the kind that says, "This cylinder liner shows lots of wear, and you had better change your quality of fuel or lubri-

cating oil and buy several hundred dollars' worth of spare parts to repair the engine."

At any rate, whether or not supervisory control is to be used, it is very obvious that much improvement in operation is necessary and is possible.

Discussion

W. L. Marston.[2] The author's statements that the cost of operating a Diesel plant can be greatly reduced by the use of heavy or boiler fuel oils is well borne out by the Preliminary Report on Oil Engine Power Costs for 1931, which has just been presented. On page 8 of this report, referring to plants 73 and 54, it will be noticed plant 73 reports a fuel cost of 0.93 mill per net kwhr. Plant No. 54 reports a fuel cost of 0.91 mills per net kwhr. These costs are less than half of any other fuel costs shown in the report, with one or two exceptions. It will be further noticed that the total production cost of these two plants is also greatly below that of any other plant. It has been stated that the use of heavy fuel oil increases the cost of maintenance. This is not borne out by the figures reported for plant 73, as its cost of engine repairs is well in line with that of any other plant. From the paper it will be seen that plant 73 uses a fuel oil of 11 to 14 deg A.P.I. Plant 54 uses a 27.2 deg A.P.I. crude oil from the pipe line.

On this same page it is stated that these two plants centrifuge their fuel oil, and with one or two exceptions they are the only plants that are centrifuging their fuel oil. This is significant. The reason is that the heavy fuel oil must be centrifuged first before it can be satisfactorily used in Diesel engines.

It is an interesting fact that on motorships the fuel-oil centrifuge is standard equipment. Practically every motorship using Diesel engines is equipped to centrifuge the fuel. Not only does this permit the ship to use a heavier gravity fuel successfully, but since there are no service stations on the high seas, it helps maintain the engine reliability at the maximum. Stationary Diesel plants likewise will reduce operating costs by using heavier gravity fuel oil. To satisfactorily use the heavier grades of oil, however, it is essential that this oil be thoroughly cleaned by centrifuging.

Edgar J. Kates.[3] Great emphasis is laid in this paper on the importance of using residual fuel oils (so-called boiler fuel oil) in order to reduce operating costs in Diesel-generating stations. However, circumstances alter cases, and the writer feels that exception should be taken to categorical statements favoring the universal use of heavy fuel oils. The question is an economic one, and while under certain operating conditions the use of cheap residual fuels is well justified, under other conditions it is far more desirable to use light fuels.

Heavy oils can be used to advantage in large engines operating at continuous heavy loads; here the cheapness of the fuel more than offsets the cost of preparing it for the engine and the increased cost of maintenance. Thus heavy oils are indicated for ocean-going motorships and for such stationary generating plants as the one described in *Power*, February 2, 1932, where a 2250-kw Diesel plant enjoyed an annual capacity factor of 71 per cent, and boiler oil was 1.95 cents per gallon cheaper than light oil. Here the difference in cost in favor of boiler oil was over $24,000 per year. On the other hand, the A.S.M.E. Oil Engine Power Cost Report contains records of small generating plants with poor load factors, which consume annually less than $2000 worth of 32 B oil or lighter, costing from 5.5 cents per gallon down to 2.52 cents. Such plants are often located where tank-truck deliveries of household furnace oil can be readily obtained, whereas no facilities exist for the delivery of small quantities of boiler oil. Even if boiler oil could be obtained for a trifle less per gallon it is obvious that the small annual saving thus effected would not nearly offset the nuisance of handling, the cost of preheating, settling and cleaning, and the increased cost of supervision and maintenance.

In the writer's opinion the latter part of the paper is the more valuable, giving as it does many excellent practical suggestions for the satisfactory use of residual fuels, which advice is evidently based on the author's own intimate experience.

It is unfortunate that the first part of the paper contains a number of statements that cannot be verified, and that may weaken the force of the author's justified plea for more general consideration of the question of using residual oils for Diesel fuel. For instance, in comparing the relative prices of high-grade Diesel fuel oil and steam coal in the Eastern part of the United States, he states that Diesel fuel costs about 40 cents per million Btu, while steam coal costs only 8 cents per million. These figures show that the author assumed Diesel fuel to cost about $5^1/_2$ cents per gallon and steam coal about $2 per ton. The facts are that in the vicinity of New York the average cost of high-grade Diesel fuel was about $4^3/_4$ cents in 1931 (it is still cheaper now), while good steam coal cost over $4 per ton. Using the corrected prices, Diesel fuel costs about 35 cents per million Btu and steam coal about 16 cents, which is a ratio of only 2.2 to 1, as compared with 5 to 1 as stated by the author.

Furthermore, the author does not give full credit to the modern Diesel engine for its actual thermal efficiency. He says that even in the largest and most efficiently operated Diesel plants 12,000 Btu is required to produce 1 kwhr. Reference to the A.S.M.E. Oil Engine Power Cost Report for 1931 shows 10 plants which did better than 12,000 Btu per kwhr, one of them (No. 164) doing 10,680.

Author's Closure

Mr. Marston points out that the statements relative to lower generating costs prevailing in the plants using heavy residual fuel oils are well borne out in the 1931 Report of the Power Cost Committee. It should also be noted that there are five plants in addition to plant 73 cited by Mr. Marston that are using fuel oil heavier than 20 deg A.P.I., and in each case not only is the fuel cost per kilowatt-hour lower than in plants using light Diesel fuel, but the overall on the switchboard cost is also well below the light fuel plants. In a discussion of this sort thermal efficiencies, maintenance, and other plant expense can be disregarded, since the subject is an economical one. The important issue is, what is the overall cost per net kilowatt-hour generated?

Mr. Marston points out that plant 73 using 11 to 14 deg A.P.I. fuel has maintenance costs in line with other plants and that the statement relative to maintenance being higher in heavy fuel plants is not borne out. The costs for maintenance in plant 73 are for parts alone, and the operating crew does the repair work, as it should. The actual cost of maintenance, however, will be the average cost per kilowatt-hour, or rather horsepower-hour per year—the average after the engines are given their 3 to 5 year overhaul and new cylinder liners have been installed. All Diesel maintenance, whether light fuel or heavy fuel is used, must be kept in cycles if the information is to be of any use, so far as statistics are concerned.

For example, Mr. Lee Schneitter[4] has told of a plant operated in Florida on heavy fuel. It is a plant with two-cycle, air-injection engines and operates under heavy load continuously. New cylinder liners are required every two years. This plant's main-

[2] Sharples Specialty Company, Philadelphia, Pa.,

[4] Diesel Engineer, Electric Bond and Share Company, New York, N. Y. Assoc-Mem. A.S.M.E.

tenance cycle is but two years. On the other hand, the author has operated four-cycle air-injection engines on heavy fuel where the cycle is five years. The cycle will vary with type of engine and supervision.

Heavy fuel oils for Diesel-engine use must be cleaned in some way, and there is little question that a centrifuge is the most efficient as well as the most economical way of doing it. That clean fuel plays an important part in Diesel-engine cylinder wear was brought out in an article in *Motorship* some time ago. Two sister motorships, one equipped with centrifuges for fuel and the other not so equipped, made trips around the world. At the completion of the trips the one with centrifuges showed but very little cylinder wear, while the other not equipped with centrifuges had to have a new set of cylinder liners. Intelligent supervision is the deciding factor of what kind of fuel should be used and whether or not it should be centrifuged.

Mr. Kates seems to feel that the author is making a plea for the general use of residual fuel oils (so-called boiler fuel). Such is not the intention. The author has pointed out that plants that are using boiler fuel show better economy than plants using light Diesel fuel and that they are showing reliable operation with maintenance costs in line (so far as the A.S.M.E. Power Cost Report shows) with other plants. The author has emphasized the fact that generating costs are, in the majority of Diesel plants, too high and that cheaper fuel oil will help reduce them. He has also emphasized the importance of better plant supervision and that it will not be a question of what kind of fuel to use with good supervision.

It is very true that small Diesel plants would not find any saving in using heavy fuel costing a "trifle" less per gallon than light Diesel fuel, but even small plants would find a saving where the difference is 100 per cent, as is the case along the Atlantic seaboard.

A plant that is generating 2,250,000 kwhr yearly would be considered a small plant, probably two 500 hp engines, and would consume about 200,000 gal of fuel oil at 5 cents per gallon, or a total of $10,000. With the same rate of consumption the same quantity of boiler fuel would cost but $5000. The saving would pay for lots of maintenance and still leave a very attractive profit. Where the cost differential is but slight, of course the heavy fuel oil would lose its attraction.

The author is mistaken in the statement that there is such a large difference in the price of Diesel fuel and of good steam coal. He had in mind certain strategically located steam plants. Such a comparison is of course out of place. He feels, however, that all of the remainder of the first part of the paper is easily verified. Mr. Kates takes exception to the statement that 12,000 Btu is required to produce a kilowatt-hour with Diesel engines. There are of course exceptions to any rule. The plant 164 referred to is one. However, there are nine other plants shown in the Cost Committee's report showing a better performance than 12,000 Btu, but each one has a very large amount of power charged against production, and the latter is a very unfair charge. Motor-driven exciters and scavenging blowers should not be included in the gross generated. When such deductions are made, it will be seen that in each case more than 12,000 Btu are required per kilowatt-hour. Not more than 2 per cent of the total generated load should be charged to production, and if it is necessary, then the Diesel engine loses a lot of its attraction as being a self-contained type of prime mover. Where fuel or lubricating oil is to be heated for centrifuging, it can just as easily be done with exhaust gas heat and at no additional cost. The net kwhr is what one must reckon with.

Referring to increase in supervision costs, due to better supervision being necessary where heavy fuel oil is to be used, most of the plants of even medium size pay from $200 to $300 per month for a plant chief engineer, but they are not always $200 to $300 per month men; the latter is reflected in the operating records of the plants having the highest labor and supervision costs in both the 1930 and the 1931 reports of the Cost Committee. For example, plant 82 spends $25,809.80 for labor and supervision and in addition spends $17,206.60 (most of which is for labor) for maintenance. The on-the-board cost per kwhr is 12.42 mills. On the other hand, plant 73 spends 16,099.09 for labor and supervision. Operating personnel does all of the repair work and spends but 1,825.13, all of which is for parts. The on-the-board cost is 3.52 mills. Plant 82 uses light fuel and plant 73 uses heavy fuel.

Metallurgical Problems of the Diesel Engine

By R. J. ALLEN,[1] NEW YORK, N. Y.

The metallurgical problems of the Diesel engine consist more in selecting the most suitable material for a given application than in trying to find the solution for a chronic condition. Most of the problems encountered in operation are ones of design, but for economical reasons they often become metallurgical. It is believed that a more careful study of the details of design, with a view to eliminating localized overstress and providing better lubrication, will end most of the troubles. Where such consideration is given, the performance of the Diesel engine is most reliable, and many engines are building up records which rival those of the older reciprocating types of steam engines.

THE metallurgical problems of the Diesel engine are similar to those of other reciprocating types of prime movers, with the exception of the ones having to do with the combustion chamber. Consequently, the knowledge gained during the years in the manufacture and operation of steam and gas engines is largely applicable to the Diesel engine. This is also true of that more recently obtained in the development of the automotive engine.

Selection of Materials

Unfortunately, there is no one metal which will function satisfactorily in all the possible applications in an engine. There is, however, no dearth of types for any particular purpose. Some materials, with slight modification, may serve a number of purposes, such as cast iron when used in the frame, cylinders, heads, liners, and pistons. Others, such as the white metal in the main bearings, are largely single-purpose metals. The metallurgical problem is therefore a matter of selecting the most suitable material, properly conditioned, for each particular application. Naturally the question of cost must be considered.

As the result of intensive effort on the part of the material manufacturers to improve their products, the simple metals and alloys have been augmented by numerous complex alloys. This applies not only to the steels, but to aluminum, cast iron, and the bronzes. Some alloying elements have, over a period of time, proved their worth and are now recognized as essential, while others are still more or less on trial.

While all the numerous alloys offered may serve a useful purpose, it must be recognized that the difference, in many cases, is slight; hence, one is better off by developing a single type to the maximum, rather than half trying every new one brought out. The improvement in some particular characteristic due to a special alloy may be offset by some detrimental feature not shown up until the parts are in service.

The physical characteristics of the more standard alloys are now well established. Charts are available showing the corresponding tensile properties and hardness numerals for many forms of treatment, and the corresponding structural conditions have been recorded by the microscope. The endurance limits are known for normal conditions, at elevated temperatures, and where corrosion influences are present. Impact figures are available for both the single-blow Izod and Charpy and the repeated-blow Stanton types. Further, improvised tests may be made, approximating more nearly the actual working conditions than are obtained in any of the standards available, and additional data may be developed concerning the probable performance of the material when put into service. Hence, there is no reason for stressing materials beyond their safe working limits under any condition of service.

To obtain the most out of a material, it must be suitably processed in all stages of manufacture. In the case of a steel casting, for instance, the conditions of manufacture must be such that the material is free from blowholes, shrinks, and segregation. Then it must be heat treated to relieve strains and to develop a suitable homogeneous structure. Slighting any operation may ruin an otherwise excellent product. Materials should therefore be purchased on the basis of quality and from reputable sources.

When a type of material is selected for use, because of certain desirable characteristics, such facts should form the basis of a specification. Such a specification should be a concise statement of the characteristics and condition of the material which have been found most satisfactory. Its function, like that of a blueprint drawing, is to present to the shop or supplier a clear picture of exactly what is wanted. However, neither is an assurance of quality; the latter can be obtained only by adequate inspection.

Whenever possible, standard specifications of the national societies should be used. A standard material regularly made is likely to be better than a special material infrequently made. Furthermore, there is usually a range of selection in standard materials not available in special varieties. However, if the standard specification does not meet the particular needs, such alterations as seem desirable should be made.

Inspection and Testing of Materials

The inspection of materials is more difficult than that of machined parts. The latter is largely a matter of checking size, the correctness of which can be determined to any degree of accuracy desired. In the case of materials, however, many factors are involved, some of which are quite positive, while others are rather intangible. The evaluation of the latter is largely a matter of personal opinion, and hence the results may vary.

The checking of materials is further handicapped by the destructive nature of most of the tests. Tests such as the X-ray, magnetic, and hardness may be made on finished pieces intended for production, but others, such as the tensile, impact, and fatigue, those most commonly used, must be made on representative pieces, and the uniformity of the product be depended upon in determining the disposition of the lot.

Hardness tests are simple to make and positive in result. They give considerable useful information as to the uniformity

Presented at the Fifth National Meeting of the Oil and Gas Power Division of THE AMERICAN SOCIETY OF MECHANICAL ENGINEERS, State College, Pa., June 8 to 11, 1932.

NOTE: Statements and opinions advanced in papers are to be understood as individual expressions of their authors, and not those of the Society.

of the product, and should be used frequently in the inspection of finished materials. The X-ray, although an excellent tool for development purposes and for the checking of special, highly stressed parts, cannot as yet be thought of as regular, routine test equipment. The magnetic test may be used for checking symmetrical sections, but it is not of great value as a general test. Iron filings are extremely helpful in detecting cracks in a hardened piece of steel, if the latter is suitably magnetized.

Acid etching or pickling may of course be used to facilitate the inspection for surface defects of individual pieces without affecting the utility of the product, and incidentally it can also be used to excellent advantage in checking cross-sections of the material for possible segregation.

The testing of large forgings and castings may be facilitated through the use of test prolongations forged or cast integral with each piece. These prolongations may be made sufficiently large for actual physical test purposes, or they may simply provide a means of obtaining a fractured surface for visual examination. With a little experience, one can tell rather accurately, from the appearance of a fracture, the physical condition of the material.

Through a conscientious application of the tests available one can determine quite accurately the suitability of any given lot of material for any given application of service.

General Types of Materials

Cast Iron. Cast iron has for years been the basic material in engine construction, largely because of its low cost and the ease with which it can be cast into intricate shapes. One does not have to look back very far to the time when it was simply a remelted pig iron, modified perhaps as to silicon content to obtain reasonable casting conditions. Eventually, the introduction of steel scrap, in small percentages, gave the cupola operator an opportunity to control the carbon to some extent and to produce a better graphite formation with corresponding increase in strength. From this beginning high-strength irons were soon developed in which the entire charge consisted of steel scrap. The term "semi-steel" has now little significance, as varying amounts of steel scrap are used in practically all cast iron made.

The strength of any given piece of cast iron is a function of its section, and this fact must be taken into consideration when making comparisons. When cast in a standard test-bar section, the high-strength irons will show tensile figures in excess of 50,000 lb per sq in. With the introduction of nickel, the strength may be increased to over 60,000 lb per sq in. and machineability be reasonably maintained. All cast irons, unfortunately, are inherently brittle, and this fact must be taken into consideration when evaluating the usefulness of the high strengths.

In plain cast irons the hardness is largely a function of the thickness of section and the silicon content. If the casting is quite irregular in shape, the heavy sections may be soft and the thin sections hard and unmachineable. When the silicon is increased to keep the light sections soft, the heavy sections are likely to be open-grained and spongy. Also, straight silicon irons oxidize readily at elevated temperatures and the combined carbon tends to break down into graphite and ferrite. Such a reaction involves an increase in size, or growth, and a decrease in strength. It is advisable, therefore, to keep the silicon as low as possible.

The addition of nickel, while supplementing the silicon in reducing chill, refines the iron and produces greater structural uniformity. It also reduces the tendency for draws and slightly increases the combined carbon, making the iron harder and more wear resistant. However, such irons are readily machineable, and a fine surface finish may be produced. Through the use of nickel the casting of many difficult sections is made readily possible.

Chromium, when added to cast iron, has the opposite effect to that of silicon and nickel, in that it tends to develop hardness through the retention of carbon in the combined forms. Such an alloy is most helpful in developing materials for use at elevated temperatures. It must be used in judicial amounts; otherwise, there will be an excess of hard combined carbon. This constituent is an excellent abrasive, and if present in a liner, for instance, may spall out in service and accelerate wear. Its presence also makes the machining exceedingly difficult.

Chromium and nickel, in suitable proportions, develop excellent characteristics in iron, particularly where resistance to wear and growth are important factors.

Molybdenum has a beneficial effect on cast iron. Its effect is intermediate between nickel and chromium, in that it tends to develop stability, without undue chilling tendencies, and a compact graphite formation which is quite beneficial in resisting fatigue. It may be used alone or in combination with nickel

Strains may be set up in irregular-shaped castings due to the differences in rate of cooling throughout the mass. If the castings are left in the sand, however, until fairly cold, the natural annealing effect of the slow cooling should effectively relieve the strains. If not relieved prior to machining, the piece may distort in service. A safe procedure, in cases where distortion may affect the operation of the unit, is to definitely anneal the castings in a suitable annealing furnace.

With facilities for annealing available, the additional step to heat treating is a comparatively simple matter. The desire for greater hardness in parts subjected to wear, such as cylinder liners, has resulted in the development of irons which are susceptible to heat treatment. Such irons ordinarily contain from 2 to 5 per cent of nickel, plus the proportionate amounts of chromium, and, like steel, may be heat treated to Brinell figures of 400 and upward. Although comparatively strong and tough, the materials are still cast iron, and as such are inherently brittle. The treatment is best confined to pieces of regular sections because of the possibility of cracks developing through the strains set up during quenching. The machining procedure follows that of treated alloy steels. The softer pieces may be machined after treatment, whereas the harder ones must be first roughed out, treated, and then finished off by grinding. Iron, heat treated for hardness, softens under heat, and hence will lose its hardness if operated at a temperature in excess of that used in tempering to develop the given hardness. However, the range is not seriously restricted, as tempering temperatures of around 900 F are usually employed during heat treatment.

The necessity for greater resistance to corrosion and stability at high temperatures has led to the development of a still more highly alloyed iron known as Ni-Resist. This iron contains some 15 per cent nickel and 7 per cent copper, with chromium varying from 1 to 6 per cent. The matrix is austenitic in type, somewhat similar to that of the 18 and 8 types of stainless steel. It is non-magnetic, tough, non-hardenable by heat treatment, and if the chromium content is not too high, reasonably machineable. Its coefficient of expansion is relatively high, approximating that of aluminum. Although comparatively soft, it will work harder in service, and develop appreciable resistance to wear. It can be produced in the foundry under standard conditions, although irregular sections may be difficult to cast because of the shrinkage.

Steel Castings. Steel castings, because of their combination of high strength and ductility, when suitably treated, and the fact that they can be produced in shapes not possible in forgings, serve many useful purposes. Like any other class of material,

they have their peculiar faults, which must be guarded against if trouble is to be avoided. Blowholes, shrinks, and segregation are the principal ailments, and unfortunately they are sometimes difficult to detect.

Cast steel lacks a constituent like graphite to counteract the effect of the metal shrinkage, and unless uniform sections are provided or provisions made to feed the heavier sections while cooling, shrinkage cracks may result. As a result, complicated castings with irregular sections are much more difficult to obtain in steel than in iron.

The beneficial effect of heat treatment on a carbon-steel casting is illustrated by the following table:

Condition	Tensile	Yield	Elongation	Reduction	Brinell	Impact
As cast.....	74,800	37,500	19.5	29.0	156	17
Normalized.....	75,650	42,000	25.5	44.0	143	21
Treated.....	84,200	57,400	31.5	65.0	160	44

Alloy-steel castings are now being produced in almost as many varieties as obtainable in bar stock, and if suitably heat treated, serve a useful purpose. The greater strength permits lighter weight, and the lighter sections tend to promote soundness. Stainless-steel castings of many grades are also being produced, although their use in Diesel engines, because of the cost, is rather limited. These steels are difficult to cast, and because of their high solidification shrinkage, usually require special pattern equipment and simpler designs.

Structural Steels. Aside from the straight carbon steels, the number of alloy steels available for structural purposes are legion. Many have been standardized by the S.A.E., and are designated by their numbers, while others, the special product of some steel company, are sold under brand names. While many of these steels have distinctive characteristics and serve useful purposes, nevertheless the number could be materially reduced with profit to the industry. As a matter of fact, most of the troubles encountered, where the steel is supposed to be at fault, are due to improper heat treatment rather than any inherent fault in the type. The fact that better results can usually be obtained in the long run through the suitable conditioning of a standard type of material, rather than through the hit-and-miss tries of special types, cannot be too strongly emphasized. All steels, particularly the alloy types, must be suitably heat treated to develop their maximum physical characteristics.

Special Steels. Numerous types of special alloy steels are also available. Such steels are of value for their ability to perform some special purpose well, such as air hardening without distortion, resisting wear, or standing up under corrosion. Chromium is the principal element in most of these steels, although nickel, molybdenum, vanadium, copper, silicon, and aluminum may play important parts.

Stainless iron, a low-carbon 12 per cent chromium material, has many useful applications. If properly treated, it has excellent physical characteristics and reasonably good resistance to corrosion. With properties quite comparable to those of S.A.E. 3140 steel, it may be safely used where strength is required. For greater stability, under severe conditions, one is forced into the austenitic steels carrying appreciable percentages of chromium and nickel, with, in many cases, an additional element such as silicon. Many modifications, of course, are available.

Nitralloy, a special type of steel which may be processed to develop remarkable surface hardness, stands up well under severe conditions of wear. Two grades, the chromium-aluminum, having exceedingly high hardness, and the chrome-vanadium, with lesser hardness but greater toughness, are in general use. The material retains its hardness through the temperature range encountered in the Diesel engine, with the possible exception of the exhaust valve. It is quite resistant to both atmospheric and alkaline corrosion, but not to acids. However, from records available, it would appear that neither type is seriously attacked by the usual fuels.

Forgings. Forging assures a sound section in the finished piece, free from blowholes or draws. Further, the quality of the stock used may be carefully checked before the forgings are made. However, drop forgings have their peculiar faults in the form of laps and cold shut. Fortunately, these, unlike blowholes and shrinks in castings, can usually be detected quite readily by visual inspection. Drop forgings have an advantage over castings in that they may be made in light sections and still retain a clean-cut surface appearance.

Unless care is exercised in forging, the structural condition of the material, despite the beneficial effect of the added working, may be utterly ruined. If steel, for instance, is soaked at a high temperature in an oxidizing atmosphere, the gases penetrate the section and oxidize the grain boundaries. As a result, the material becomes quite brittle, and the condition is not corrected by any normal heat treatment. Some indication of this condition, if present, can be detected by examining the pickled surface, but the only safe method is by an actual fracture test.

As the material is elongated under the hammer it tends to accentuate the directional grain flow normally found in bar stock. The ductility, when tested across the direction of flow, is usually much lower than when tested with the grain. In some pieces, such as a crankshaft, the directional grain is an asset, providing the fibers are continuous throughout the length, while in other parts such as gears, where the direction of stress application is continually changing, it is not. The directional tendency may be broken up by suitable cross-forging, and the desirability of so doing must be considered when designing stressed members.

Forgings, like castings, must be properly heat treated to secure uniformity of structure, relieve strains, and obtain the maximum combination of strength and ductility. Light sections should be fully heat treated, while heavy sections may be normalized and annealed.

Aluminum Alloys. Aluminum in its pure condition, like iron, is a soft, tough metal, but when suitably alloyed with copper, magnesium, and other elements, develops many desirable physical characteristics. All of the alloys may be cast into useful form, while some, in addition, may be forged, rolled, or extruded. Many of the alloys are naturally soft and tough, others are comparatively strong but brittle, while some, when heat treated, develop a good combination of strength and ductility. In the wrought form, treated, tensile strengths of over 50,000 lb per sq in. with elongations of around 20 per cent may be obtained. The modulus of elasticity, however, is only one-third that of steel.

The aluminum alloys are unique in that their physical characteristic tends to run to extremes, and, unfortunately, some of them conflict in their usefulness. Light weight, the outstanding characteristic, is offset to a certain extent by the low modulus. The high heat conductivity in many cases is an advantage, while in others it is not. The high coefficient of expansion, common to most of the alloys, does not work out well with cast iron. The bearing characteristics are not good, and the resistance to alkaline corrosion is low.

While the aluminum alloys are regularly used for many purposes, particularly where weight is a consideration, the selection of the most suitable type must be given careful consideration.

Bronzes. The various types of bronze alloys available under various standard specifications are exceedingly numerous, The range of characteristics, which is dependent on the elements alloyed with the copper, is probably greater than for any other class of material.

Some of the alloys are soft and tough, others are hard and

brittle, while still others have a good combination of strength and toughness. A few, such as the aluminum bronzes, respond to heat treatment.

Many of the bronzes are excellent bearing metals, particularly when tin and lead are present. In general, all the bronzes are resistant to atmospheric corrosion and, with suitable modification, can be made to resist the attack of any of the conditions encountered in Diesel-engine work.

The majority of the bronzes are used in the cast form, although many may be die cast and forged. The ease with which they can be fabricated and their resistance to corrosion tend to make them attractive as structural members, but these advantages are in most cases offset by the low modulus of elasticity, weight, and comparatively high cost. In bearing service, however, their use is well established.

The bronzes, as a class, oxidize readily when molten, and unless care is used in the foundry to prevent such a condition developing, their physical characteristics may be seriously impaired. Such a condition will show up in a tensile test, largely through low ductility, although the condition can readily be detected by means of a simple fracture test. Oxidation in a tin-bearing bronze is particularly bad, as any of the extremely hard tin oxide formed, and scuffed out in running, may seriously score the shaft. The temperature of casting also has an important effect on the strength and ductility of many of the bronzes.

Monel metal, because of its combination of strength, when suitably processed, higher modulus of elasticity, wear resistance, and ability to withstand most forms of corrosion, is an excellent intermediary material between the bronzes and steel. It is readily available in wrought form, but sound castings, if irregular in shape, are not so easily obtained.

Bearing Metals. An ideal bearing metal consists of two constituents. There should be a tough base metal which acts as the body or matrix to carry a hard, finely dispersed element or alloy, which, in the aggregate, acts as the bearing surface. The hard constituent resists wear; the soft constituent provides the degree of conformability necessary to relieve any local high spots, and through its natural tendency to recess, assists in maintaining the oil film. Cast structures, because of the natural arrangement of the grains, are usually better than those which have been mechanically worked. Bearing materials should have a low coefficient of friction, although under running conditions the actual friction is dependent on the pressure, speed, temperature, and lubrication.

The white metals, which are essentially alloys of tin, lead, copper, and antomony, are the commonly recognized bearing metals. The tin-base or babbitt metals have a better combination of strength and plasticity than the lead-base alloys, and hence are more generally used in Diesel work, even though more expensive. However, considerable work is being done with the lead-base alloys, and some worth-while results are being obtained.

The white metals are sensitive to variations in composition, and small changes in the hardening elements or some impurity may either render them brittle or lower their melting point appreciably. The metals oxidize readily when molten, and hence extreme care must be exercised in both the melting and pouring operations.

The high-lead bronzes, with or without small percentages of tin, are closely associated in application with the white metals. Such alloys do not conform to the true concept of a bearing metal, but are actually the reverse, in that the copper matrix is harder than the dispersed load. However, they seem to function quite well within their working range, which is the fusion point of the lead. A rather high coefficient of expansion and possible lead segregation are the two features most likely to give trouble in the use of this material.

The harder cast bronzes, carrying an appreciable amount of tin, lead, and possibly some phosphorus, are good bearing metals when operating against hardened steel. Such bronzes have good strength and resistance to wear, but good alignment and adequate lubrication are essential to their satisfactory performance. If the oil film fails, the resulting seizure is likely to be disastrous to the shaft. Numerous types of bearing bronzes are available, and the selection is largely a matter of past experience. The structural condition of the material used should be checked by fracture tests.

The beryllium-copper alloys, capable of being treated to a Brinell hardness of around 400, are being advocated as bearing metals. Their use, however, has not spread sufficiently to warrant any satisfactory conclusions being drawn as to their probable performances.

Chromium Plating. "Hard" chromium plating is being used quite extensively because of its excellent wear-resisting characteristics. The type must not be confused with "decorative" plating, wherein an extremely thin film of chromium is applied, more or less as a lacquer, to preserve the copper-nickel plating underneath.

The hard plate is applied directly to the base material in thicknesses varying from one-half to three-thousandths of an inch, depending on the conditions of service. Either steel or bronze, as a base material, plates quite satisfactorily; cast iron, because of the graphite, does not provide such a suitable base.

When properly finished by grinding and polishing, the plated chromium presents a hard, low-friction, wear-resisting surface quite suitable for bearing purposes. The plate, although sufficiently tough and adherent for normal bearing conditions, is not suitable for use under shock or extreme pressures such as might be applied through high spots in a hard packing material. Chromium works best as a bearing when mated with a soft packing such as a leaded bronze; cast iron, particularly if it contains free cementite, is likely to score the plate through an indentation of the softer base material.

The hardness of plated chromium is dependent on the presence of the hydrogen deposited during plating, and if heated sufficiently high, in the neighborhood of 1400 F, the plate becomes soft.

Unless the conditions of plating are carefully controlled, strains are set up in the deposited metal sufficient at times to cause it to crack. Such cracks may, in the extreme, extend through the entire depth of plate, in which event the tendency to spall is increased and the resistance to corrosion decreased. However, because of a better knowledge of the variables responsible for this tendency, the plate being produced at the present time is comparatively free from these defects and should perform well in service.

Chromium works well on shafts, pins, and similar parts where good bearings and adequate lubrication are provided. It also functions well as a protection against galling on liners or plugs which are assembled with a close fit and which may later have to be removed. Worn surfaces may in many instances be built up with chromium and satisfactorily salvaged. Further, chromium-plated surfaces, when worn, may be renewed at small expense.

Chromium plating, like all other materials, has its field of useful application and, when rightly applied, gives excellent results.

Welding. The technique of welding has reached the point where it has ceased to be a metallurgical problem in so far as steel construction is concerned. With suitably coated rods of the same composition as the base material, a skilled operator can lay welds having substantially the same physical characteristics as the original plates. A low-temperature strain-

relieving treatment, however should follow the welding of all complicated sections that are likely to be subjected to vibratory stresses. In the case of the higher carbon and alloy steels, the temperature should be carried above the critical transformation point of the material, so that, in addition to relieving the strains, there may be a refinement of the coarse grain developed during the welding operation.

Cast iron can be welded under favorable conditions, but on the whole the results are not overly satisfactory. The structure of the iron matrix is badly upset, and incipient cracks may develop in and about the weld unless the operation is most carefully controlled.

Design, in built-up structures, is all important and far outshadows the metallurgical considerations. The liberal fillets in castings, to avoid shrinkage draws which tend to develop at sharp corners or sudden changes in section, and a reasonable thickness of metal to prevent misruns automatically serve to stiffen the structure and smooth out any tendency for concentration of stress. As a result, castings are usually quite rigid because of foundry considerations and so many of the engineering problems disappear. In built-up structures, however, the reverse is true. The material is strong and tough, and as far as static stresses are concerned, can be used in light sections; the fillets naturally are small. Unless proper precautions are taken, therefore, to stiffen such a structure by suitable bracing, flexing in service is likely to occur, and with it concentration of stresses in the welds. Such a condition usually results in ultimate failure, not because of a faulty weld, but because of insufficient design.

Where weight is an important consideration, welding undoubtedly provides a means of keeping it down.

While the welding of structural members represents sound practice, the building up of worn or undersized working parts is open to question. Many failures have been traced to this cause. Active parts are usually made of medium-carbon or alloy steels which do not weld as satisfactorily as the low-carbon structural steels. The higher strength materials are more likely to be spongy when welded, and a suitable structural condition after welding can be developed only by heat treatment. Such a heat treatment, accompanied by surface scaling and distortion, is of course ruinous to a finished piece. Where the stresses are inherently low and the welding is not being performed at a change in section, the procedure may not be harmful if done under competent supervision, but otherwise it should be looked upon with disfavor.

Failures

Failures may be due to either faulty material or faulty design. A material may be considered at fault if some irregularity, not common to a properly conditioned piece, has contributed to the failure. The irregularity may be a cold shut, segregation, poor structure, deep tool marks, or similar defect. The design or selection of material may be considered at fault when a sound homogeneous piece, properly conditioned, fails for no apparent reason. As a rule, occasional failures denote faulty material, whereas repeated failures tend to throw suspicion on the design.

While it is not practical to positively establish the soundness of each piece of material, nevertheless, with close supervision over the methods of manufacture and adequate inspection in the shop, the chances of faulty material getting into service are not great.

Changes in material can be made without any outward evidence of it having been done. Changes in design, however, usually involve not only the piece actually in trouble, but other mating parts as well, to say nothing of tools, fixtures, and the interchangeability of parts. Consequently. where a trouble may be corrected through the substitution of another type of material, it is logical that such a change should be made. The result, however, is that many problems that are fundamentally ones of design automatically become ones of metallurgy. Although a piece of alloy steel may be substituted for a carbon steel or a piece of Nitralloy for hardened tool steel, the extent to which material changes may be made is comparatively limited, and hence considerable thought must be given to the original design and selection if trouble is to be avoided.

Operating problems in which the material is involved may be grouped under three general headings: first, breakage; second, excessive wear; and, third, corrosion and oxidation.

Breakage. The first class, breakage, assuming the material is correct, is of course the result of overstress. Pieces made of excellent material and operating under low calculated values of stress occasionally fail. The cause, although not always apparent, can usually be traced to a concentration of stresses. In irregular-shaped pieces the average stress is of little practical importance, as failures are the result of maximum stresses. Each type and condition of material has a certain maximum stress value, called the endurance or fatigue limit, under which the piece will withstand an indefinite number of applications of stress without failure. If this stress is exceeded, however, even though over a minute area, a crack will ultimately form and failure occur.

Stress concentrations may be due to sudden changes in section, deep tool marks, inclusions, or anything which tends to break the smooth continuity of the section, or they may be the result of misalignment and excessive vibrations.

While the intensity of the stress concentrations due to changes in section may be difficult to calculate, their probable location and approximate magnitude can often be obtained through the use of bakelite models and a polariscope. Under the action of polarized light, the stress distribution in a section of bakelite may be observed by color variations in the material. Such a method of investigation is simple and instructive.

As stress concentrations are the most prolific cause of breakage, effort should be employed to keep them to a minimum. Fillets at shoulders in stress sections are recognized as essential, but slow tapers, if practical, are better. Similarly, splines distributed around the surface of a shaft are better than a single key. Whitworth threads are better than vee threads because, in the case of bending, the stress concentration at the roots is much lower with the smooth radius than with the sharp notch. For the same reason, studs, with the body turned down to the root diameter of the thread, are much better than those with full-sized bodies; the reduced diameter of the body, aside from reducing the stress at the roots of the thread, provides greater flexibility along the entire length and less tendency for concentration at any point.

There is a tendency in design to lay too much emphasis on the elastic limit and tensile strength and not enough on the so-called toughness of the metal. The fatigue or endurance limit, obtained with a smooth, symmetrical specimen running without impact, seems to be a function of the ultimate strength. In actual service, however, such conditions rarely exist, and aside from the irregularities of operation, parts are seldom regular in section. Stress concentrations, not considered in the fatigue limit, are therefore an important consideration in actual practice. If the material is brittle, a crack once started will progress very rapidly, whereas if the material is tough, the condition of overstress may be relieved through a local readjustment of the grains in the area of stress. Even though the formation of a crack cannot be avoided, the tougher material may seriously retard its progress.

Unfortunately, the toughness which tends to retard the

formation and subsequent development of a fatigue crack is not indicated by any available mechanical test. Pieces having the same tensile and impact values may show decidedly different performances in service. The microscope seems to be the most useful method of checking this characteristic. In steels, for instance, a coarse-grained, pearlitic structure, under many conditions, is not as resistant to fatigue as a normalized structure consisting of a fine-grained intimate mixture of ferrite and pearlite. The soft, tough ferrite seems to provide the mobility which is so important in resisting the spread of cracks. High-tensile alloy steels, not suitably treated, may fail more quickly than a comparatively soft, low-strength material.

Good balance must be maintained between strength and toughness, and when specifying some of the more highly stressed parts, the microstructure should be included.

Excessive Wear. The second class of failure, excessive wear, may be due to faulty material, although high pressures, due to abnormal conditions of operation, and inadequate lubrication are more likely to be the real causes.

Wear is the result of a rubbing, metal to metal, contact between two surfaces. If the surfaces are continually separated by a thin film of oil, wear is largely eliminated, and is reduced to a mere matter of erosion, and possible chemical attack, by the oil used. If the film is periodically broken, however, wear may be quite rapid.

The normal working pressures are readily calculated and may be amply provided for in the original design. Abnormal stresses due to periodic vibrations or the whipping of shafts are not so easily determined, and the resulting pressures may be sufficiently high to break the oil film. Misalignment, surface finish, and dirt are potential sources of wear, although all three may be readily controlled, and hence should not be serious factors in actual operation.

Numerous types of metals suitable for operating in contact with one another are available, and if worked within their corresponding limitations of pressure and temperature, under adequate conditions of lubrication, a satisfactory performance is assured. The selection of the most suitable combination of metals should be given careful consideration, as in addition to obtaining long life as a whole, the conditions should be such that the least expensive of the two pieces in contact will wear most. A hard bronze bushing may readily score and gall a soft steel shaft, whereas a soft bushing will not. A soft material in the presence of dirt, however, may load up and, as a result, lap away a hard material quite rapidly.

In order to maintain a good oil film, assuming proper alignment, finish, and rigidity, it is necessary that the elements of temperature, pressure, feed, clearance, and oil viscosity be held within limits. The viscosity of an oil decreases with an increase in temperature, and if thinned down too much, the resulting film may not be sufficient to carry the load. The pressure, taking into consideration the surface velocity, should be within the limits which experience has proved most satisfactory for the metal combination employed. The clearances must be adjusted to suit the viscosity of oil being used; if the clearance is too small, the film will not be established, and if too large, the oil may work out and not maintain a continuous film. The arrangement of the feed must be such that the distribution, developed in the unloaded area, is uniformly directed to the zone of pressure.

Perfect lubrication is never attained in actual operation; hence, metal-to-metal contact does occur, even though only at the time of starting, and therefore wear is inevitable. Through careful utilization of available materials under proper conditions of operation, it may be maintained at a very small rate, however.

Corrosion and Oxidation. The third class, corrosion and oxidation, is more likely to be a metallurgical problem than the first two, as, despite the best the designer can do, the materials must contact with the corroding or oxidizing medium.

The exhaust valve is probably the hot spot in all internal-combustion engines and may reach a rather high temperature. The other parts, however, which can be more readily cooled, do not become excessively hot.

The Diesel engine, however, unlike the gas or gasoline engines, draws in air undiluted with fuel and compresses it to a temperature at which the oxygen becomes active before the fuel is admitted. The oxygen, therefore, in the absence of fuel, is free to attack the iron or other materials forming the surface of the combustion chamber. Fuel oils for Diesel engines are usually not as highly refined as gasoline, for instance, and may contain appreciable amounts of sulphur which become quite active chemically.

Although the injected fuel is carefully atomized, there is in many cases a tendency for flame impingement. In the case of iron pistons, if the heat is localized, particularly at the center, growth takes place due to the combination of temperature variation, and a crack may develop. The upper portions of the liners, also, wear more rapidly than the lower portion, largely because of this same condition.

Material Application

Frames. Important considerations in the design of a frame are strength, rigidity, and weight. Frames may be made of cast iron, aluminum, or welded steel. The ease with which cast iron can be fabricated and its comparatively low cost account for the majority of the engine frames being made in that material. Welded steel frames, however, are being given consideration because of their possible lighter weight.

If made of cast iron, the composition may vary all the way from a straight silicon to a high-test alloy, depending upon the particular requirements of service. Care must be exercised to keep the sections reasonably uniform, if casting shrinks and strains are to be avoided.

Welded frames are usually made of soft steel and are finally annealed. If made of high-carbon or alloy steel, the entire frame should be heat treated to eliminate the brittle area which develops near the welds and to fully develop the advantage of the higher strength materials. Rigidity must be considered if weld failures are to be avoided. The frames of small units, where the minimum weight is desired, may be made of aluminum.

Cylinders. In smaller units the cylinders may be integral with the frames, whereas in the large units they are made separate. When the cylinder is to provide its own liner, considerable attention must be paid to the type of material used if minimum wall wear is to be obtained; otherwise, the casting may be made of any type of material that will develop the required strength. Care should be taken to see that a smooth water-jacket surface is provided with as little attraction for scale as possible. The casting should be given a low-temperature anneal to relieve strains and prevent subsequent distortion.

Liners. Cylinder wear is an important consideration in the operation of a Diesel engine. The rate of wear is dependent upon one or more of several factors such as lubrication, ring pressure from the gas reaction, dirt, oxidation, and type of material.

Lubrication and ring performance are matters of design, while dirt, if a factor, may be controlled to a large extent by the use of a suitable air cleaner. Oxidation, while influenced by the fuel, is more dependent on the temperature attained, and hence varies with the conditions of cooling. Thin liners, for this reason, are better than thick ones.

Liners may be either of the dry or wet type. The dry type is mostly confined to the small sizes because of the thicker section

of the two walls and the difficulty of providing the close fit essential for good heat conductivity. The metal conditions are much more difficult to control in the dry type than in the wet type because of the larger casting involved.

To resist wear, the liner material should have a reasonably hard, dense structure, with good bearing characteristics and stability under the conditions of operation. To meet these requirements the majority of liners are made of cast iron, although some are being made of steel and hardened Nitralloy. In cast iron, this necessitates low silicon to resist growth, low total carbon to develop denseness, and eutectoid ratio in combined carbon and fine grain size to develop resistance to wear. Nickel and, if the size will permit, chromium are helpful in obtaining the desired conditions.

Because of their symmetrical section, liners may be cast centrifugally and a denseness and uniformity of structure obtained not easily reproduced in a sand casting. If cast in the ordinary manner, the mold should be vertical and the casting should be machined, so that the bottom, or drag end as cast, will be uppermost in the cylinder. In this way the denser metal will be placed at the point of maximum wear and excellent results obtained.

Under usual conditions the Brinell hardness of a straight silicon iron cannot much exceed 180 and that of the regular chrome-nickel iron 220, without free carbides being present. Such carbides are objectionable because of their abrasive characteristics when scuffed free of the iron. If a higher hardness is desired, it should be obtained through the use of a heat-treated iron. Nickel, plus some chromium, in a cast iron, when suitably treated, will permit the development of an excellent structure with Brinell hardness figures of 400 or more.

A 60-point carbon steel, normalized or heat treated for greater hardness, has, when adequately lubricated, proved quite satisfactory as a liner material. Thin sections may be employed and excellent cooling obtained.

Ni-Resist cast iron offers excellent possibilities as a liner material in combination with aluminum, as the coefficient of expansion is about the same in both materials. It is quite resistant to attack from either heat or the normal gases, and its soft, austenitic matrix tends to take on a work-hardened glaze which makes it quite resistant to wear.

Nitralloy steel, nitrided, is being used on many of the smaller units with apparently good results, and, aside from possible attack where high sulphur fuels are used, there is no reason why its use should not spread.

Heads. Cylinder heads are usually made of cast iron, although steel may be used on the larger units and aluminum on the smaller ones. The head must be sufficiently strong to resist the combustion pressures and have the necessary stability to resist the attack of the air and gases of operation.

Head sections on the single-acting engines are usually rather complicated because of the manifold passages and water-cooling chambers. As a result, the heat stresses may be rather high, and this fact must be taken into consideration in drawing up the design and selecting the material. If made in cast iron, the head may provide its own valve seat; if made in aluminum, some other material must be inserted. Aluminum bronze and Ni-Resist are frequently used for this latter purpose.

The water jacket should be smooth and clean to resist the adherence of scale. Attention must be paid to the cooling water used with aluminum; otherwise, porosity, the result of corrosion, may develop.

Pistons. The conditions imposed upon the piston, like those of the liner, are quite severe. A piston should have light weight, strength, good bearing characteristics, an expansion rate comparable to the liner, good heat conductivity, and resistance to the attack of the hot air and gases. There is no single material which will meet all these requirements; hence the one selected must be a compromise.

Cast iron is largely used, however, because its coefficient of expansion may be the same as the liner, its bearing characteristics are good, and it is comparatively inexpensive. The pistons, like the liners, should be made of a dense, fine-grained material. The majority are sand cast, although some of the smaller sizes may be made in semi-permanent molds.

The straight silicon irons oxidize readily in contact with hot oxidizing gases, and if there is a tendency for a local hot spot in the center of the piston, it may fail rapidly through growth and fatigue. The use of a nickel or nickel-chromium iron will delay this type of failure.

In the event of seizure with a cast-iron piston, the resulting damage to the liner may be rather disastrous.

Aluminum, because of its light weight, is being used extensively for pistons in the smaller high-speed units. It may replace iron on larger sizes where water cooling would otherwise be necessary. Its rather high coefficient of expansion can be controlled in the smaller units through the use of inserted Invar rings, and the tendency to slap, when cold, can be eliminated. In some cases, the expansion is taken care of through the use of a split skirt.

Aluminum has the disadvantage of being a comparatively poor bearing material, and hence requires good lubrication in a place where it is not easily maintained. Also, being a soft material, it loads up with dirt and acts as a lap on the liner. Seizure is not as severe, however, as with the iron piston.

Pistons of the aluminum type are usually made of a copper-magnesium-nickel alloy, heat treated to develop a Brinell hardness of around 120. Because of the low modulus, there is a tendency for distortion under load, which must be taken care of with additional clearance in the vicinity of the piston pin.

Steel is not generally used as a piston material because of the difficulty of obtaining satisfactory castings and its tendency to gall under failure of lubrication. Piston heads may be made in steel and used with iron skirts, however.

Piston Rods. One of the most likely sources of trouble in a double-acting Diesel engine is the piston rods. The diameter of the rod must be kept small, in order to interfere as little as possible with the capacity of the lower combustion chamber. This means that the working stresses must be high. The rods also must act as carriers for the piston-cooling medium. If the rod is hollow bored to permit a circulation of the cooling liquid, the temperature gradient stresses may be quite appreciable. If the cooling liquid is carried by means of an external sleeve, the actual rod diameter must be kept smaller than would otherwise be necessary, and the resulting stresses are again high. If water is the cooling medium, the matter of corrosion must be given consideration. Corrosion not only lowers the endurance limit of the steel, but it causes pits which localize the stresses which further accelerate failure.

Because of the high working stresses and packing wear, the natural tendency is to make the rods of alloy steel, suitably heat treated to develop strength and hardness. However, such rods do not seem to stand up as well as those made of the softer steels, because they apparently lack that inherent toughness which is so essential to resisting the progressive type of failure. Either straight carbon or some soft alloy of the nickel-manganese type seems to work out best.

Piston Rings. Piston rings are usually made of a straight silicon cast iron regardless of the type of liner used. Excellent results have been obtained through the use of nickel iron, and its use for this purpose should spread. Steel, of approximately spring temper, may be used in the smaller sizes. Experiments

have been conducted with other types of iron and hardened steels, but the results have not been sufficiently outstanding to cause any general change.

Piston Pins and Bushings. The chief requirements of a piston pin are that it be light, have sufficient strength to carry the load, and the proper hardness to resist wear. With adequate lubrication and a suitable fit, a piston pin should resist wear indefinitely. Pins may be made of hardened tool steel, although they are more usually made of carburized and hardened steel. Nitrided and chromium-plated pins have also been used with considerable success. A smooth, highly finished surface is essential to long life.

Bearing bronzes of the composition type are most generally used for bushings, although the copper-lead type seems to be meeting with favor because of the smaller damage to the pin in the event of seizure. Either, under normal conditions, works satisfactorily.

Crankshafts. One of the desirable characteristics in a crankshaft is that the directional grain flow of the metal follow the contour of the section and be continuous throughout its length. Such a condition eliminates the transverse stressing of the material. Single-piece forgings are preferable to built-up sections because of the better stress distribution at the changes in section. Failures, when they do occur, however, are usually the result of critical vibrations, and the stresses developed in this manner are generally more than any metal can be expected to carry.

In order to obtain the necessary rigidity in a crankshaft, the section is large, and hence the working stresses are low; consequently, the question of strength is not such a serious matter. Bearing wear is one of the important considerations in selecting the type of material to use.

Most crankshafts are made of a straight carbon steel, although on some of the higher speed units a harder material may be desirable. In such cases the bearings may be hardened by case carburizing or by nitriding. The latter, although more expensive, is perhaps the preferable method.

Connecting Rods. Connecting rods present few, if any, metallurgical problems. The majority are made of carbon steel, suitably treated, although on some of the smaller high-speed units alloy steels may be required.

Aluminum may be satisfactorily used, but as a rule the expense is not warranted. With a careful distribution of the metal in a steel rod, the section can be made quite light and suitable results be obtained at much less cost.

Bearings. In the small high-speed units the bearing conditions in the Diesel engine may be quite severe, but on the whole they are quite normal.

As a rule, the crankshaft bearings, both main and connecting rod, are made of a thin layer of white metal backed up with a strong steel shell. The tin-base alloys, because of their greater strengths, are preferred. In the fabrication of the bearings care must be taken to see that there is a good bond between the white metal and the base and that the metal is not overheated in pouring. A poor bond usually results in cracking and higher temperature of operation. The serious disadvantage to the use of the white metals is their low-temperature operating range.

When the operating temperatures are higher than the white metals can safely stand, the leaded bronzes may be used. Their operating limit, reached through a fusion of the load, is in the neighborhood of 600 F. Because of a high coefficient of expansion, these materials must either be used as a thin lining on a steel back or else fitted with appreciable clearance. Seizure, if it occurs, is quite positive, but usually not destructive.

The leaded bronzes are frequently used on small plain bearings and in guides where the conditions of lubrication are not good. In the presence of dirt, however, they tend to load and act as a lap:

Camshafts and other accessory bearings are taken care of by any one of a number of the standard copper-tin-lead mixtures regularly available. Such bearings give excellent results when the hardness is suitably adjusted to the mating steel. Good alignment, smooth finish, and adequate lubrication are essential requirements. In the event of seizure, the shaft may be badly scored.

Valves. The exhaust valves, being perhaps the hottest spot in the engine, naturally must be made of a material that will withstand the temperatures involved. In the larger engines, cast iron does very well, particularly if alloyed with chromium and nickel. In the small units, where the conditions are more severe, better materials, such as the chrome-nickel-silicon steels, may be necessary. Ni-Resist, stainless steel, and the straight chrome-nickel steels are also used. To reduce costs, a heat-resisting alloy head may be welded to a carbon-steel or alloy stem.

The heat-resisting materials are rather poor conductors of heat, and the heat dissipation has in some cases been improved by inserting a cone of salt or copper within the head and stem. Under severe conditions, such as are found in the smaller high-speed units, such types may serve a useful purpose.

The inlet valves, being continually cooled by the incoming air, do not require particular attention. Good results are obtained with cast iron on the larger units and with the straight alloy steels, such as a medium carbon-chrome-nickel, on the smaller units.

The clearance between the valve stem and valve guide must necessarily be small, and the conditions for lubrication are not good. As a result, the valve stems must be made as hard as practical. Attempts have been made to do this through the use of chromium plating, but the results have not been overly successful. The guides are, as a rule, made of a medium-hard cast iron or a bronze.

Valve seats are usually cut directly in the cylinder-head material, and, generally speaking, the results are quite satisfactory. Inserted seats of some harder or heat-resisting material may be used, but mechanical difficulties in keeping them tight make their use undesirable.

Fuel System. Because of the high pressures involved, and at times the corrosive nature of the oils handled, the spray nozzles and pump parts must be made of a hard, corrosion-resisting material. The stainless steels, suitably heat treated, seem to meet the requirements quite well.

Conclusions

The metallurgical problems of the Diesel engine are not serious and consist more in selecting the most suitable material for a given application than in trying to find the solution for a chronic condition. Most of the problems encountered in operation are fundamentally ones of design, but for economical reasons they often become metallurgical. There is no complaint on this score, but it is believed that a more careful study of the details of design, with a view to eliminating localized overstress and providing better lubrication, will eliminate most of the troubles now encountered. As a matter of fact, where such considerations are given, the performance of the Diesel engine is most reliable, and many engines are building up records which rival those of the older reciprocating types of steam engines.

Discussion

J. S. Vanick.[2] The author has presented a splendid summary of the actual and potential applications of various metals to Diesel construction, and such comment as can be offered will be

[2] Development and Research Department, International Nickel Co., Inc., New York, N. Y.

more in the nature of elaboration upon items of special interest which he has mentioned. The critical point of view with which we examine Diesel materials of construction is concentrated toward bringing out their best performance, without changing the basic character of the material we work with. If cast iron is widely applied, it is possible to accentuate certain desirable qualities of the material by means of alloys without changing the method of construction or design.

The discussion bases a comparison of fabricated welded-steel structures with cast iron possessing a strength of 24,000 lb per sq in. and modulus of 12,000,000, but the writer happens to know that the author's firm specifies for engine parts a 40,000 or 45,000 lb per sq in. tensile cast iron which is alloyed and can produce a 50,000 or 60,000 lb per sq in. cast iron. Such cast irons possess better than double the strength and modulus of 24,000 lb per sq in. tensile and 12,000,000 modulus and are commercially producible in progressive foundries. Tentative specifications for cast irons to possess 40,000, 50,000, and 60,000 lb per sq in. tensile are being prepared for presentation before the committee on cast iron of the American Society for Testing Materials. Such high strengths can be obtained by using 60 to 90 per cent of steel in the cupola charge along with 1 or 2 per cent of silicon, manganese, and nickel. Such an iron will analyze about 2.80 to 3.20 C, 0.80 to 1.75 Si, 0.80 to 1.10 Mn, and 1.25 to 2 Ni. Its application has been most useful for frames, crankcases, and pistons.

Strength is not so important for other parts of the engine, and liners are an example where less than 40,000 tensile is satisfactory, but a high, uniform hardness over 200 Brinell becomes essential to reduce wear. Wear tests in our laboratories and others have shown clearly the need to maintain a high uniform hardness in cast iron for maximum wear resistance. Such irons may be patterned after the high-test type, except that cupola grades can contain 30 to 60 per cent steel and analyze 2.90 to 3.40 C, 0.80 to 1.75 Si, 1.25 to 2.50 Ni, and 0.40 to 1 Cr. Limitations of present-day machine tools keep the upper level of hardness under 240 to 260 Brinell. Pistons and rings frequently require a composition similar to liners, but higher in silicon and lower in nickel and chromium to compensate for their thinner sections; that is, 2.90 to 3.40 C, 1.25 to 1.90 Si, 1.25 to 2.50 Ni, and 0.30 to 0.50 Cr. Heads and exhaust manifolds require resistance to heat, with hardness and strength unimportant; hence low-silicon compositions higher in chromium than liners are more useful—as represented, for example, in the following composition: 3.10 to 3.45 C, 1.10 to 1.75 Si, 1.25 to 1.75 Ni, 0.50 to 0.90 Cr.

These modifications of cast iron are intended to accentuate some useful property such as strength, hardness, resistance to wear, or resistance to heat inherent in the material without changing its primary, useful properties. From our position on the skirmishing line in the development of newer cast-iron compositions we can see opportunities for further increasing the resistance to wear, to heat, and to corrosion by raising the alloy level from a limit of about 3 per cent nickel plus chrome, as at present, to $4^1/_2$ per cent nickel plus $1^1/_2$ per cent chrome, and as the limit of maximum machinable hardness is pushed up, from a top of 240 Brinell to possibly 300 or 350, liner compositions will follow the progress in machining. As an alternative, heat-treated cast irons, machined prior to hardening by oil quenching, offer opportunities for future development.

The author mentions the tendency for designers to lay too much emphasis on strength and not enough upon toughness. This factor is worthy of reemphasis, especially with respect to steels used in large units. It is impossible to work to millimicrometer tolerances, and the perfect fit, like perfect lubrication, becomes an ideal rather than a practical fact. Here, Diesel designers might take a page from the experience of locomotive builders who realize that heavy rods and castings must possess toughness and resistance to fatigue to endure the weave and whip of a locomotive bouncing over the rails. The result is that they guard the toughness factor in their steels jealously, and specifications in such parts as locomotive frame castings require high ductility or toughness to absorb dimensional irregularities in assembling and later to resist the vibrational stress and fatigue set up during operation.

These comments are intended merely to emphasize that much benefit remains to be derived by taking advantage of qualities inherent in the materials now used in engine construction.

OGP-55-5

Inertia Supercharging of Engine Cylinders

By E. S. DENNISON,[1] PHILADELPHIA, PA.

A theory is developed for the supercharging effect produced in an engine cylinder when a long suction pipe is attached. As a preliminary to this theory, equations are given for suction and exhaust flow where no inertia effects are present. Results of the theory are compared with experiment, and some data are given on engine performance when supercharged in this manner.

A SMOOTH straight pipe of proper proportions, attached to the suction of a four-cycle engine cylinder, will effect an increase of its volumetric efficiency and hence of its capacity to develop power. This fact is known through various publications and needs no introduction. The supercharge is produced by accelerating the air column to a high velocity in the mid-part of the suction stroke; the kinetic energy so developed is then expended to force a surplus of air into the cylinder before valve closure. The process differs from supercharging with an auxiliary blower in that the compression power used is abstracted directly from the indicated power of the cylinder instead of being taken from the shaft; there are no extra mechanisms, no moving parts.

If the pipe is very long, oscillation of the column in its natural frequency plays a dominant part. Theoretically, maximum supercharge is attained when resonance occurs between pipe frequency and engine speed, i.e., when the period of free oscillation of the column is equal to the time required for the crankshaft to turn through 180 deg. With still greater lengths, the effect of oscillations may be favorable or adverse.

Based upon the condition of resonance as thus stated, Capetti[2] gives a formula for the most favorable length of intake pipe:

$$L = 7.5\, w_s/N$$

in which

L = length of pipe, inches
w_s = velocity of sound, about 1127 ft per sec at 70 F
= 1127 × 12, or 13,524 in. per sec
N = rpm of engine.

This formula leads to inconvenient lengths of pipe. At 500 rpm it gives 200 in., at 1000 rpm 100 in., etc. These lengths are such that they ordinarily could not be tolerated in practice.

Referring to actual tests, including some made at Langley Field by the N.A.C.A., Capetti finds that actual optimum lengths are less than given by the formula. This is still the case, as he finds, even after correcting for the effect that motion of air in the column has upon its period of oscillation. The resonance assumption alone is not a reliable guide in estimating a desirable pipe length.

Nevertheless, reported tests have usually shown the necessary length of pipe to be so long as to be impracticable for many purposes. Klüsener[3] obtained about 7 per cent maximum increase in volumetric efficiency using an 88-in. pipe attached to a small engine (4.73 in. bore by 7.09 in. stroke) operating at 750 rpm. He concludes that ordinarily a pipe several meters long would be required to obtain the best result. Such an addition to the engine is not easily justified if the gain is to be limited to 7 per cent or thereabout. Klüsener does not mention the diameter of pipe used in his tests.

Aside from possible resonance, the pipe may be considered merely as a device for storing kinetic energy. Then the diameter of pipe used is readily seen to be of first importance.

The mass of air in the column may be expressed as $M = C'LD^2$, its velocity as $w = C''/D^2$, and its energy as $E = CL/D^2$, in which D = pipe diameter, C, C', C'' = constants. Therefore, other things being equal, we should expect a higher supercharge if a small pipe is used. Other things, of course, are not equal; both resonance and pipe friction are affected in more or less significant ways.

Capetti applies a factor to the optimum length as found by the simple resonance formula, to correct for air motion in the pipe. It is derived by averaging the velocity of wave propagation outward contrary to the direction of motion, and inward with the motion. The factor is:

$$z = \left(1 - \frac{w_m^2}{w_s^2}\right)$$

in which w_m = mean air velocity in the pipe.

If w_m has even a high value, say $^1/_3\, w_s$, the factor $z = 0.89$; that is, it is not far from unity. But so far as it goes, it is in the right direction; for it reduces the length of pipe at which optimum conditions are to be expected.

The pipe-friction formula (Equation [21]) can be reduced to the form:

$$\Delta_p = \text{const.} \times \frac{G^2 L}{D^5}, \text{ approx.}$$

for a given density of air, in which G = rate of flow, lb per sec.

Because of the inverse fifth power of D in this formula, we must expect friction to set a limit to the useful reduction of pipe diameter. Also, since friction is directly proportional to length L, it helps to explain why the optimum length as found by test is less than the calculated, especially if the diameter is relatively small.

Contributed by the Oil and Gas Power Division and presented at the Fifth National Oil and Gas Power Meeting, Pennsylvania State College, State College, Pa., June 8 to 11, 1932.

[3] Dr.-Ing. Otto Klüsener, "Saugrohr und Liefergrad," V.D.I. "Dieselmaschinen V," 1932.

NOTE: Statements and opinions advanced in papers are to be understood as individual expressions of their authors, and not those of the Society.

Preliminary experiments were made using a cylinder of 8¼ in. bore by 12 in. stroke. The engine could be operated at speeds up to 900 rpm. There was no means of knowing volumetric efficiency with accuracy. Instead, the compression pressure was used as a measure of the air charge. Some results of these tests are given in Table 1.

TABLE 1

Compression pressures, 8¼-in. by 12-in. cylinder
(Lb per sq in. abs, corrected to standard barometer)

Tests at 800 Rpm			
Pipe diameter, in.	3.75	2.50	2.00
Ratio of cylinder section/pipe section	4.85	10.9	17.0
Pipe length, in.:			
0	395	395	395
12	...	...	430
36	414	445	432
48	...	466	428
54	...	468	...
60	...	474	418
72	...	474	411
Tests at Variable Speed			
Pipe diameter, in.		2.50	None
Pipe length, in.		48	0
Engine rpm:			
300		381	376
400		387	379
500		406	385
600		421	390
700		444	394
800		466	395
900		464	401

Comparing results at 800 rpm with 36-in. pipe, the advantage of the 2.50 in. diameter over the 3.75 in. is striking. Tests with large diameters were carried no further. Similarly the 2.00 in. diameter fails to give an advantageous result in any length; friction is excessive. The optimum pressure increase with 2.50-in. pipe is 20.0 per cent; the corresponding increase in weight of charge was roughly estimated at 14 per cent.

It is interesting to compare the best length of 2.50-in. pipe at 800 rpm with estimates based upon resonance:

Optimum length, test, in.	66
Resonant length, no velocity correction, in.	127
Resonant length, with velocity correction, in.	119

Optimum length by test is 52 per cent of simple resonant length. Actually little is gained by going beyond 48 in., due to flattening of the curve.

The outcome of these tests was so promising as to justify carrying the experiment further. Accordingly a cylinder head for an engine 9 in. bore by 12 in. stroke was so designed that inertia supercharging might be readily applied to it. Based upon the foregoing tests, together with an analysis, a diameter of 3 in. was selected, and the head arranged for connection of this size tubing. It was estimated that this diameter, in proper length, would be suitable up to a speed of 1000 rpm, or a piston speed of 2000 ft per min.

Tests of volumetric efficiency, also indicator cards and other data, have since been obtained from a single-cylinder engine fitted with the new head and attached suction pipe. At the same time an effort has been made to develop the theory of such a system so far that optimum pipe diameter and length, and a dependable estimate of volumetric efficiency, might be precalculated for any new design. The outline of this theory, with a comparison between calculated and test results, forms the subject of the present paper.

It should be observed that the particular type of application to which this discussion applies is the relatively high-speed engine, the piston velocity being 1500 ft per min or more. In such cases it is possible to obtain quite effective supercharging with a moderate length of suction pipe, provided the relative diameter of the pipe is small. Such results are obtained using a ratio of cylinder section/pipe section as high as 10 and in some cases perhaps higher. Incidentally, it usually follows that the pipe section is less than the area of the valve ports through which the air enters the cylinder.

Theory of Suction Process Without and With Inertia

It has been shown that the most favorable length of suction pipe is much less than was to be anticipated from the theory of resonance. Allowing for flattening of the volumetric efficiency curve near its maximum, a length only about half the resonant length may be preferable. Such being the case, the possibility of pipe resonance has little more than academic interest.

The theory of resonance is based upon a consideration of the harmonics of the piston motion and the resultant waves produced in the column.[4] In such a calculation, flow resistance at the valve, as well as pipe resistance, is usually ignored. This is probably justifiable with low-speed engines in which the valves are relatively large. It is not the case with engines operated at high piston speeds such as are discussed here. Instantaneous pressure drop at the valve may exceed 5 lb per sq in. Air being an elastic fluid, the movement of the piston is not directly effective to propagate waves in the column. Wide discrepancies are likely to arise from a computation based upon harmonics, unless an allowance for the valve resistance is properly made.

No attempt has here been made to do this. Instead the thermodynamic conditions affecting flow into the cylinder (or in some cases, out of it) have been made the starting point of the discussion. These are investigated first for cases in which no air column inertia is present. With this foundation established, the column is made to respond directly to forces estimated to act upon it; the case is treated as one of purely forced vibration. In general, a check of results indicates that the assumption is reasonably accurate for a pipe well under the resonant length.

In developing the theory, a little sacrifice of accuracy has been thought justifiable whenever it resulted in much easier use of the method. A calculation of this kind is of value only if it can be used as design procedure; this is impossible if complications are excessive. In any event it is well to avoid an appearance of accuracy which may be fictitious. It is thought that the method has been brought within limits of ordinary procedure.

System of Units

An unconventional system of thermodynamic constants is introduced for the sake of simplicity in calculation. It is obtained by applying consistently the following units:

Length	Inch
Force	Pound
Time	Second

The usual state equation for a gas has the form

$$p'v' = R'T$$

in which

p' = lb per sq ft
v' = cu ft per lb
R' = gas constant, ft-lb per lb per deg F. For air the numerical value is 53.35; the pound-mol constant for any gas is 1544
T = deg F abs.

In the present system pressure is expressed in lb per sq in. and specific volume in cu in. per lb; hence, the new constant R has the unit of in-lb per lb per deg F. Numerically it is $12 \times 53.35 = 640.2$ for air; the pound-mol constant for any gas is $12 \times 1544 = 18{,}528$.

Our state equation for air is then

$$pv = 640\,T \quad \ldots\ldots [1]$$

[4] P. Voissel, *Z.V.D.I.*, vol. 56, p. 721 (1912).

in which

p = pressure, lb per sq in.
v = specific volume, cu in. per lb.

The so-called mechanical equivalent of heat as determined at the Bureau of Standards is 778.54 ft-lb = 1 mean Btu. Converting this figure to the smaller unit, we have 9342.5 in-lb = 1 Btu; that is $J = 9342.5$.

The use of the constant J or its reciprocal A can be avoided by expressing all heat quantities in the mechanical unit, in-lb. In the present case this is accomplished by converting the specific heats of air:

At constant pressure c_p = 0.241 Btu per lb per deg F
= 2245 in-lb per lb per deg F
At constant volume, c_v = 0.172 Btu per lb per deg F
= 1605 in-lb per lb per deg F

$$\text{The ratio } k = \frac{c_p}{c_v} = \frac{2245}{1605} = 1.40$$

$$\text{Also } c_p - c_v = R$$

$$= 2245 - 1605 = 640.$$

This confirms the value for R directly calculated above. The gravity constant $g = 386$ in. per sec^2 completes the list of constants.

The adoption of these constants avoids once for all the recurring factors 12, 144, and 1728; likewise no further attention need be given to converting heat and work quantities where they occur in the same equation.

We may now proceed to a consideration of the several cases which arise in calculating air or gas flow either in intake or exhaust. First will be given the forms which the equations take when no inertia effects are present.

Case I—Inflow, Without Inertia Effects (refer to the sketch, Fig. 1).

The piston P is moving away from the cylinder head and drawing in air through the valve, of which the effective area is A_n. At a given instant the volume to the left of the piston is V, and the contained gas is at temperature T and pressure p; the latter is less than atmospheric pressure. Atmospheric conditions T_a and p_a exist outside the valve. We will consider the effects of an infinitesimal change; for convenience, the various quantities may be referred to an element of time dt.

It is evident that the process is irreversible; it involves the degradation of mechanical energy to thermal energy. Moreover, it is discontinuous; it cannot here be assumed that air passing through the valve with considerable pressure drop will issue into the cylinder at atmospheric temperature. That assumption is good only where the rate of flow is constant—as it is, for example, normally through a throttling valve. It is necessary to build up suitable equations from first principles, but it will be seen that this does not lead to any great complexity.

Setting up the elementary equation for energy changes in the fluid contained in the cylinder:

$$dU = dQ - dW \quad [2]$$

in which

U = total intrinsic energy of gas contained within the cylinder, in-lb
Q = energy added thermally, in-lb
W = external mechanical work done, in-lb.

To make use of Equation [2], we shall have to express the energy quantities in ascertainable common terms such as pressure and volume. For convenience, these quantities will be discussed in the reverse order. dW is work done against the piston. Then:

$$dW = pdV \quad [3]$$

in which dV is the increment of cylinder volume in time dt.

dQ is the thermal energy introduced by the incoming air. (Heat transfer from the cylinder walls is ignored.) Energy thus introduced is made up of two parts:

(*a*) Intrinsic energy of entering air. Assuming that c_v = constant within the range of temperature to be considered, this is $c_v \times T_a \times dG$, in which dG is an elementary weight of air, lb
(*b*) Flow work of entering air = $pvdG = RT_adG$

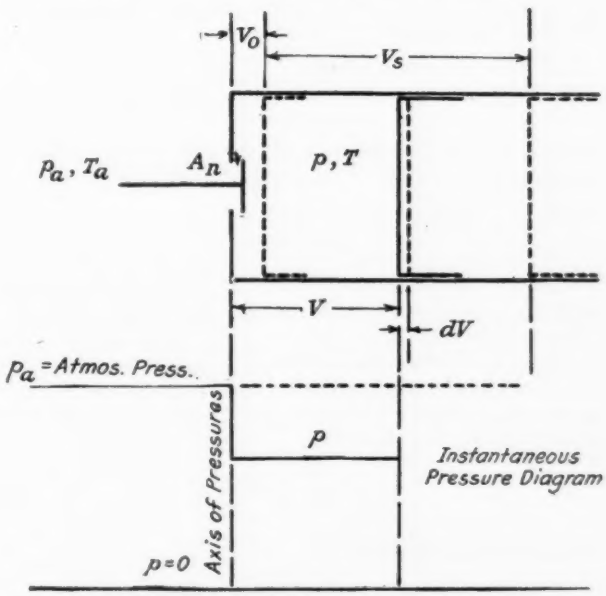

FIG. 1 DIAGRAMMATIC SKETCH, INERTIA EFFECTS ABSENT

Combining (*a*) and (*b*) we have:

$$dQ = (c_v + R)T_adG$$

$$= c_pT_adG = kc_vT_adG \quad [4]$$

dU is the change of intrinsic energy of the gas in the cylinder.

Following the assumption just made,

$$U = Gc_vT \quad [5]$$

in which G is weight of air in the cylinder, lb.

Now $pV = GRT$ and $GT = pV/R$. Substituting this expression for GT in Equation [5], we obtain:

$$U = \frac{c_v}{R}pV$$

But $R = c_p - c_v$, and $\frac{c_v}{c_p - c_v} = \frac{1}{k-1}$. Then:

$$U = \frac{1}{k-1}pV \quad [6]$$

That is, the intrinsic energy in volume V of a given gas is fully determined when p and V are known, the expression being independent of temperature T.

We may now combine Equations [3], [4], and [6] in Equation [2]:

$$\frac{1}{k-1}\,d(pV) = kc_vT_adG - pdV$$

$$pdV + Vdp = (k-1)\,(kc_vT_adG - pdV)$$

$$Vdp = (k-1)\,kc_vT_adG - kpdV$$

But $(k-1)c_v = R$, therefore, $Vdp = k(RT_adG - pdV)$, and:

$$dp = \frac{k}{V}(RT_adG - pdV) \quad \ldots\ldots\ldots\ldots\ldots [7]$$

To go further, it is necessary to express dG in terms of the variables which fix the rate of flow—namely, pressure p, valve section A_n, also T_a and p_a. A simple form of flow equation is desirable, for example:

$$G = c\mu A\,\frac{\sqrt{(p_a-p)p}}{\sqrt{T_a}}\,t \text{ lb}^5 \quad \ldots\ldots\ldots\ldots [8]$$

in which A = area of orifice, sq in., and μ is the flow coefficient. For the present purpose $\mu A = A_n$, by definition.

t = time, sec
c = a constant.

With the present system of units, $c = 1.094$ approximately, when $(p_a - p)$ is small relative to p_a; the formula is usually applied only to such cases.

It can easily be learned, however, how much error arises if the same formula is applied to a wider range of pressures. To take an extreme, assume $p = 0.53\,p_a$, the critical ratio. The exact theoretical formula then gives:

$$G = 0.53\,A_n\,\frac{p_a}{\sqrt{T_a}}\,t \quad \ldots\ldots\ldots\ldots [8a]$$

whereas the trial formula gives:

$$G = 1.092\,A_n\,\frac{\sqrt{0.53 \times 0.47}\,p_a}{\sqrt{T_a}}\,t$$

$$= 0.545\,A_n\,\frac{p_a}{\sqrt{T_a}}\,t$$

In other terms, the trial formula becomes accurate at the critical ratio if

$$c = 0.53/0.545 \times 1.092 = 1.062$$

Between the two extreme ratios of pressure, the variation of the adjusted value of c is nearly linear. For the present purpose we then take $c = 1.08$, and

$$G = 1.08\,A_n\,\frac{\sqrt{(p_a-p)\,p}}{\sqrt{T_a}}\,t \text{ lb} \quad \ldots\ldots\ldots [9]$$

This form may be used throughout with an error averaging about 1 per cent. Its accuracy is adequate, in view of possible errors for example in A_n.

Substituting in Equation [7], in the differential form:

$$dp = \frac{k}{V}\left[1.08\,RA_n\,\sqrt{T_a}\,\sqrt{(p_a-p)p}\,dt - pdV\right] \ldots [10]$$

A little inspection will show that this expression for dp does not lend itself to a direct solution. If t is taken as the independent variable, dV may be expressed in those terms, but A_n only with difficulty. Thereafter, the algebra is certain to become involved. A step-by-step solution must be accepted instead. This may be obtained in several ways. The procedure developed here is convenient and reasonably accurate; also it has the advantage that trial-and-error methods are avoided.

Let θ = engine crank angle. Divide Equation [10] through by $d\theta$; also factor p out of the bracket.

$$\frac{dp}{d\theta} = \frac{kp}{V}\left[1.08\,RA_n\,\sqrt{T_a}\,\sqrt{\frac{p_a-p}{p}}\,\frac{dt}{d\theta} - \frac{dV}{d\theta}\right] \ldots [11]$$

If n = rps of the engine,

$$\theta = 360\,nt$$

and

$$\frac{dt}{d\theta} = \frac{t}{\theta} = \frac{1}{360\,n}$$

Then:

$$\frac{dp}{d\theta} = \frac{kp}{V}\left[\frac{1.08\,RA_n\,\sqrt{T_a}}{360\,n}\,\sqrt{\frac{p_a-p}{p}} - \frac{dV}{d\theta}\right] \ldots [12]$$

Now $R = 640$, and we may assume $T_a = 530$ F abs (70 F scale).

Substituting,

$$\frac{dp}{d\theta}^6 = \frac{kp}{V}\left[\left(44.2\,\frac{A_n}{n}\,\sqrt{\frac{p_a-p}{p}}\right) - \frac{dV}{d\theta}\right] \ldots [13]$$

The quantities V and $dV/d\theta$ are fixed for any value of θ by engine dimensions: piston area, crank radius r, and ratio r/l of crank radius to connecting-rod length; the familiar equations need not be set down here. The quantity A_n is based upon instantaneous valve section A and flow coefficient μ. From known data this can be estimated for a given case. These three quantities may be tabulated for various crank positions θ.

Given then the cylinder pressure p existing at any point, Equation [13] enables one to calculate quite readily the *slope* of the pressure line with respect to crank angle. To avoid the difficulty of integration, it is now assumed that $dp/d\theta$ for any point a may be taken as a constant for the purpose of extrapolation to the next point b. That is,

$$(\Delta p)_{ab} = \left(\frac{dp}{d\theta}\right)_a \Delta\theta \quad \ldots\ldots\ldots\ldots\ldots [14]$$

and

$$p_b = p_a + (\Delta p)_{ab} \quad \ldots\ldots\ldots\ldots\ldots [15]$$

A check was made upon this procedure using a trial-and-error method developed from Equation [10] with results substantially identical. The results of Equations [13–15] converge in the sense that an error arising in one step tends to be corrected in

[5] S. A. Moss, Trans. APM-3, 1928.

[6] NOTE: Instead of dividing Equation [10] by $d\theta$, it may be divided by dV, resulting in a form simpler than Equation [13]. In place of Equation [11], we then have:

$$\frac{dp}{dV} = \frac{kp}{V}\left[1.08\,RA_n\,\sqrt{T_a}\,\sqrt{\frac{p_a-p}{p}}\,\frac{dt}{dV} - 1\right] \ldots [11a]$$

Reducing this as above, we obtain:

$$\frac{dp}{dV} = \frac{kp}{V}\left[\left(44.2\,\frac{A_n}{n}\,\frac{d\theta}{dV}\,\sqrt{\frac{p_a-p}{p}}\right) - 1\right] \ldots [13a]$$

The product $44.2\,A_n(d\theta/dV)$ is predetermined by engine design and the routine calculation becomes very simple. However, this procedure was not used, for angle (i.e., time) increments are more advantageous than volume increments, especially when dealing with acceleration and velocity, as will later be done.

the next. At most, where the change in $dp/d\theta$ is rapid, the calculated line will be a "zig-zag" if $\Delta\theta$ is too large. Practically, intervals of 5 deg are required near top center; at 40 deg and over from top center, intervals of 10 deg or more may be used.

A sample calculation based upon the foregoing equations is given in Fig. 11. The usual procedure is to start at top center, assuming atmospheric pressure in the cylinder, and to continue to the point of closing of the inlet valve.

Case II—Outflow, Without Inertia Effects ($p < 2p_a$).

This case arises in considering the exhaust process, also sometimes near the close of the suction process.

Equation [7] applies here as in Case I. But to find dG we must use:

$$G = -1.08\, A_n \frac{\sqrt{(p - p_a)p_a}}{\sqrt{T}}\, t \text{ lb} \quad \ldots\ldots\ldots [16]$$

Proceeding as before, we obtain:

$$\frac{dp}{d\theta} = \frac{k}{V}\left[-\frac{1.08\, RA_n\sqrt{T}}{360\, n}\sqrt{(p - p_a)p_a} - p\frac{dV}{d\theta}\right]$$

$$= -\frac{k}{V}\left[\left(\frac{7.36\, A_n}{n}\sqrt{T\,(p - p_a)}\right) + p\frac{dV}{d\theta}\right] \ldots [17]$$

For exhaust gas at 1200 F, $k = 1.36$ approximately.

To be exact, we should have to take account of the relation

$$\frac{T}{T_o} = \left(\frac{p}{p_o}\right)^{\frac{k-1}{k}} \quad \ldots\ldots\ldots\ldots [18]$$

in which p_o, T_o refer to any initial state, such as the point of release. This can be conveniently done for the purposes of Equation [17] by plotting the relationship in the form:

$$\sqrt{T} = \text{constant} \times (p)^{0.1325} \quad \ldots\ldots\ldots [19]$$

in which the exponent $0.1325 = \dfrac{k-1}{2k}$

Case IIa—Outflow ($p \geqq 2p_a$).

This case arises immediately after the point of release, the cylinder pressure being then high.

The flow formula for this case is that of Equation [8a]. The equation reduces to the form:

$$\frac{dp}{d\theta} = -\frac{kp}{V}\left[\left(\frac{0.943}{n}\, A_n\sqrt{T}\right) + \frac{dV}{d\theta}\right] \quad \ldots\ldots [20]$$

To secure reasonable accuracy in this case, the temperature relation, Equation [19], must be used.

Case III—Inflow Including Effect of Inertia in Attached Pipe.

Mention has already been made of basic assumptions used in this case, particularly the neglect of possible resonance. However, the working assumptions require a detailed statement and some discussion. Not all variables can be taken in account. The problem is to make such a choice that the principal factors shall be allowed for and that the resulting equations shall not be unwieldy.

Assumptions:

1 Mass flow continuity. At any instant the mass rate of flow past each point in the path is assumed constant
2 Density changes of air *in the column* are assumed negligible. For purposes of the column calculation, air is treated as an incompressible fluid having the density of atmospheric air
3 Flow resistance in the pipe is assumed negligible. This is to say, in effect, that if preliminary calculation shows that friction will be a considerable item with a particular pipe size, a larger size should be selected. However, see Appendix A
4 Velocity pressure in the column is assumed to be completely converted to static pressure before the valve.

Actually, assumption 2 follows from 1. For, manifestly, we may not allow density changes in the column without also providing that at some time air entering is not equal to air leaving.

The function of the column is to serve as a reservoir of kinetic energy. The effect of assumption 2 is to underestimate somewhat the energy which will be stored under given conditions. As an example, assume that air is flowing through a tube of 3 in. diameter at a rate of 1.5 lb per sec. Calculated from the assumption,

$$\text{Velocity } w = 4900 \text{ in. per sec}$$

and kinetic energy

$$E = \frac{1}{2} \times \frac{7.07}{23{,}100} \times \frac{(4900)^2}{366}$$

$$= 9.52 \text{ in-lb-per inch of length.}$$

The figure 7.07 (sq in.) is the area of a 3-in. pipe; 23,100 (cu in. per lb) is the specific volume of atmospheric air.

Taking account of the compressibility of air, we find that the actual conditions in the pipe will be:

$$p = 13.18$$
$$T = 513$$
$$v = 24{,}900$$
$$w = 5280 \text{ in per sec}$$
$$E = \frac{1}{2} \times \frac{7.07}{24{,}900} \times \frac{(5280)^2}{386}$$
$$= 10.24 \text{ in-lb per inch of length.}$$

Thus the energy is underestimated by about 7 per cent in this case.

Quite high air velocities can be used without resulting in excessive pipe friction. To take again the example used in discussing kinetic energy (1.50 lb per sec through a 3-in. pipe) we will refer to the first case, in which atmospheric density of air is assumed to hold. The pressure drop in a pipe, for a fluid in turbulent motion, is given by:

$$\Delta p = \frac{2\, fL\rho w^2}{gD} \quad \ldots\ldots\ldots\ldots\ldots [21]$$

in which

L = pipe length
ρ = density of fluid
w = velocity of flow
D = diameter of pipe
g = acceleration of gravity
f = coefficient of friction

and in which any consistent set of units may be used.

Using the data of McAdams,[7] we find in this case $f = 0.0043$ for ordinary steel pipe. Then $\Delta p = 0.0078$ lb per sq in. per inch of length. For a length of 50 in. this becomes only 0.39 lb per sq in.; this is quite small as compared with the pressure loss simultaneously occurring at the valve. A rule might be to exclude from consideration by preliminary estimate any case

[7] Walker, Lewis, and McAdams, "Principles of Chemical Engineering," pp. 73–88.

in which maximum pipe resistance would exceed 0.50 or 0.75 lb per sq in., and in the calculation to neglect resistance. This is done in the derivations here given. Appendix A shows how a resistance correction may be applied to the calculation.

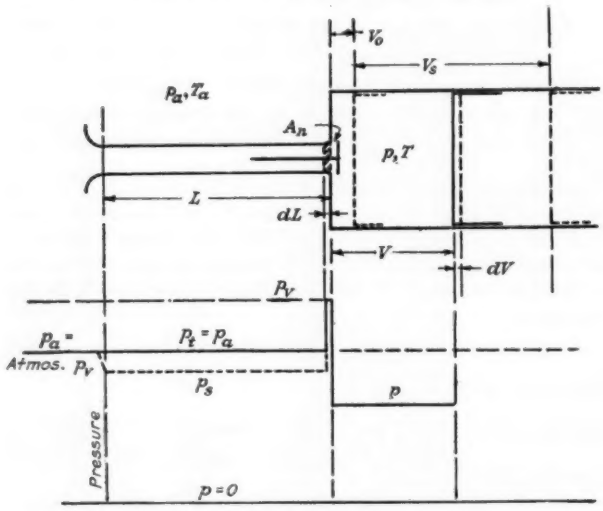

FIG. 2 DIAGRAMMATIC SKETCH, SUCTION PIPE ATTACHED

Assumption 4 does not involve any approximation when the junction between the pipe section and the ports is well shaped. But both assumptions 1 and 4 fail to hold if a considerable dead space exists between the column and the valve. In that case large losses may intervene, and the methods of calculation here given would require modification.

Accepting the assumptions as laid down, the derivation proceeds as follows:

The case is represented schematically by Fig. 2. Atmospheric pressure p_a exists at one end of the air column; pressure p_v (and temperature T_v) at the inner end in the last element of pipe length before the valve. The difference in the two pressures at any instant is a measure of the force acting to accelerate the column. Applying the second law of motion,

$$a = \frac{dw}{dt} = \frac{F}{M} \text{ in. per sec}^2$$

in which

F = force acting on air column, lb
M = mass of column, lb/g.

Evaluating,

$$F = A_p (p_a - p_v)$$

and

$$M = \frac{LA_p\rho_a}{g}$$

in which A_p = cross-section of pipe. Note that velocity and acceleration are taken positive in the inflow direction.
Then

$$\frac{dw}{dt} = (p_a - p_v)\frac{g}{L\rho_a} \quad \text{[22]}$$

and

$$\frac{dw}{d\theta} = (p_a - p_v)\frac{g}{360\,L\rho_a n} \quad \text{[23]}$$

An expression for dG is obtainable from consideration of the pipe:

$$dG = wA_p\rho_a dt$$

A second expression is based upon valve conditions:

$$dG = 1.08\,A_n\frac{\sqrt{(p_v - p)p}}{\sqrt{T_v}}\,dt$$

Equating the two expressions, we have:

$$wA_p\rho_a = 1.08\,A_n\frac{\sqrt{(p_v - p)p}}{\sqrt{T_v}}$$

$$\frac{(p_v - p)p}{T_v} = \left(\frac{A_p\rho_a}{1.08} \times \frac{w}{A_n}\right)^2$$

$$p_v - p = \frac{T_v}{p}\left(\frac{A_p\rho_a}{1.08} \times \frac{w}{A_n}\right)^2 \quad \text{[24]}$$

Referring to Equation [12], we obtain a similar expression for the present case:

$$\frac{dp}{d\theta} = \frac{kp}{V}\left[\frac{1.08\,RA_n\sqrt{T_v}}{360\,n}\sqrt{\frac{p_v - p}{p}} - \frac{dV}{d\theta}\right] \quad \text{[25]}$$

If a general analytical solution is sought, this must be built up from Equations [23], [24], and [25]. The difficulty here exceeds that of the previous case. Instead, the procedure for a step calculation is given.

A simplification of Equations [24] and [25] will first be made. In those expressions T_v is a function of p_v given by the relation $T_v/T_a = \left(\frac{p_v}{p_a}\right)^{\frac{k-1}{k}}$. If Equation [24] is used to solve for $(p_v - p)$, the variation of T_v must be allowed for by trial and error. But the variation of T_v is actually small, and its average approximates closely to T_a. Substitution of T_a for T_v simplifies the work. A trial has shown that the error so introduced is very slight.

Now introducing $T_a = 530$ and substituting other numerical values, the required equations can be summarized as follows:

$$\frac{dw}{d\theta} = 24{,}800\,\frac{(p_a - p_v)}{Ln} \quad \text{[26]}$$

$$\frac{dp}{d\theta} = \frac{kp}{V}\left[\left(44.2\,\frac{A_n}{n}\sqrt{\frac{p_v - p}{p}}\right) - \frac{dV}{d\theta}\right] \quad \text{[27]}$$

$$p_v = \frac{8.53 \times 10^{-7}}{p}\left(A_p\frac{w}{A_n}\right)^2 + p \quad \text{[28]}$$

The procedure in a step calculation is now given. Assume that for point m the quantities p, p_v, and w are known; other quantities determined by design are also known. We will proceed to point n.

(1) Using Equation [26], calculate $\left(\frac{dw}{d\theta}\right)_m$

(2) By extrapolation, obtain w_n:

$$\Delta w = \Delta\theta\left(\frac{dw}{d\theta}\right)_m$$

$$w_n = w_m + \Delta w$$

(This extrapolation of w is similar in principle to that of p.)

(3) Using Equation [27], obtain $dp/d\theta$. By extrapolation calculate p_n.

(4) Given w_n and p_n calculate p_{vn} from Equation [28].

This completes the step computation, which is then repeated. Fig. 12 gives a sample calculation. Steps of 5 deg must be taken until 40–50 deg past top center. Thereafter 10-deg or 15-deg intervals suffice.

Case IV—Outflow, With Attached Pipe:

This case arises where inertia in an exhaust column is used to improve scavenging of the clearance space. Some outflow occurs also just before closure of the inlet valve.

The derivations are similar to the foregoing and need not be repeated in detail. The equations take the following forms:

$$\frac{dw}{d\theta} = \frac{1.072\ (p_a - p_v)}{L\rho_p n} \quad \text{..... [29]}$$

Here ρ_p is density of gas in the pipe and may be estimated from average exhaust gas temperature.

$$\frac{dp}{d\theta} = -\frac{k}{V}\left[\left(\frac{7.36\ A_n}{n}\sqrt{T\ (p - p_v)}\right) + p\ \frac{dV}{d\theta}\right] \quad \text{.... [30]}$$

$$p_v = p - 0.0584\ T\left(\frac{wA_p\rho_p}{A_n}\right)^2, \text{ approx} \quad \text{..... [31]}$$

The procedure in calculation is similar to that in case III. Velocity w and pressure p are extrapolated, and p_v computed to complete the step.

Volumetric Efficiency

A step-by-step computation of weight G flowing into the cylinder can be made simultaneously with any of the foregoing, and volumetric efficiency μ_v estimated. This is unnecessary. The energy Equation [2], together with the expression for intrinsic energy, Equation [6], can be used instead, much more easily.

Apply Equation [2] to the entire period from start of suction to closure of the inlet valve. Transposing:

$$Q = \Delta U + W \quad \text{..... [32]}$$

in which

ΔU = increment of intrinsic energy within the cylinder

W = total work done by air pressure against piston

Q = thermal energy added. In this case, since heat transfer from the walls is ignored, this must all be accounted for by incoming air.

For estimation of W, refer to Fig. 3. The net work area to the point of closure is:

$$W = A_1 - A_2$$

$$A_1 = p_a V_s - A_1'$$

in which A_1' is the area $msnm$ and V_s is stroke volume.

$$A_2 = p_a \Delta V + A_2'$$

in which A_2' is the area $rqnr$ and ΔV is the partial return stroke volume.

$$A_1 - A_2 = p_a(V_s - \Delta V) - (A_1' + A_2')$$

$$= p_a\ (V_f - V_o) - p_m V_s \quad \text{..... [33]}$$

in which

V_o = clearance volume

V_f = cylinder volume at valve closure

p_m = mean indicated pressure from area $msnqrm$

Applying Equation [6],

$$U = U_f - U_o$$

$$= \frac{1}{k-1}\ (p_f V_f - p_o V_o)$$

Taking $k = 1.40$ and $p_o = p_a$

$$U = 2.50\ (p_f V_f - p_a V_o) \quad \text{..... [34]}$$

in which p_f is final pressure, lb per sq in. abs.

Combining,

$$Q = 2.50\ (p_f V_f - p_a V_o) + p_a(V_f - V_o) - p_m V_s$$

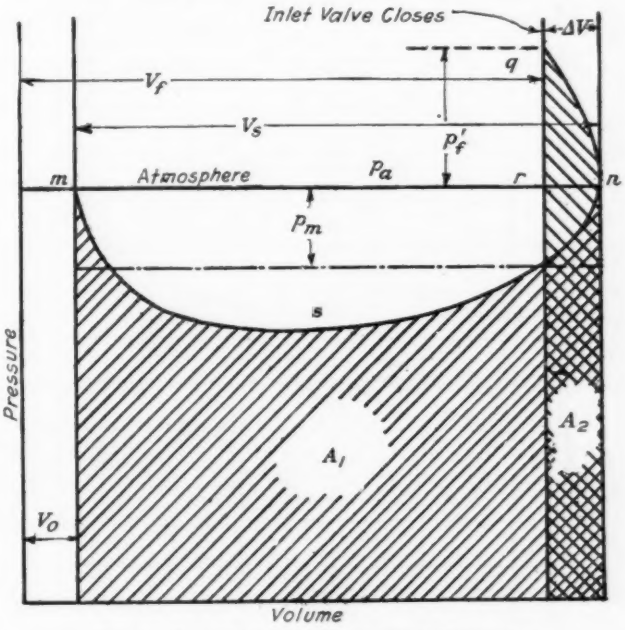

Fig. 3 Calculation of Volumetric Efficiency

Now let $p_f' = p_f - p_a$, so that p_f' = gage pressure at closure. Then:

$$Q = 3.50\ p_a(V_f - V_o) + 2.50\ p_f' V_f - p_m V_s \quad \text{.... [35]}$$

This equation expresses in in-lb the net heat which has entered the cylinder. The heat per lb of air is

$$q = c_p T_a$$

Therefore, the weight entering is

$$G = \frac{Q}{c_p T_a}$$

Volumetric efficiency is then

$$\mu_v = \frac{G}{G_s} = \frac{G}{V_s \rho_a} \quad \text{..... [36]}$$

In which G_s is the weight of atmospheric air required to fill stroke volume V_s.

This method may be applied to any case. A slight error arises from the fact that any small amount of air flowing outward carries with it a little more energy than atmospheric air flowing in; this can be overlooked. The method applies where a pipe is attached, since our assumptions provide that pipe velocity at valve closure shall be zero. Hence, no kinetic energy is unaccounted for.

The two pressures, p_f' and p_m, are seen to be the direct results of the computation. For a given trial pipe diameter, two or three values, together with those for $L = 0$, will suffice for plotting curves of each. From these the volumetric efficiency curve follows readily.

Results of Tests and Comparison With Theory

Both volumetric-efficiency tests and low-pressure indicator cards have been obtained with the 9-in. by 12-in. single-cylinder

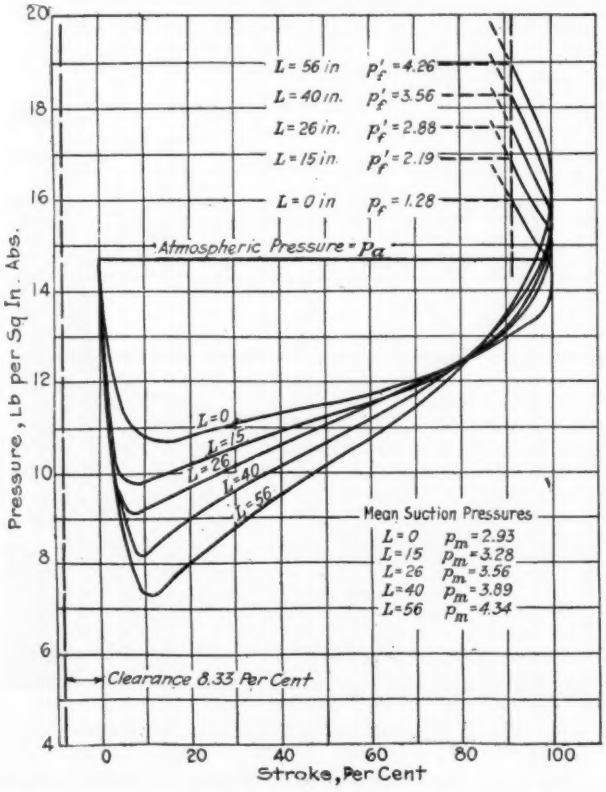

Fig. 4 Calculated Pressure-Volume Diagram of Suction Stroke

(Cylinder, 9 in. by 12 in.; 1000 rpm; pipe diameter, 3 in.; two-suction valves 2⅜ in. diam, open 10 deg B.T.C., close 42 deg A.B.C.)

test engine already mentioned. These data afford an opportunity for comparison with the results of theory, at least for one fairly typical case.

The engine is so designed as to permit adjustment of valve timing and of compression ratio. However, the test conditions selected for comparison were all made with one setting of valves, as follows:

Exhaust valve opens	45 deg B.B.C.
Exhaust valve closes	20 deg A.T.C.
Inlet valve opens	10 deg B.T.C.
Inlet valve closes	42 deg A.B.C.

This timing is not represented as necessarily the best; for example, certain results indicate that in this design the inlet-valve opening should be earlier. However, experiments showed that later closing of the intake valve would in no case have any marked advantage. The engine is fitted with two intake and two exhaust valves; port diameter is 2.625 in. and valve lift 0.625 in.

For the volumetric efficiency measurements, the engine was fitted with an equalizing tank attached to the suction. The tank volume was about 220 times the piston displacement, and it was suitably baffled to quiet the air movement within. Air was drawn in through one or another of a series of rounded nozzles, special attention being given to obtaining a smooth surface finish. Thus the tank was maintained a little under atmospheric pressure, the test calculations requiring correction for this fact. Owing to the large volume of the tank, pressure fluctuations as recorded by manometers were very slight, being limited to $^1/_{32}$ in. of alcohol, approximately. An estimate of errors indicated that individual readings should be correct to about 1 per cent. The scattering of points is greater than this. However, an independent check was obtained by overlapping the range of speeds tested with two different sizes of nozzle, so that the tank pressure and other conditions were quite changed. Owing to the good check so found, it can be said that average results are in error not more than 1 per cent.

Indicator cards were taken with a point-by-point balanced-pressure diaphragm-type indicator as made by the American Instrument Company; certain minor alterations have been made. Care was taken to employ a short passage from combustion space to diaphragm. Using a thin diaphragm (0.003 in.) and correcting when necessary for the pressure difference required to "click" the instrument under static conditions, very satisfactory and consistent results are obtained. Individual

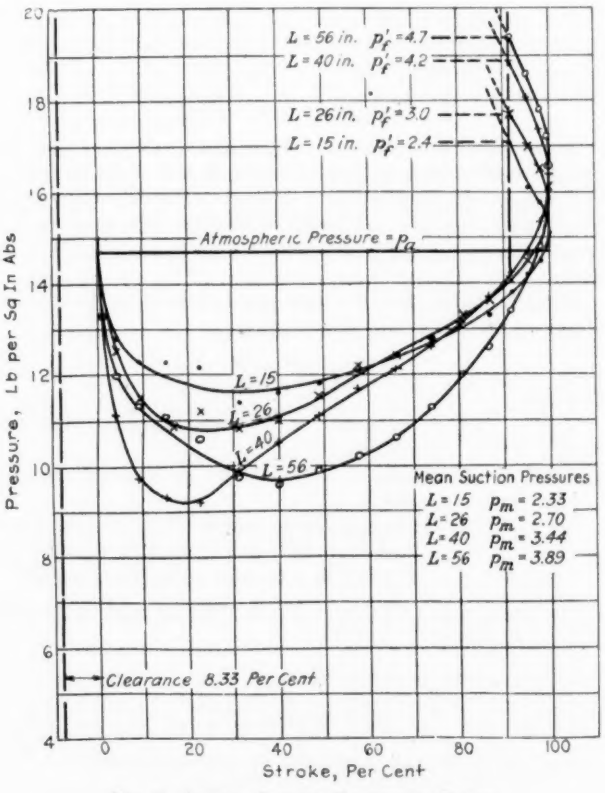

Fig. 5 Actual Suction Indicator Cards

(Tested under conditions assumed in calculating Fig. 4.)

readings on low-pressure cards appear to be good to 0.2 lb per sq in.

All experimental results involve a certain length of suction pipe before the valve and in all cases used in comparison the diameter is 3 in. The design of the head is such that about a 10-in. column is an unavoidable part of the system. After attaching the necessary rounded mouthpiece, the minimum length for which reliable data can be obtained is 15 in. So test results for pipe length $L = 0$ are unavailable. This prevents,

for example, a direct check upon the formula, Equation [13], for calculating a suction card where inertia is absent.

For indicator-card calculations a knowledge of the valve coefficient μ or the effective area A_v is necessary. In this case actual tests were available.[8] From those and other published data probably any design could be estimated within 5 per cent—a sufficient degree of accuracy for design purposes.

Fig. 4 represents a series of theoretical cards; the actual cards (Fig. 5) are taken under the same conditions assumed in the calculation. In general a fair agreement is obtained. Certain characteristic differences are evident:

(1) The calculated minimum pressure is always too low
(2) The calculated mean indicated pressure p_m is too high
(3) The calculated final gage pressure p_f' (at valve closure) is generally low. The error here is small, averaging 0.35 lb per sq in.

The principal sources of error are undoubtedly (*a*) heat transfer to the air, which is ignored, and (*b*) inaccuracy of A_v for a given condition of flow. It is unlikely that defective performance of the indicator contributes much to the discrepancy. An exception may be the case $L = 56$; here the test card seems inconsistent with the others and departure from the theoretical card is greatest.

A more detailed picture of the case $L = 40$ in. is given by Fig. 6. The characteristic differences mentioned are apparent here.

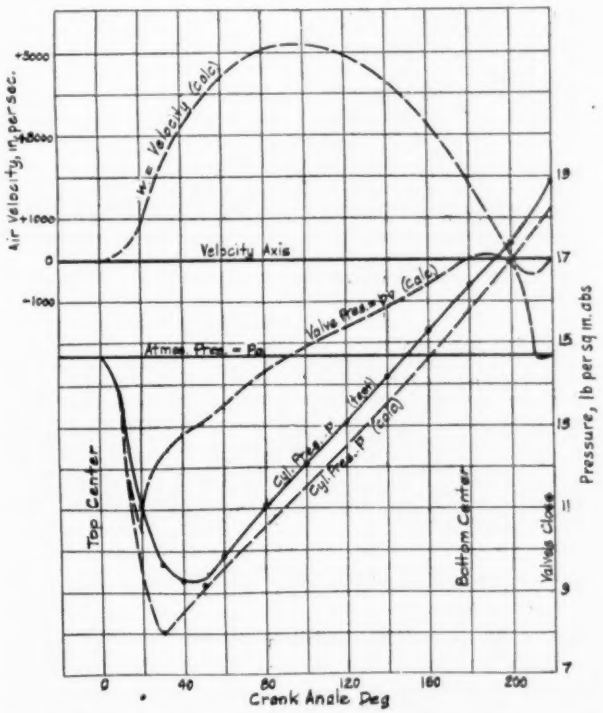

FIG. 6 CRANK ANGLE-PRESSURE DIAGRAMS BY CALCULATION AND TEST
(Rpm, 1000; $L = 40$ in.; also shows calculated valve pressure p_v and air velocity w.)

However, the agreement in the general shape of the curves for cylinder pressure p is satisfactory. The course of the calculated pressure p_v, before the valve, is of interest. No measurement of the corresponding actual pressure has been made. Similarly there is no direct check upon the computed velocity of air w.

[8] Trans. OGP-53-6 (1931).

Volumetric efficiency at 1000 rpm is shown by Fig. 7. As might be expected, the calculated figures are too high, the negative effect of heat absorption from the walls having been neglected. The average correction ($L = 15$ in. to 56 in. inclusive) is —8.0 per cent.

The test result curve is somewhat steeper than the calculated.

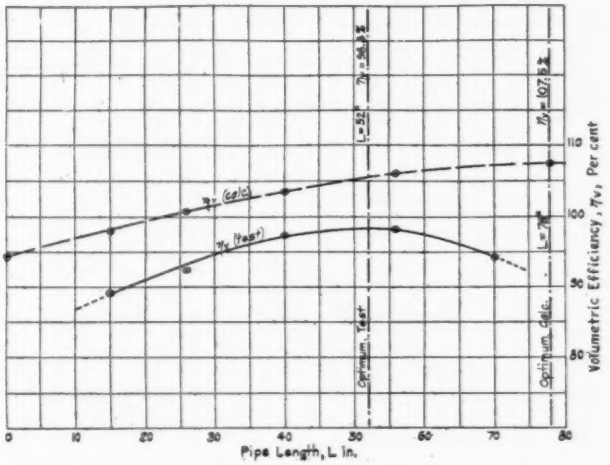

FIG. 7 VOLUMETRIC EFFICIENCY BY CALCULATION AND TEST
(Rpm, 1000; pipe diameter, 3 in.)

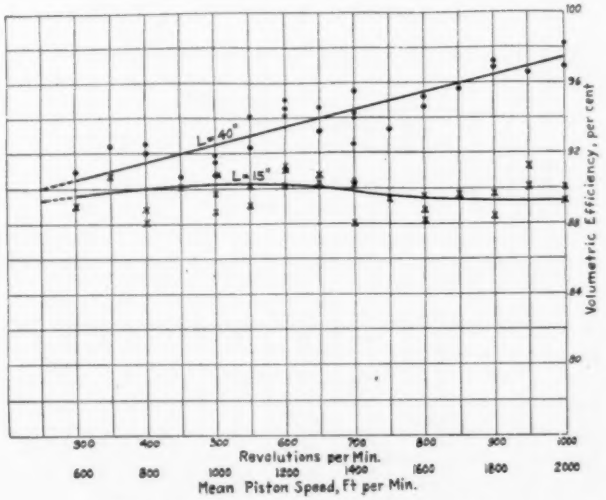

FIG. 8 VOLUMETRIC EFFICIENCY BY TEST
(Cylinder 9 in. by 12 in., with suction pipe 3 in. diam.)

This is possibly due to underestimating kinetic energy of the column; that error increases with pipe length.

The discrepancy in optimum length shows up again in this case. What part pipe friction may play is not known, for no calculation has been made in which this was allowed for. A comparison of best length can again be made:

Optimum length, test, in.....	52
Optimum length, present calculation, in.....	78
Resonant length, no velocity correction, in.....	101
Resonant length, with velocity correction, in....	94

Here again the best test length is 52 per cent of the simple resonant length; agreement with the first case can be only coincidence.

The actual maximum efficiency as tested (98.3 per cent) is itself of some interest. At $L = 15$ it is 89.3 per cent, or an in-

crease of 10.0 per cent in weight of charge. The test curve extrapolated to $L = 0$ gives about 82.5 per cent. While this figure cannot be confirmed, it is not unduly low for a mean piston speed of 2000 ft per min. If this estimate can be accepted, the increase of charge due to the pipe is 19.1 per cent.

Fig. 8 gives the effect of engine speed, with $L = 40$ in. and $L = 15$ in. The continual increase of air charge throughout the tested speed range, using $L = 40$ in., is striking. The effect is somewhat higher with light loads and lower when operating over 90 bmep. Increased load capacity is shown by exhaust temperature; the reduction is normally 100 F, and more with a large load. The limit of load with clear exhaust was raised by 15 bmep approximately.

In these tests compression ratio was adjusted to give 410 lb per sq in. gage compression pressure in each test. The fuel injection system has not yet been specifically adapted to supercharged operation.

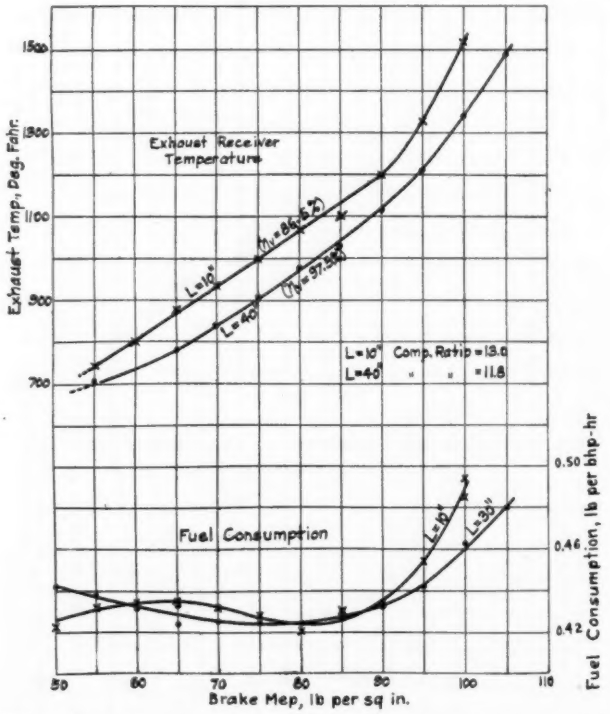

FIG. 9 FUEL CONSUMPTION AND EXHAUST-RECEIVER TEMPERATURE (Single-cylinder engine; suction pipe, 3 in. diam; L = suction pipe length; 9-in. bore by 12-in. stroke; 1000 rpm.)

FIG. 12 SAMPLE CALCULATION, SUCTION WITH PIPE

with $L = 15$ is to maintain practically constant efficiency with rising speed. The normal expectation is a drooping curve.[9]

Fig. 9 compares engine test results with $L = 10$ in. and $L = 40$ in. While not outstanding in themselves, they serve to show some typical effects of supercharging. Specific fuel consumption

Exhaust temperatures may appear excessive. They were taken in a lagged receiver in which the exhaust gases are mixed and brought to rest. A thermocouple in an uncooled exhaust pipe immediately adjacent to the engine reads 150 to 200 F lower, due to failure to represent the mean gas temperature. Aside from this, it will be noted that the specific operating speed is high.

[9] P. H. Schweitzer, "Is the High-Speed Two-Cycle Diesel Possible?" *Power*, June 19, 1928.

Power Cost of Supercharging

Extra indicated power must be expended in the cylinder to obtain the increased air charge. Whether this power cost is excessive can easily be estimated from engine-indicator cards, without detailed theoretical comparison. Refer to Fig. 10, which is illustrative and not to scale. The shaded area A, determined by suction and compression curves, is a measure of the work expended to draw in and compress the charge, preparing it for combustion. The ratio of this work to the weight of charge is the desired criterion. A comparison was made between $L = 10$ and $L = 40$, resulting as follows:

Pipe length L, in.	10	40
Compression pressure, lb per sq in. abs.	425	425
Compression ratio	13.0	11.8
Volumetric efficiency, per cent	86.5	97.5
Air drawn in per cycle, lb	0.0286	0.0322
Mean indicated pressure of compression, lb per sq in.	47.0	51.2
In.-lb work per lb air	1,255,000	1,214,000

We may disregard the slight advantage shown with $L = 40$ and assume the work amounts equal. Then the extra air charge is obtained with proportionate power expenditure only. This is exactly as if the engine size were increased in the ratio of the air charges with equal quality of design.

Conclusions

The long suction pipe is an effective means of increasing volumetric efficiency and load capacity of an engine. The best results are obtained with high air velocities, which may approach one-half the velocity of sound. A compact and efficient installation is obtained with high ratios between cylinder area and pipe area; this ratio may with advantage exceed 10.

The increase of air charge may be as much as 19 per cent under favorable conditions, over what is obtainable when inertia is absent. The engine work expenditure to obtain the extra air is nearly proportional to the increase of charge, and therefore justifiable economically.

The supercharge effect will normally increase with speed, resulting in a specific load capacity which rises with engine rpm.

Engine performance reflects the advantages of the increased air supply. The characteristics become those of an engine larger by the ratio of the increase in air charge.

The theory as developed offers a satisfactory method of anticipating indicator cards, suction power loss, and volumetric efficiency. Theoretical efficiency must be corrected by about 10 per cent in the size of engine tested. In larger engines the correction will be smaller, and in small engines larger.

Appendix A

ALLOWANCE FOR PIPE FRICTION

The friction coefficient f in Equation [21] is an experimental function of the Reynolds number. From data such as that of McAdams[7] obtain f for the estimated maximum rate of flow. With sufficient accuracy, f so found may be used as a constant. Then for a given pipe diameter, Equation [21] takes the form:

$$\Delta p = \text{constant} \times Lw^2 \quad \ldots\ldots\ldots\ldots [21a]$$

This Δp acts at all times to retard the column, whatever the direction of motion. Equation [26] then becomes:

$$\frac{dw}{d\theta} = 24{,}800\,\frac{(p_a - p_v - \Delta p)}{Ln} \quad \ldots\ldots\ldots [26a]$$

while Equation [29] becomes:

$$\frac{dw}{d\theta} = \frac{1.072\,(p_a - p_v + \Delta p)}{L\rho_p n} \quad \ldots\ldots\ldots [29a]$$

The effect of heat of friction upon the density of air in the pipe is neglected (Assumption 2, case III). However, the valve conditions are changed by the resulting temperature rise. The amount of this rise must be estimated.

$$\text{Work} = \text{Force} \times \text{Distance}$$

or

$$W = \Delta p A_p w \text{ in-lb per sec}$$

This energy is added as heat to the air simultaneously flowing through.

$$G = A_p p_a w \text{ lb per sec}$$

The temperature rise is then:

$$\Delta T = \frac{W}{c_p G} = \frac{\Delta p A_p w}{c_p A_p p_a w}$$

$$= \frac{\Delta p}{c_p p_a} = \frac{23{,}100}{2245}\,\Delta p$$

$$= 10.25\,\Delta p$$

Specific heat c_p is used here, not c_v, for the reason already pointed out, that we are concerned with the amount of energy carried through the valve, and this is Gc_pT in-lb per lb (see Equation [4]). We must have equality of energy as well as of weight passing the valve section at any instant.

In view of Equation [21a], we may reduce the expression for ΔT in a given case to

$$\Delta T = \text{constant} \times w^2 \quad \ldots\ldots\ldots\ldots [21b]$$

The calculation procedure as given in case III is then modified to the following (data for point m are assumed to be known):

(1) Compute Δp (Equation [21a])

(2) Compute $\left(\frac{dw}{d\theta}\right)_m$ and w_n (Equation [26a])

(3) Compute $\left(\frac{dp}{d\theta}\right)_m$ and p_n (Equation [25]; T_{vn} will not equal T_a)

(4) Compute $(\Delta T)_n$ (Equation [21b]); then $T_a + \Delta T_n = T_{vn}$, neglecting $T_v = f(p_v)$, as before

(5) Compute p_{vn} (Equation [24]).

Discussion

K. J. DeJuhasz.[10] Using the intake and exhaust pipe as active means for increasing the cylinder charge is an attractive problem which, if successfully solved, would result in increased power output of the engine. The paper, containing a theoretical analysis and experimental procedure with several novel features, and also experimental results of promise, is a valuable contribution to the existing literature on this subject.

Some years ago the writer took part in indicating tests carried out by a large European company manufacturing motor cars and internal-combustion engines. The purpose of these tests was to secure the greatest possible power output from a given engine. On a supercharged racing-car engine with a speed up to 6000 rpm, modification of the valve timing and suitable shaping of the exhaust pipes resulted in a power increase of about 4 per cent. On a car engine of normal design, a noticeable increase of mean effective pressure was obtained by highly polishing the inside surface of the intake manifold and by eliminating the obstructions in it.

A survey of the improvements attained in latter years by

[10] Assistant Professor of Engineering Research, Pennsylvania State College, State College, Pa.

suitably dimensioning the inside of the combustion chamber leads one to the justifiable expectation that benefits could be realized also by close attention to the design of engine parts extraneous to the cylinder—i.e., to the intake and exhaust system. Applied to Diesel engines, such gain would be especially valuable as it would tend to compensate one of the disadvantages of the Diesel, the comparatively low mean effective pressure.

With the object of exploring the possibilities in this direction an investigation has been started at the Engineering Experiment Station of the Pennsylvania State College on the inertia charging of a two-stroke cycle engine.

The author performed a timely service in focusing attention to this possibility of bettering engine performance.

RALPH MILLER.[11] Has the author investigated the effect of elbows and bends in the suction line? It is impractical to build suction pipes straight as shown on the illustration. Can the same effect be produced where manifolds are used as on multiple-cylinder engines without unbalancing the degree of supercharging for each cylinder?

The investigation is applicable to compressor design, but of little value in Diesel-engine design when it is remembered that engines with the most highly developed combustion cannot be operated satisfactorily with mean effective pressures above 80 lb, and this limitation is not imposed by lack of air.

HARTE COOKE.[12] In connection with the arrangement for pressure charging given by the author, the power required of course comes from the engine, and as the arrangement mentioned by another discussor accomplishes the same thing with greater efficiency, it just means that the supercharging was done as a smaller expenditure of power on the engine itself.

In regard to the vibrations in the piping, these are of considerable magnitude and of a very complicated nature. The writer at one time observed a very marked fall in pressure in the high-pressure cylinder of a certain engine immediately after the beginning of the exhaust stroke, apparently due to the inertia of the steam going out of the cylinder. Indicator cards were taken from the exhaust pipe, and very peculiar vibrations of considerable magnitude were noted in the pressure in this pipe which showed that the pressure immediately after release, due to the puff of steam, was reduced considerably below the normal receiver-pressure for the first part of the exhaust stroke; also, these complicated vibrations were repeated perfectly over a period of a minute or so.

AUTHOR'S CLOSURE

The progress of Professor DeJuhasz's two-cycle experiments will be of much interest. In an ideal system, all scavenging power should be taken from the exhaust "puff." Here also a difficulty will be found in making the process effective over a wide speed range, and to initiate it at a low speed.

In reply to Mr. Miller, the introduction of elbows, if properly formed, does not greatly influence the results obtained. The radius of the bend should be large, i.e., equal to about two pipe diameters. An engine has been operated in which a 90-deg elbow was present in the pipe, adjacent to the head. Increase of compression was only slightly less than in the preliminary tests quoted in the paper. A similar effect can be produced where a manifold supplies, for example, a group of three cylinders. Such results were quoted by Capetti. However, the pipe resonance frequency is encountered at a much lower engine speed, because of the multiple impulses. At higher speeds the amount of supercharge decreases rapidly.

Because an engine does not use in combustion all air present in the cylinder, it does not follow that it will not benefit from a further addition. The supercharged engine development of Mr. Büchi, for example, would be impossible if a limit such as is mentioned by Mr. Miller existed; fortunately it does not. The limit of clear exhaust for the present test engine was raised from 85 to nearly 100 bmep by pipe supercharging. High-speed engine operation is in fact limited by the possibilities of dissipating heat from the combustion space, and in this respect a further surplus of air is plainly helpful. In the present tests this is reflected in a reduction of exhaust temperature.

Exhaust pipe waves, mentioned by Mr. Cooke, were in one case found to have an amplitude as high as 3 lb per sq in. These waves may be utilized to aid scavenging, but unfortunately the favorable effect is confined to a rather small speed range.

OGP-55-6

Some Phases of Light-Weight Diesel-Engine Design

By P. B. JACKSON,[1] CLEVELAND, OHIO

The paper analyzes the economics of light-weight Diesel-engine design. This is justified if these points are satisfied: Lower cost per unit (cost per horsepower), lower cost of operation for the unit, reduction in time of work accomplished, and reduction in engine size. The proper coordination of three principles will produce an engine very much under conventional weights, these being increased mean effective pressure, increased piston speeds, and intelligent use of material having a high ratio of strength to specific gravity.

THE introduction of this paper is a condensed analysis of the economics of light-weight design. The economic soundness of any project must be determined early in its conception to insure a lasting success. The recognition of the importance of the economic side of a venture prompts the use of a short discussion of its phases before starting with the design problems.

The light-weight Diesel engine is justified economically if one or more of the following premises are satisfied:

1 Lower cost per unit (cost per horsepower)
2 Lower cost of operation for the unit
3 Reduction in time of work accomplished
4 Reduction of engine size.

The almost axiomatic clearness of the first premise need not be enlarged upon. Methods that accomplish this lower cost per horsepower are discussed later in this paper.

The second item in the foregoing list needs some exposition. The use of Diesel power in mobile equipment has been retarded because of the weight of this type of engine. The cost of operation of mobile equipment is measured in units of cost per ton-mile. The engine in many of these units constitutes the major portion to the overall weight and therefore should receive first consideration in a weight-saving program. The close relation that the weight of the engine bears to the weight of the balance of the unit results in a unit which either is smaller and lighter or a unit capable of handling a higher percentage of pay load. In either case there is a saving in the cost of transportation.

Reduction in the time of work accomplished is frequently desirable, but in every instance requires more power. There are many types of equipment which have reached the limit of size or weight, and unless increases in power are made without increasing the weight of the power plant, the possibility of reducing the time for a given amount of work is impossible. Two excellent examples are found in the Diesel dredge and the Diesel-electric locomotive. The dredge is limited in size and draft by the operating conditions; this, in turn, determines the weight of the power plant. The premium paid for light weight in a case of this kind is sound economically and is generally recognized by both the operators and the builders of this equipment.

The Diesel-electric locomotive requires weight for tractive effort, but there is a limit of load per axle, as well as a limit for the number of wheels. These limits predetermine the weight of the power plant, and, by this token, the specific weight of an engine becomes a very important factor. The loads pulled and the speed attained are both essentially a direct function of available horsepower. It is the opinion of many engineers that the future of the Diesel-electric locomotive will depend on the development of engines of large output and low specific weight.

The fourth item, reduction of engine size, has a twofold economic interest. Space is frequently the determining factor for engine installations, and engines of high output that will go into a small space will find new markets as well as satisfy the demand for relatively small installation dimensions that are dictated by the size of the unit in which the engine is to be installed.

There are many examples that would amplify the foregoing discussion, which has just barely touched the high points. The subject would make a very interesting paper in itself. Due to the amount of material to be discussed under the heading of ways and means of designing the light-weight Diesel engine, no more time will be given the economic side of the picture.

Assuming that the foregoing has justified the light-weight Diesel engine from the economic point of view and that the engine builders are recognizing many, if not all, of the advantages of this type of engine, the next step in the procedure is the investigation of various methods to attain the desired result. The proper coordination of three general principles will produce an engine very much under conventional weights. These principles are:

1 Increased mean effective pressure
2 Increased piston speeds
3 Intelligent use of material having high strength-specific-gravity ratio.

Each of these methods has problems which must be fully recognized and in which definite provision must be made for the proper functioning of the parts involved. It is the prime object of this paper to discuss the problems and to offer a solution of them.

Increased Mean Effective Pressure

Increasing mean effective pressure involves problems that may be classified under two general headings, i.e.:

1 Combustion
2 Heat.

The first, combustion problems, are going to be given little consideration in this paper. It is sufficient to say that the research work that is being done at State College, combined with that of the N.A.A.C., as well as of private enterprises, is producing results that will ultimately be reflected in the industry by increased m.e.p. rating.

The second problem, that of heat, is a vital one with present m.e.p. ratings. When these ratings are increased, the difficulties encountered are magnified, and steps must be taken to avoid failure of the parts that are subjected to the intensified conditions.

Increases in the m.e.p. ratings, at the sacrifice of specific fuel consumption, may or may not be justified. Unquestionably, the present low specific fuel consumption places the Diesel en-

[1] Engineer, Aluminum Company of America. Assoc-Mem. A.S.M.E.

Presented at the Third National Oil and Gas Power Meeting, State College, Pa., June 12 to 14, 1930, of The American Society of Mechanical Engineers.

Note: Statements and opinions advanced in papers are to be understood as individual expressions of their authors, and not those of the Society.

gine in an enviable position as a prime mover. By that token, the aim should be higher rating, with the same or a lower figure for specific fuel consumption. Assuming, then, unchanged specific fuel consumption and heat balance, an increase in m.e.p. would increase the amount of heat to be dissipated in direct proportion. It is this extra amount of heat that will cause mechanical failures if due recognition of its presence is not considered and means for its dissipation provided.

The four essential parts of the cylinder unit that are subjected to the heat of combustion are:

1 Cylinder head
2 Cylinder liner
3 Exhaust valve
4 Piston.

Each will be discussed under a separate heading.

Cylinder Head

In considering a cylinder head from the standpoint of heat dissipation, several things are apparent. The temperature gradient, between the hot and cold sides of the cylinder head, is a function of the thermal conductivity of the material and the thickness of the section through which the heat must flow. Due to the restraint offered by the rigid attachment of the cylinder head to the cylinder, the temperature gradient in the bottom face of the head sets up stresses which, unfortunately, are increased if metal sections are increased. By this same token, a reduction in the metal thickness would reduce the thermal stresses. However, the maximum cylinder pressure must be considered, and therefore is a determining factor for this dimension.

TABLE 1 PHYSICAL PROPERTIES OF SEVERAL ALUMINUM ALLOYS

Alloy No.	Ultimate T. S.	Yield point	Elongation, per cent
Casting Alloys			
195-HT-4[a]	28,000–38,000	13,500	6–12
195-HT-10[a]	36,000–50,000	27,000	0–5
195-HT-16[a]	30,000–40,000	21,000	3–8
43	17,000–22,000	7,000	3–7
112	19,000–24,000	11,000	1–2½
Forging Alloy			
25 ST	55,000–63,000	30,000–40,000	16–25

[a] These casting alloys are heat-treated.

The selection of a material having a higher thermal conductivity offers a method for the reduction of thermal stresses. Aluminum, with a conductivity factor some 4½ times that of cast iron, thus recommends its use. Other requirements, however, must be considered. Referring to Table 1, it will be seen that the alloy specified as 195-HT-16 has physical properties equal if not better than cast iron. The Brinell hardness, however, is low, which will necessitate a special design for a valve seat. There are two methods of incorporating a valve seat being used at the present time. An aluminum-bronze ring (90 per cent Cu, 10 per cent Al) shrunk into a recess or counterbore provides a valve-seat surface having a Brinell hardness of approximately 225. This is not only being used in Diesel practise, but has been the practise in both water- and air-cooled aircraft engines. The latter is much more severe service due to the high temperatures of the air-cooled cylinder head (500 to 550 deg. fahr.). Aluminum bronze was chosen because of its high Brinell hardness, its higher coefficient of expansion (approximately 0.00001 in. per deg. fahr.), and a higher thermal conductivity.

At least one American Diesel-engine builder is using steel valve seats cast into the aluminum head and has experienced no trouble from loosening in service. This construction becomes a necessity when valves are so close together that it is impossible to get sufficient material around the individual ring or valve seat. There is no objection to this practise from the foundry standpoint. All available information would indicate that there is little to choose between the two constructions.

The problems of corrosion must be recognized, but with proper precautions does not preclude this material for use in salt water. Differentiating between corrosion and electrolysis, tests indicate that corrosion alone is not serious, and with the use of inhibitors and protective coatings, trouble should not be encountered. Electrolytic action, however, is a most serious problem, and it is essential that materials other than aluminum, which are in contact with the cooling water, should be insulated by nonmetallic gaskets. Stud holes should be "blind" tapped, and copper-based alloys should be avoided as far as possible in the system. Where bronze pumps and water piping are used, the connections to the aluminum parts of the engine should be made with rubber hose.

All water-jacketed aluminum parts, such as cylinder heads, cylinders, and exhaust manifolds, should be treated with a corrosion inhibitor, as well as a protective coating which consists of baked linseed oil. To avoid erosion, designs should be so made that the water entering the engine does not impinge directly against the aluminum surface. If these precautions are taken, little if any apprehension should be felt. With fresh water cooling, the system is generally "closed," and highly alkaline water may be treated, thus avoiding all corrosion.

Cylinder Liner

The heat dissipated through the cylinder liner is considerably less than through the cylinder head, which, in turn, results in lower thermal stresses. The relative simplicity of the liner also readily lends itself to the use of stronger materials, should high thermal stresses become apparent. Steel liners could be made much thinner than the conventional cast iron, thus reducing temperature gradient, and with the exception of cost differential, the steel liner seems to be entirely practical.

Exhaust Valve

A very prominent aircraft-engine designer measures engine performance by a comparison of horsepower per inch of exhaust-valve size. This is just an indication of the heat problems that have been experienced in his field where high m.e.p. and high speeds are encountered. If the light-weight Diesel engine is produced by the methods suggested earlier in this paper, the exhaust-valve problem will approach the conditions existing in present-day aircraft engines.

When it is realized that the amount of heat which is absorbed by a valve is a function of the cube of its diameter and that the outlet for that heat varies only directly with its dimensions, it becomes apparent that this particular point will require careful consideration. There are two outlets for the heat in an exhaust valve—through the stem and through the seat. In either case the heat must pass through to the cooling water, and by the same reasoning as was used earlier in regard to the cylinder head, a greater amount of heat will be passed with the aluminum head than with the conventional cast iron.

In automotive practise 35 to 45 carbon exhaust valves have replaced, with better results, the special heat-resisting steels, when aluminum heads were used in place of cast iron. Unfortunately, there were no quantitative figures of the actual temperatures of these valves, but a comparison of the appearance of each valve indicated very clearly a cooler valve in the aluminum head.

Most valve-stem guides to date have been made of cast iron, but it is hoped that in the near future data will be available to show that aluminum valve-stem guides are practical. If this

can be shown, there will be further opportunity of reducing exhaust-valve temperatures.

The use of dual exhaust valves will go far in solving this temperature problem and will undoubtedly be a necessity in engines of large bore. Serious consideration should be given to the use of exhaust valves smaller than inlet valves. Data are available which show that the losses in an engine with an exhaust-valve diameter one-half that of the inlet-valve diameter were negligible with piston speeds up to 2300 ft. per min. While these figures were found on a gasoline engine, it is reasonable to believe that results in the same general direction would obtain in Diesel-engine practise. The advantage would be twofold—cooler exhaust valves and larger inlet valves. The advantages of both are obvious.

The design of the water passages around the valve parts can be so arranged as to give the much-desired high cooling-water velocities at this point. The insulating effect of the more stagnant water is eliminated, as well as steam pockets and the formation of scale due to localized high temperatures. The temperature reduction in the valve is very apparent.

Cast-iron cylinder heads weigh from 6 to 9 lb per horsepower. It is perfectly practical to design an aluminum head that will weigh from $2^1/_2$ to 5 lb per horsepower, weight well worth saving, as it affects overall engine weight.

Piston

Every Diesel-engine piston, regardless of design or material, shows the undeniable evidence of high temperatures. This evidence ranges from discoloration to heavy deposits of carbon on the under side of the head in cast-iron pistons. The next step is the cracked head, which in practically all instances is the result of excessive thermal stresses. Heat balance tests show that approximately 30 per cent of the total heat supplied an engine finds its way into the cooling water. Parday, supported by others, makes the claim that some 12 per cent of this heat is dissipated through the piston head. (These figures relate only to uncooled pistons.) Actual piston designs based on these data prove by their successful operation the essential truth of these figures.

A large manufacturer of aluminum pistons has established the fact that the greatest portion of heat leaving the piston is conducted through the piston rings (between 70 and 80 per cent is thus accounted for). These figures have been verified by Taylor at the Massachusetts Institute of Technology. With these figures established, B. Isidin has evolved formulas for the design of aluminum-alloy pistons which have been used in designs of pistons which function well in enough different sizes to justify their use as a standard regardless of the material used.

The important points which are established in this paper are:

1 Head thickness is a direct function of the heat supplied with any given material
2 The allowable temperature gradient for cast-iron pistons is 350 deg. (This produces a temperature stress of approximately 15,000 lb per sq in.)
3 The allowable temperature gradient for an aluminum piston is 130 deg. (The resulting temperature stress is 7000 lb per sq in.)
4 The thermal conductivity of cast iron taken as 1 gives a comparative conductivity of aluminum of 4.4
5 The head thickness of a piston varies inversely as the conductivity factor (allowable temperature gradient × thermal conductivity).

From these figures it can be shown that a cast-iron piston should have a head thickness some 82 per cent greater than an aluminum piston for similar service to be within safe design factors. Mr. Isidin places the limit of uncooled aluminum pistons at some 300 bhp per piston. The accuracy of this prediction should be confirmed within the next six months.

The large amount of heat going through the piston rings demands that careful consideration be given to the design of the ring belt. Laboratory and actual experience has shown that the ring width has little effect on heat dissipation. The number of rings and the depth of the ring in the groove are the two factors which should be carefully determined. The minimum number may be determined by formulas, while the depth of ring is dictated by the physical characteristics of the ring material. This should be 0.040 per inch of cylinder bore, and rings so designed can be furnished by any ring manufacturer who uses a good quality of iron.

Good practise on ring widths is as follows: 5 to 7, $^{15}/_{16}$ to $^3/_{16}$ in.; 8 to 10, $^{15}/_{16}$ to $^1/_4$ in.; 11 to 13, $^{15}/_{16}$ to $^5/_{16}$ in.; 14 to 16, $^{15}/_{16}$ to $^3/_8$ in.; 17 to 21, $^{15}/_{16}$ to $^7/_{16}$ in.; 22 and larger, $^1/_2$ in.

The top or fire ring should be placed a reasonable distance from the top of the piston; 10 to 15 per cent of the diameter gives satisfactory results.

When it comes to the selection of the alloy for the Diesel piston, a number of requirements are prerequisite to satisfactory operation. Of first importance is the selection of a material having sufficiently high physical properties at the operating temperature of the piston to withstand the stresses involved.

In the casting alloy identified as 142-HT, it will be noted that the drop in ultimate tensile strength and yield point of this alloy at elevated temperature is among the lowest. Its Brinell hardness is high enough to give long life to ring grooves, and a last consideration, and one of no mean importance, is the absence of permanent growth. There are no other commercial alloys that combine all these factors, and the only compromise in the selection of this alloy is slightly lower Brinell hardness than the alloy identified as 122-HT. This alloy has permanent growth and lower physical properties at high temperature.

The subject of pistons will be again discussed briefly under the heading "Higher Piston Speeds," but for the sake of continuity one or two points of piston design will be discussed at this time, even though the increased heat of the higher m.e.p. and piston speeds do not affect, to any marked degree, the remaining design problems.

The question of piston clearance has probably retarded the general acceptance of aluminum pistons more than any one thing. Conclusions based on the knowledge of the relative coefficients of expansion of aluminum and iron alone would indicate that approximately twice as much clearance is required for aluminum pistons as for cast iron.

Experience has proved that this, in general, is not the case. It is customary with solid trunk-type aluminum pistons to grind the skirt taper so that when the piston attains a balanced temperature the sides of the skirt will be essentially parallel. With this practise the clearance above the pin is from 0.0012 to 0.0015 per inch, while the bottom of the skirt will run with from 0.0008 to 0.0012 per inch. This range is caused by ratings, piston-ring set-up, water temperatures, combustion characteristics, etc.

In a well-designed aluminum trunk-type piston, where the skirt wall is relatively thick and the stiffness rib which runs from one wristpin boss to the other is wide at its base, the resulting skirt stiffness has a marked effect on the ability of the piston to stay round under operating conditions. This inherent roundness provides nearly ideal conditions for lubrication and results in long life.

Due primarily to the difference in expansion of steel and aluminum, full floating wristpins are much to be preferred. There is no tendency of the piston to distort due to the influence of the

pin, and the proper fitting of the pin is more readily accomplished with this construction. The loading of wristpins should not exceed 2000 lb per sq in. There are several instances where that figure has been exceeded, but temporary failure of lubrication, distortion of the pin, or variations in the hardness of the piston pin are apt to cause excessive wear if not a definite failure.

Several methods of retaining the piston pin have been used. The plug construction that seems to have more to recommend it than any other is one that allows the use of a long pin, prevents oil from free communication to the cylinder wall, and has practically an indefinite life. The plugs should be made from the same material as the piston to avoid variations in expansions.

The stepped wristpin boss should be proportioned so that the unit pressures in the piston and rod are reduced materially on the expansion stroke, while the unit pressures caused by inertia do not exceed those due to expansion pressures. Lighter piston pins are also possible with this design.

The lubrication of aluminum pistons is essential because of inherent characteristics of the piston alloy. "Scuffing" is the term used to describe the results of using aluminum on a dry cast-iron or steel surface. The aluminum tears and is deposited on the other surface. The heat generated from the high friction causes expansion. This expansion in the case of a piston causes a seizure. The same conditions with cast iron would cause excessive wear, but only in extreme cases would a seizure result. It is not the volume or quality of lubrication, but it is the early establishment and maintenance of lubrication that is the essential requirement.

Increased Piston Speeds

The reduction of specific engine weight by increasing engine speed produces results in exactly the same order as increased b.m.e.p. The limiting factors come under four general headings:

1 Combustion
2 Volumetric losses
3 Bearings
4 Heat.

Combustion problems at higher rotative speeds apparently are more easily overcome than those encountered when trying to increase m.e.p. Several engines in this country are running at 1000 r.p.m. and over with good economy. This in itself would indicate that this point is not insurmountable. It is the opinion of several Diesel engineers that the limit of speed increase lies within the remaining three headings.

Volumetric Losses

The volumetric efficiency of any internal-combustion engine reaches a point where speed increases do not increase horsepower. Valve lift and timing influence this critical point. It is possible to get good volumetric efficiency with mean air velocities of 13,000 to 14,000 ft per min. This would require a valve lift of sufficient height to provide an area under the valve seat 25 to 30 per cent in excess of the clear diameter of the valve. With a single valve having a clear diameter one-third the cylinder diameter, the allowable piston speed would be one-ninth of 13,000, or some 1450 ft per min. Two inlet valves per cylinder would increase this allowable piston speed to some 2900 ft per min.

From this reasoning it would appear that volumetric losses will not stand in the way of increasing Diesel-engine speeds for some time to come.

Mechanical Problems

The mechanical problems encountered when increasing engine speed are almost entirely those of crankshaft main bearings and crankpin bearings. The limit of speed increase is determined by allowable PV (pressure-velocity) values. Unfortunately there is quite a range of opinion as to just what this figure should be. It is, however, generally conceded that the ratio of P to V in the factor materially affects the maximum value, as do such design characteristics as rigidity of bearings, oil pressure, oil temperature, the maximum temperature at the bearing surface, and the ratio of maximum to mean pressure.

Neglecting combustion pressures, the work done on the crankpin increases as the cube of the speed. (Actual loads increase as the speed squared, while the V, or velocity, factor is a direct increase.) The maximum combustion and compression pressures act against the inertia forces, resulting in lower maximum crankpin-bearing pressures. When combining the two into a resultant crankpin load, it is found that the PV values do not increase quite in the ratio of cube of the speed.

An analysis of several conventional four-cycle Diesel engines using cast-iron pistons and steel connecting rods and running at piston speeds of from 800 to 1200 ft per min showed that from 60 to 80 per cent of the total work done on the crankpin was the result of inertia and centrifugal force. This was determined by making a diagram the ordinates of which represent resultant crankpin pressures, while the abscissa is equally divided and represents crank angles. The compression and combustion pressures are additive to inertia and centrifugal forces, with the exception of a portion of the crank travel some 76 deg before and after top dead center. If the area of a diagram for centrifugal and inertia forces is taken for the four strokes less 76 deg at each end of the diagram and compared with the original diagram, the results will be in the order mentioned.

Inertia and centrifugal forces are a direct function of the weight of the parts, and a reduction of those weights is desirable if engine speeds are to be increased. The limit of this speed increase is dependent on possible weight saving in the piston and connecting rod and the allowable PV values.

Take a more or less specific case where the following conditions are assumed:

1 Present PV value not to be exceeded
2 Allowable weight reduction of present piston and rod 50 per cent
3 Present piston and rod account for 80 per cent crankpin work.

It may be estimated that the mean pressure has been reduced a total of 40 per cent. Having established a figure of 0.6 of the original mean pressure, it becomes apparent that the value of the velocity factor in the PV factor may be increased as $3\sqrt{1/6}$, or some 18 per cent. The inertia forces due to this increase in speed will not be sufficient to overcome compression and combustion pressures to the same extent as with the original heavy pistons and rods, but the increase in mean pressure due to this is so small that it may be neglected.

It is practical to design an aluminum piston that will weigh less than one-half the weight of a well-designed cast-iron piston; in fact, experience has shown that the weight of an aluminum piston with pin and rings actually is about one-half that of a cast-iron piston in the same condition. With connecting rods it is somewhat more difficult to predict the weight saving due to the wide range of stresses used in the design of steel rods. The comparison in weights of a well-designed steel and aluminum rod complete with bolts and bushings will show a weight saving of from 45 per cent to 35 per cent. With this reduction in the weight of the rod and piston, the foregoing reasoning appears to be correct.

Aluminum Connecting Rods

The prime object of using aluminum for connecting rods is of

course the saving in weight. This weight saving must not, however, be accomplished with sacrifices in factor of safety or lack of rigidity in either the wristpin or crankpin end of the rod. The low modulus of aluminum (10,000,000) requires a redesign of the bearing ends of the rod to provide the added material for stiffness. The stiffness of a beam is a direct function of the amount of inertia of the section and the modulus of elasticity of the material. The moment of inertia varies as the cube of the section, and the ratio of the elastic modulus of steel to aluminum being 3, the additional depth of the section to give equal rigidity is $3\sqrt{3}$, or 44 per cent. This section will weigh 49 per cent less than a steel section of equal rigidity. This increase in section reduces the stress due to bending more than 50 per cent, a feature in all-aluminum design which is extremely desirable from a safety factor standpoint.

The direct babbitting of aluminum connecting rods has many desirable features. Its use allows for an increase in the diameter of the crankpin equal to twice the thickness of a bronze- or steel-backed babbitt-lined shell, which materially increases the torsional rigidity of the shaft and reduces the unit bearing pressures to some extent.

The heat in a bearing is generated at the two rubbing surfaces and must be absorbed by the oil and the material making up the bearing. The removable shell-type bearing restricts heat flow through to the rod due to the high resistance of the joint between the rod and shell. An experiment several years ago revealed that some 20 times as much heat passed out of a direct-babbitted aluminum rod as with a steel rod with a separate shell. This figure was influenced to a large extent because of the high thermal conductivity of the aluminum rod. One objection to a direct-babbitted steel rod is the injury to the crankshaft should the babbitt melt out. This objection does not hold with aluminum due to the fairly good bearing characteristics of the alloy. Experiments have shown that aluminum connecting rods may be run on nitralloy crankshafts without babbitt.

The special technique required to babbitt aluminum rods is readily acquired. The only disadvantage in a direct-babbitted rod is the replacement feature, which should not exclude its use.

The material used for aluminum connecting rods is a wrought alloy having a minimum tensile strength of 55,000 lb per sq in., 17 to 25 per cent elongation, and a fatigue limit of 15,000 lb per sq in. in the heat-treated condition. It may be hand-forged or die-forged as the conditions require. The advantages to be gained are apparent and justify any increase in cost.

Valve Gear

Increased rotative speed imposes added problems in the design of valve gear. The weights of all of the moving parts must be reduced to a minimum in order to avoid heavy valve springs. This is particularly true with high lift valves. The careful design of cams will do much to reduce the stresses in the system.

Aluminum may be used for rocker arms and pushrods with savings in weight in the order of 50 per cent for these parts. Unfortunately, the temperature and wear conditions of the rest of the system preclude the use of light alloys anywhere else. One engine builder is using aluminum pushrods primarily to keep valve clearances uniform over a wide temperature range. This happens to be one of the few places where the high coefficient of expansion of aluminum is not bothersome.

Heat

The increase of heat input at higher rotative speeds is quite the same problem as that of higher b.m.e.p.'s. The points discussed earlier in the paper are applicable here and need not be further amplified.

Summarizing the advantages of obtaining light weight by increasing speed and b.m.e.p., it is very apparent that the changes in design and material specification will have relatively small effect on the overall cost of the engine. The reduction in specific weight is quite marked and may be estimated by the following reasoning. The use of aluminum for cylinder heads, pistons, connecting rods, and valve-gear parts will probably reduce the total engine weight 10 per cent. If the original engine was rated at 100 bhp at a piston speed of 1000 ft per min, and weighed 50 lb per hp, or a total of 5000 lb, the new weight would be 4500 lb. An increase in mean effective pressure of 15 per cent would increase the bhp to 115 at 1000 ft per min. The increase in speed of 18 per cent would further raise the bhp to 138 at 1180 ft per min; a specific weight of some 33 lb per bhp (4500 ÷ 136) results.

The size of the engine would not be changed in any way, and the resulting economy in space would be of value in many installations. The life of the engine should be just as long due to the adherence to similar design standards in each case.

The foregoing analysis of weight reductions by means of increasing the horsepower for cubic inch of piston displacement was based on very conservative figures, particularly in the case of the possible increase in speed. If this increase in output can be sold for the same price per horsepower as was received for the original engine, the profit obtained per engine would be very attractive. This fact, coupled with the reduction in installation dimensions, should result in a readily salable engine, which in the final analysis is the aim of every manufacturer and engineer.

Intelligent Use of Material Having High Strength-Specific-Gravity Ratio

The principle reason for the use of aluminum alloys for the parts discussed in the foregoing is that the peculiar properties of these alloys are preeminently suited to the application for which they are recommended. The saving in weight, as it affects total engine weight, is a second or third consideration. The balance of the discussion will be confined to the use of materials that will reduce the weight of the parts fabricated from the light alloys.

The outstanding and most generally recognized property of aluminum is its low specific gravity. It weighs 0.1 lb per cu in., as compared to 0.26 for cast iron, 0.28 for steel, and 0.31 for bronze. While these figures are very attractive, the low weight of aluminum alloys is only one of many physical characteristics that must be recognized when using this material in engine construction. The relatively low modulus of elasticity should be given careful consideration, particularly when replacing steel, whether in cast or forged form. For rigidity equal to steel, the moment of inertia must be increased three times. This increases sections approximately 30 per cent, with a resulting saving in weight of some 40 per cent and a reduction of stress of 56 per cent.

When determining sections of equal rigidity of cast iron the moment of inertia must be increased 50 per cent, which results in sections 10 per cent larger than the cast iron. The actual aluminum castings designed with these increased sections will be approximately 55 lb lighter than cast iron and have a stress factor 26 per cent less than the iron castings. It is well for the designer of aluminum parts to become thoroughly familiarized with these relating facts. Stress is laid on this point, because the majority of parts which may be made of aluminum are stressed by bending, and the rigidity of the design is the most essential consideration. Invariably, when parts are sufficiently rigid, the stress is so low as to eliminate any need for anxiety.

There are two general methods of fabricating aluminum Diesel-engine parts—casting and forging. There are a large variety of

commercially available casting alloys, each suitable to a particular purpose. They in turn are divided into two groups and may be classified as heat-treated and un-heat-treated castings. The heat-treated castings are used where high physical properties are necessary. The treatment may be varied to give great ductility at the sacrifice of ultimate strength and yield point or low ductility with a marked gain in both yield point and tensile strength. Table 1 shows the properties of an alloy designated as 195. The figures following the HT designate the treatment that varies the physical properties as soon in the list. This particular alloy has a very wide use in the mechanical field, the technique of casting it is highly developed, and its use to replace cast ferrous materials entails very little of an experimental nature.

There are several other available heat-treated alloys which have special physical characteristics, such as high Brinell hardness, good physical properties at high temperatures, etc. Their application, however, is limited to very few parts, such as piston castings and bearings, and in special cases they are used for particularly difficult casting to help the foundry.

The un-heat-treated alloys are used for parts which carry light loads. The nature of the casting as well as the work it has to do determines the selection. Alloy 43 is used where oil-tightness is a requirement. It casts well, and extremely thin castings may be made from it. A casting 6 ft sq can be made with a metal thickness of $^1/_4$ in. if there are no heavy sections. Its machine characteristics, however, are not as good as the heat-treated alloys nor the alloy designated as 112.

No. 112 alloy is the general-utility material for large and small castings which require little shock resistance. It is easy to cast, machines well, and has had many years of use. The physical properties are very near those of ordinary cast iron.

The use of forgings in Diesel construction is more or less limited to connecting rods and valve rocker arms. The Diesel aircraft piston might be added to that list, but the development of the art for this type of forging is quite new. As stated in another section of this paper forgings either may be hand forged or die forged, depending on the economics of quantities, size, etc.

One very attractive feature of reducing the specific weight of an engine by substituting aluminum for iron and steel is that bearing sizes, cylinder centers, and in fact all the important characteristics of the engine remain unchanged. The engine builder who has built a successful engine can reduce its specific weight a material amount without going through a long stage of development. Several builders are making both aluminum and cast iron parts from the same pattern equipment. The saving in weight when this is done is approximately 62 per cent.

From 70 to 80 per cent of the total weight of a Diesel engine is available for aluminumization, and when it is realized, that saving will average some 55 per cent. It is apparent that this method of attack should be given serious consideration. The reduction in specific weight by this method is something better than 40 per cent. Its only drawback is that it increases the cost of the engine, but it must not be forgotten that low engine weight has a very definite economic appeal in many fields. Experience has shown that the cost of reducing weight by this process is approximately 25 cents per pound saved.

In conclusion, it is of interest to estimate the total saving in engine weight possible by using the three methods discussed in the foregoing. Going back to the specific example of the 100-hp engine which weighed 500 lb as built in the more conventional materials the total saving in weight by using aluminum is 2000 lb, resulting in a weight of 3000 for the light engine. The horsepower increase was estimated as 36, which when added to the original power results in a total of 136 hp. The weight per horsepower obtained from these figures is almost exactly 22 lb, a saving of 56 per cent.

From the cost standpoint, the saving of 2000 lb at 25 cents a pound would increase the cost of the engine $500. If the original engine cost would be $5500, dividing that figure by the new horsepower rating, the resulting cost per horsepower will be $40.50. This represents a saving of 19 per cent. This weight and cost analysis, if found correct in practise, should satisfy the economic phase of the light-weight engine. Experience in actual applications of all the various parts of the engine which have been discussed has proved by their successful operation, the mechanical soundness of those parts.

It is hoped that this paper will in some small way stimulate and encourage the Diesel-engine industry to produce light weight engines that will open new and profitable markets.

OGP-55-7

Spray Characteristics of a Jerk-Pump Fuel-Injection System

By O. F. ZAHN, Jr.,[1] STATE COLLEGE, PA.

Tests were conducted with special spray-research apparatus in the Oil Spray Laboratory at Pennsylvania State College, aided by the loan of jerk-pump injection equipment. The application of the conclusions reached is summarized as follows: Variables that could be changed in engine installation are speed, load, and nozzle-opening pressure. These would affect the combustion line on the indicator card only as they changed temperature, turbulence, and spray characteristics. Within the range tested of these operating variables, only opening pressure would change spray characteristics enough to produce a notable effect on the combustion. It would also limit the minimum load that the engine could carry. The effects of speed and load on the spray would be negligible compared to their effects on temperature and turbulence. Combustion would be practically free from the effects of changing spray characteristics with a constant nozzle-opening pressure.

THE special spray-research apparatus of the Oil Spray Laboratory at the Pennsylvania State College and the loan of jerk-pump injection equipment through the courtesy of the United American Bosch Corporation made possible these experiments. Acknowledgments are due to these two institutions and their personnel for assistance and supervision. The laboratory apparatus, shown schematically in Fig. 1, is fully described in References 1 and 2. The injection equipment was made up of the following standard commercial units:

Fuel Pump. This was a constant-stroke, single-cylinder unit of the general design shown in Figs. 2 and 3. Oil enters the plunger space through a cylinder port and discharges through a spring-loaded delivery valve. Metering is effected by a channel cut in the plunger overrunning the inlet port. Cut-off can be adjusted to take place earlier or later by rotating the plunger with the metering rack, according to the load.

The manufacturer's specifications give the maximum pump discharge as 350 cu mm (0.0214 cu in.), which would mean 0.30 g when using oil of 0.864 specific gravity. The maximum discharge corresponds to about 100 per cent overload of a suitable engine, and never would be used. A discharge of 0.15 g with 40 per cent excess air corresponds to a cylinder size of about $5^1/_2$ in. by 7 in. Further specifications are: Plunger diameter, 9 mm, or 0.354 in.; plunger stroke, 10 mm, or 0.394 in.

Oil Line. This was a steel tube connecting pump and nozzle. The length was 36 in.; inside diameter, 0.10 in.; outside diameter, 0.25 in.

Fuel Nozzle. The nozzle, shown mounted for spray tests in Fig. 4, was of the spring-loaded differential-valve-stem type. The valve carries a small pintle which projects through the orifice. This is shown in Fig. 5. Oil issues through the annular space between pintle and orifice walls. The pressure at which the valve opens is adjusted by turning a bolt compressing the spring. Through the bolt and spring passes a small feeling pin which may be used to feel the lifting of the valve. The valve diameter was 5 mm, or 0.1965 in.; orifice diameter, 1.094 mm, 0.0431 in.; pintle diameter, 1.043 mm, 0.0411 in.; opening pressure, adjustable, 0 to 5000 lb per sq in.

Test Conditions. Table 1 is a comparison of conditions under which solid-injection equipment may operate in engines in one case and with the test apparatus of the Oil Spray Laboratory in the other case, for the three main spray tests: rate of discharge, velocity of spray, and dispersion of spray.

Oil. The oil used was Diesel fuel oil having 0.864 specific gravity and 48 sec Saybolt viscosity at 79 F.

Miscellaneous Tests

Before the spray tests proper, tests were made on leakage, line pressure, temperature rise, and metering.

Leakage and Residual Pressure. The nozzle was connected to a hand pump, and the leakage was noted. When the nozzle opening pressure was set at 900 lb per sq in., leakage was observed at all pressures down to about 300 lb per sq in., but was so slight below 400 lb per sq in. that it took some time to appear. When the nozzle opening pressure was raised to 4000 lb per sq in., the leakage became similarly slight at a pressure of about 3500 lb per sq in.

The nozzle was then connected to the jerk pump and oil line

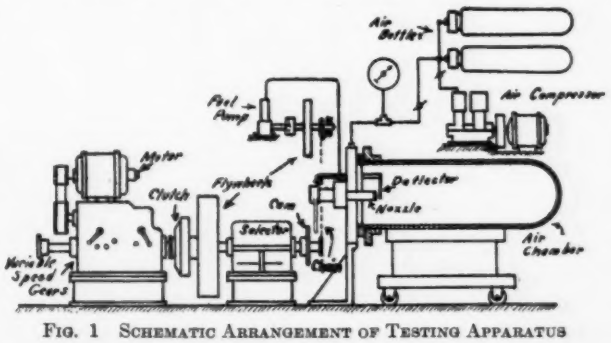

Fig. 1 Schematic Arrangement of Testing Apparatus

described, and a spring-balanced-diaphragm electrically recording pressure indicator (Ref. 3) was placed in the line at a distance of 10 in. from the nozzle. The position of the pump shaft where approximately 500 lb per sq in. started and stopped was recorded. It was found that this pressure existed for 360 deg for the range of speeds tested, 131 to 506 rpm, with a nozzle-opening pressure of 900 lb per sq in. This means that while the pump is running, the residual line pressure does not drop below approximately 500 lb per sq in.

---

[1] Assistant in Engineering Research, Pennsylvania State College. Jun. A.S.M.E. Mr. Zahn received his B.S. in Mechanical Engineering from California Institute of Technology in June, 1930, and his M.S. in Mechanical Engineering from Pennsylvania State in January, 1932. The paper is based on a thesis for the Master's Degree.

Presented at the Fifth National Meeting of the Oil and Gas Power Division of The American Society of Mechanical Engineers, State College, Pa., June 8 to 11, 1932.

Note: Statements and opinions advanced in papers are to be understood as individual expressions of their authors, and not those of the Society.

While thus normally operating, the equipment showed no leakage whatever between sprays, indicating that with this residual pressure leakage was so slight that it did not have time between successive injections to make its appearance.

Temperature Rise. Due to "working" of the oil, the issuing spray will be hotter than the oil in the pump-supply reservoir.

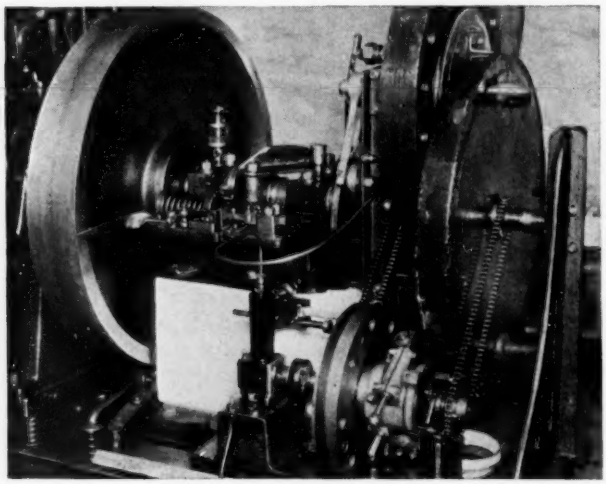

FIG. 2 MOUNTING OF INJECTION EQUIPMENT
(In this picture the spray stroboscope is also set up for rate of discharge tests.)

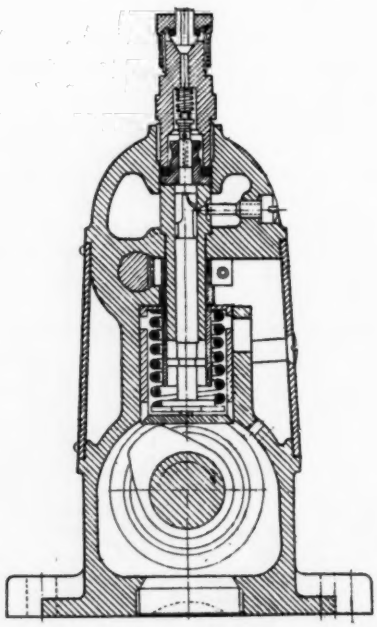

FIG. 3 TYPE OF PUMP TESTED

TABLE 1

Comparison	Spray test	Laboratory conditions	Engine conditions
Injection equipment	All	Identical	Identical
Pump speed	All	50–800 rpm	25–1000 rpm
Fuel oil	All	Identical	Identical
Air temperature	All	80 F	1500–2500 F
Air pressure, Air density	Dispersion	0–300 lb per sq in.; 0.073–1.46 lb per cu ft	450–850 lb. per sq in.; 0.95–1.17 lb per cu ft
Air pressure, Air density	Velocity	0–300 lb per sq in; 0.073–1.46 lb per cu ft	450–850 lb per sq in.; 0.95–1.17 lb per cu ft
Air pressure, Air density	Discharge rate	0 lb per sq in. (gage); 0.073 lb per cu ft	450–850 lb per sq in.; 0.95–1.17 lb per cu ft
Air turbulence	All	Not present	Present
Combustion	All	Not present	Present
Vibration	All	Less	More

The temperature rise was found to be independent of the amount of discharge, but it varied with speed, as is shown in Table 2.

TABLE 2

Speed, rpm	Reservoir temperature, F	Spray temperature, F	Temperature rise, deg
131	76	82½	6½
202	76	83	7
314	76	84	8
506	76	86	10

At higher speeds more energy is imparted in a given time; hence the oil temperatures are higher. At 506 rpm, this rise changes the viscosity of the oil from 49 to 46 sec Saybolt.

Metering. The effect of the air pressure at the nozzle and the speed of the pump on the maximum discharge were next examined. Five injections were caught in a cotton-filled cup and weighed. The averaged results are given in Table 3.

TABLE 3

Air pressure, lb per sq in.	Pump speed, rpm	Fuel discharge, grams
0	131	0.2874
	202	0.2870
	202	0.2887
	314	0.2788
	314	0.2877
	506	0.2941
Average		0.2873
200	131	0.2869
	202	0.2784
	202	0.2823
	314	0.2806
	506	0.2785
Average		0.2813
Mean of averages		0.2843

The position of the pump-throttle rack which rotates the plunger and meters the discharge was tested for partial discharges. The results are plotted in Fig. 6. "Metering rack displacement" is the distance from dead-end position, and "Discharge" is an average of several injections. At high nozzle-opening pressures there is a practical limit of minimum discharge because of missing. An injection does not take place at every revolution of the pump when the amount of discharge is too small to properly overcome the compressibility of the oil. This region is indicated by the dotted portions of the curves.

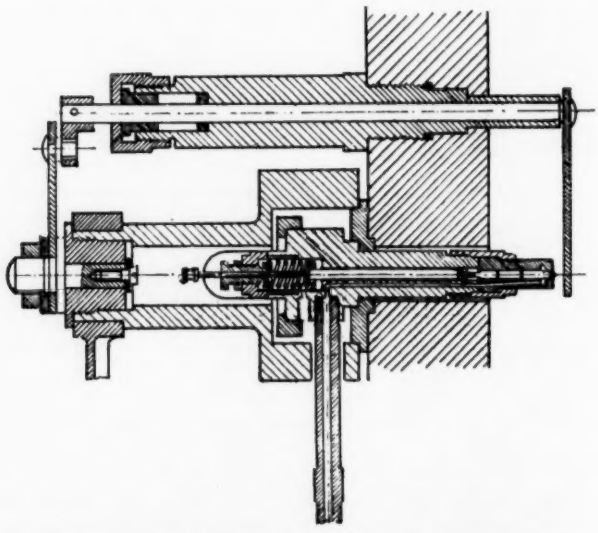

FIG. 4 NOZZLE IN MOUNTING WITH SPRAY DEFLECTOR ARM

At higher opening pressures the atomization of the spray is much finer. The best accuracy of metering was observed at an opening pressure of 2500 lb per sq in., but seems independent of speed or amount of discharge.

In the ensuing spray tests the percentages of discharge signify the following amounts of discharge:

100 per cent discharge	0.28 gram
75 per cent discharge	0.21 gram
50 per cent discharge	0.14 gram
25 per cent discharge	0.07 gram

Rate of Discharge of Spray

The rate of discharge of the injection, in grams per degree of pump-shaft rotation, was found with the spray stroboscope (Ref. 1). This apparatus consists of a disk having a small slot 2 deg wide, which revolves 1 in. in front of the nozzle. The disk is enclosed by a guard casing holding a cup (see Fig. 2). A part of the spray passes through the slot into the cup, but the remainder is stopped and drains away. The disk was chain driven at three times the pump speed through a differential gearing which permitted its phase relationship with the pump to be changed while rotating. Tests were made at atmospheric air pressure, at 131 rpm pump speed, and at 25, 50, 75, and 100 per cent discharges.

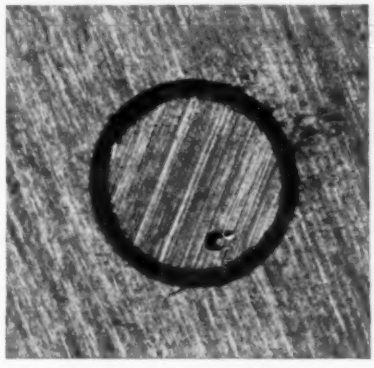

Fig. 5 Annular Orifice of the Nozzle Tested

[The annulus has an outer diameter of 0.0431 in. The inner wall is formed by the pintle (0.0411 in. dia) in the center.]

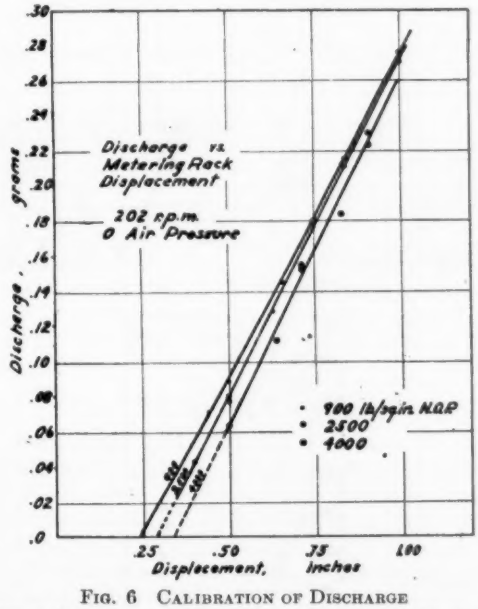

Fig. 6 Calibration of Discharge

(Metering rack displacement is plotted against the weight of discharge at three settings of the nozzle-opening pressure: 900, 2500, and 4000 lb per sq in. The dotted portions indicate the lower limits of weight of discharge.)

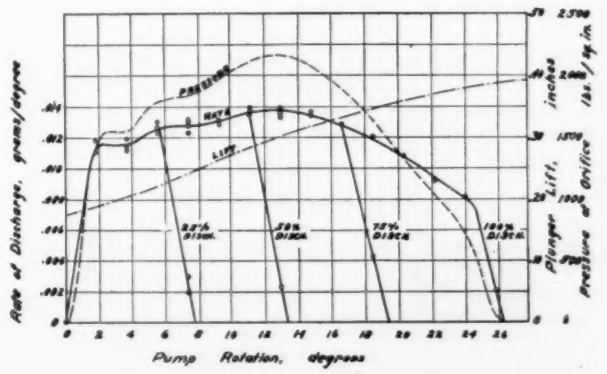

Fig. 7 Rate of Discharge

[The rate, in grams per degree of pump rotation, is plotted against pump (camshaft) rotation in degrees. The total discharges are 100% (0.28 gram), 75% (0.21 gram), 50% (0.14 gram), and 25% (0.07 gram). Speed, 131 rpm. Air pressure, 0 lb per sq in. gage. Calculated pressures at the orifice and the plunger lift have also been plotted.]

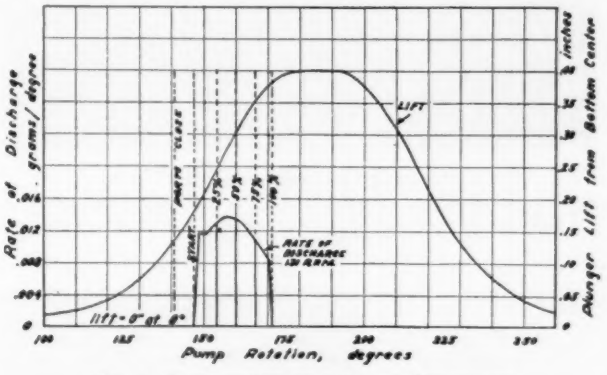

Fig. 8 Plunger Lift and Rate of Discharge

(The rate curve of Fig. 7 is here on a different scale, showing the relation of the injection period to the plunger lift and the closing of the pump ports.)

The results are plotted in Figs. 7 and 8 and show sharp beginning and cut-off of the spray. Cut-off is sharp, particularly for discharges lower than 75 per cent. No tendency to leakage is shown by the curves. Injection always begins at the same angle of pump cam, irrespective of weight or speed. The areas under the rate curves represent the weights of discharge, and upon measurement gave 0.287 g, 0.216 g, 0.139 g, and 0.068 g, at 100, 75, 50, and 25 per cent discharges, respectively, which agree within the limits of accuracy with the metering tests. The mean rate of discharge is highest at 75 per cent discharge and lowest at 25 per cent discharge, but is fairly uniform over the whole injection period.

The period of injection is nearly directly proportional to the weight of discharge, up to 75 per cent discharge.

Assuming a coefficient of discharge of 0.8 and a constant orifice area, the oil pressures back of the orifice were calculated from the rate curve and plotted in Fig. 7. The nozzle-opening pressure was 900 lb per sq in., but the maximum calculated pressure is over 2100 lb per sq in.

The lift of the plunger, obtained with a dial micrometer, is plotted in Figs. 7 and 8 to show the relative position of the cam during the injection period.

Tests at 202 rpm, not included here, gave curves very similar to the tests at 131 rpm, except that the peaks in the early part of injection were amplified.

Velocity of Spray

The velocity of the spray was found by a ballistic pendulum (Ref. 2) shown in Fig. 9. Spray impinges on the 6-in. plate and the momentum mv is recorded by a pencil line on the drum. Knowing the mass of the spray, the mean velocity was determined by

$$v = 1/m\ (MV + K)$$

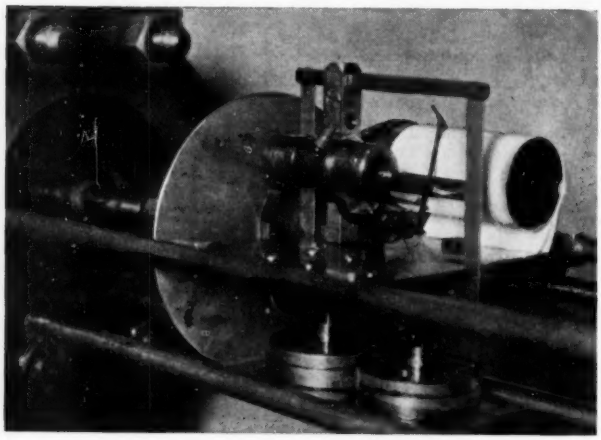

Fig. 9 Ballistic Recording Pendulum

[The spray momentum is found at various distances from the nozzle. The deflection of the 6-in. disk under the impact of the spray (from left) is recorded on the drum.]

where

- v = mean spray velocity
- m = total spray mass
- M = mass of pendulum + spray
- V = velocity of pendulum after impact
- K = frictional correction.

K was experimentally found to be 10.4 gram-meters. Unfortunately, the corrections for velocity become comparatively large when using spray masses as small as 0.28 g and 0.21 g, and introduce an uncertainty in the absolute values of spray velocity. The pendulum was designed for much greater weights of discharge.

The mean velocities were found with the pendulum at increasing distances from the nozzle in atmospheric and dense air, and plotted in Fig. 10. The issue velocities vary between 80 and 130 m per sec (262 and 426 ft per sec). In atmospheric air the velocities drop but slightly in 14 in., while in air of 200 lb per sq in. gage, corresponding to the density of air compressed 14 to 1, the drop is much greater. In both cases the curve is close to a straight line. In some tests in atmospheric air the recorded velocity is greater, not at the nozzle as would be ex-

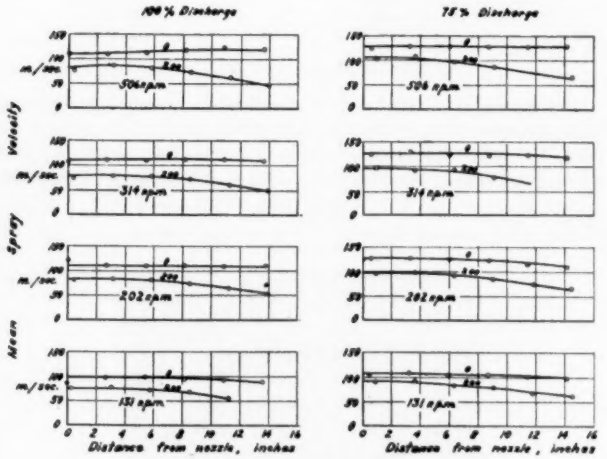

Fig. 10 Spray Velocity

[The mean velocity of the spray in meters per second is plotted against distance from the nozzle in inches. Air pressure, 0 and 200 lb per sq in. gage. Pump speed, 506, 314, 202, and 131 rpm. Weight of discharge, 100% (0.28 gram) and 75% (0.21 gram).]

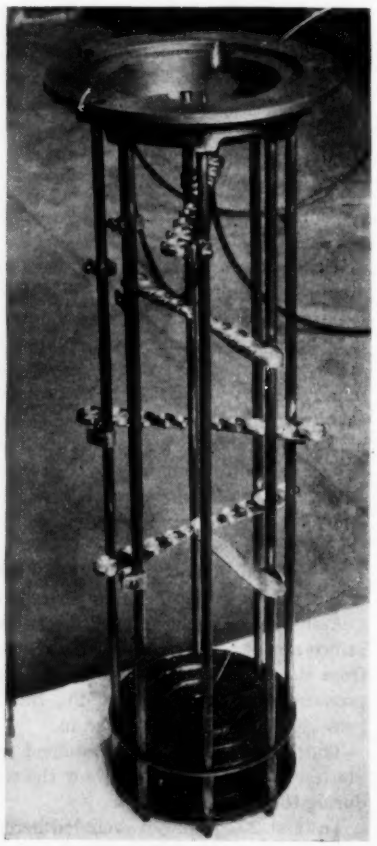

Fig. 11 Dispersion Rack

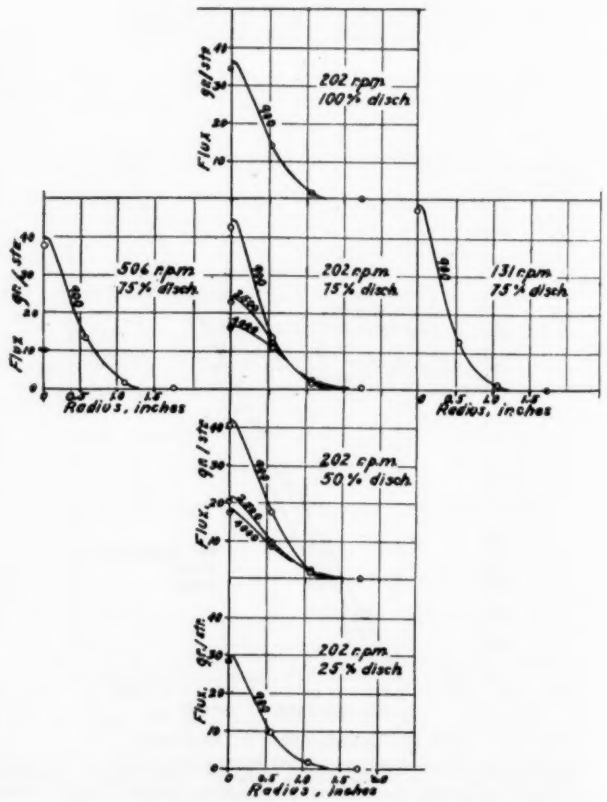

Fig. 12 Specific Flux of Spray

[Flux, in grams per solid angle (steradian), is plotted against radius from axis of spray at 7 in. from nozzle. Air pressure, 200 lb per sq in. gage. Pump speed, 506, 314, 202, and 131 rpm. Nozzle opening pressure, 900, 2500, and 4000 lb per sq in. Weight of discharge, 100% (0.28 gram), 75% (0.21 gram), 50% (0.14 gram), and 25% (0.07 gram).]

pected, but at some distance from it. This is obviously an error, caused by variation in air movement or elastic impact when the pendulum plate is too close to the nozzle.

The velocities at 75 per cent discharge are slightly higher than at 100 per cent discharge. This may be attributed to the fact, seen in Fig. 7, that the average rate of discharge at 75 per cent discharge is higher than at 100 per cent, and to possible errors in the calibration factor K. Otherwise, these curves show about what would be expected, i.e., negative acceleration becomes greater with increased distance and air pressure.

The spray velocities seem unaffected by pump speeds except at 131 rpm, at which speed all velocities are slightly lower.

It is to be borne in mind that the pendulum records the mean value of velocity; each oil particle is traveling at a different speed, ranging from zero to much greater than that recorded. Where the mean velocity is zero, however, it means that all of the oil has zero velocity; hence, it is the maximum penetration of the fuel spray. This would be at the intersection of the velocity curve with the "distance" axis.

In most actual engines it is certain that with this nozzle and setting and fuel oil, the spray would hit the walls of the combustion space. Ignition lag is considered very short if it is not more than 0.002 sec. In that time the spray would have traveled $0.002 \times 100 = 0.2$ m, or a distance of about 8 in.

At higher nozzle pressures the discharge velocity will be even higher at the nozzle, but due to finer atomization and consequent increased air resistance, it no doubt falls off more rapidly with distance.

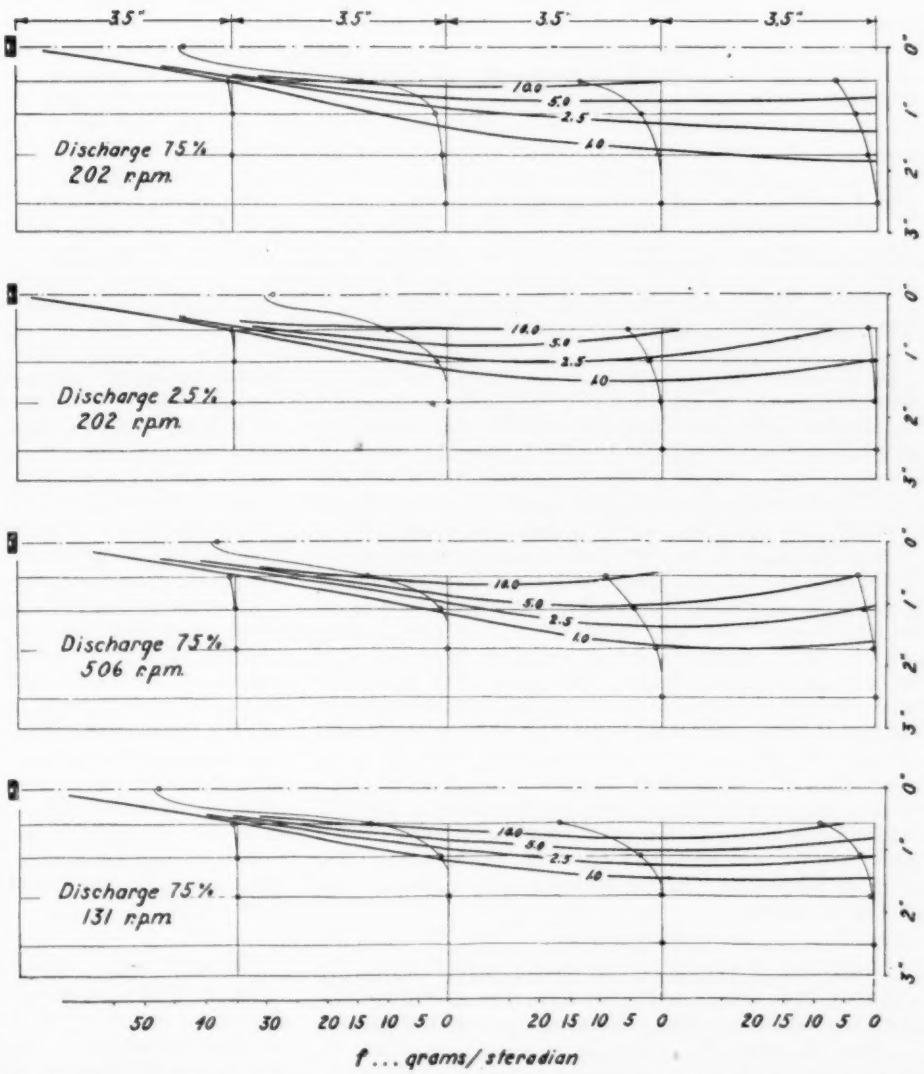

FIG. 13 SPECIFIC FLUX OF SPRAY AT SEVERAL DISTANCES, CONNECTED BY LINES OF CONSTANT FLUX

[Flux, in grams per solid angle, is plotted against radius from spray axis at 3.5, 7, 10.5, and 14 in. from nozzle. Lines of constant flux of 10, 5, 2.5, and 1 gram per solid angle connect the four flux curves. Weight of discharge, 75% (0.21 gram) and 25% (0.07 gram). Speed, 506, 202, and 314 rpm.]

DISPERSION OF SPRAY

The shape of the spray was determined with a "dispersion rack" (Ref. 2) which held small blotting pads in various positions in front of the nozzle. Two arms, each holding five pads, were placed on the rack at 3.5, 7, 10.5, and 14 in. from the nozzle, as shown in Fig. 11. For some tests, four of these arms and a fifth arm holding one pad in the center line of the spray were placed 7 in. from the nozzle.

Before each test, the axis of the rack was made coincident with that of the spray by the aid of a preliminary injection in atmospheric air. Then each pad was weighed and placed in position on the rack. The chamber was closed and filled to the desired air-pressure, and one or more injections were made. After opening the chamber, the pads were immediately weighed again. The difference in weight divided by the number of injections is the amount of oil which has been intercepted by the pad.

The weights of intercepted oil from several duplicate tests were added and divided by the total weight of discharge, giving a weight corresponding to 1 g of discharge. This specific weight, divided by the area of the pad, gives the density in grams per square inch. Dividing the density by the square of the distance of the pad from the nozzle gives a density in grams per unit solid angle, termed hereafter "specific flux."

Fig. 12 shows the distribution of spray flux (grams per steradian) at 7 in. from the nozzle. Specific flux is plotted against radius, or distance in inches from the spray axis. Lines having the properties of probability curves (Ref. 4) have been drawn through the points.

Four of these curves are again shown in Fig. 13, with similar ones taken at other distances from the nozzle.

Heavy lines connect the locations having flux values of 10, 5, $2^1/_2$, and 1 g per steradian, giving a picture of the longitudinal distribution of the spray in space.

TABLE 4 EFFECTS OF TEST VARIABLES ON INJECTION CHARACTERISTICS

	Increasing test variables					
Injection characteristics	Weight of discharge	Pump speed	Air pressure	Nozzle-opening pressure	Distance from nozzle	Remarks
Metering		None	None	Decreases	.....	See "Metering"
Mean rate of discharge	Increases slightly up to 75%	None	No test	No test	.....	See "Rate of discharge"
Start of discharge	None	None	No test	No test	.....	See "Rate of discharge"
Duration of discharge	Increases proportional to 75%	None	No test	No test	.....	See "Rate of discharge"
Velocity of spray	Slight	Decreases below 131 rpm	Decreases greatly	No test	Decreases	See "Velocity of spray"
Cone angle of spray	None	Increases slightly	Increases greatly	Increases greatly	.....	See "Dispersion of spray," Fig. 13
Portion of spray traveling 7 in.	Depends on N.O.P.	None	Decreases greatly	Depends on discharge	.....	See "Dispersion of spray"
Atomization, fineness of	Slight, if any	Slight, if any	No test	Increases greatly	Increases	Observed visually
Temperature rise of oil	None	Increases	No test	No test	.....	See "Temp. rise"

Fig. 12 shows that the nozzle-opening pressure is the most influential variable on dispersion. Increasing the opening pressure flattens out the flux curves (increases the cone angle of the spray). Speed has practically no effect. Weight of discharge has some effect. Analysis of Fig. 12 indicates that at 202 rpm a much smaller portion of the spray travels 7 in. at 25 per cent discharge than at higher discharges with the nozzle opening pressure 900 lb per sq in. At nozzle-opening pressures of 2500 and 4000 lb per sq in., this difference is noted between 50 per cent and 75 per cent discharges. The explanation of this lies in the air resistance offered to the spray; with a given opening pressure, the atomization and cone angle, and hence the total air resistance, remain constant. Decreasing the amount of issuing spray therefore increases the unit resistance encountered, and less of the spray travels a given distance. Increasing the opening pressure increases both atomization and cone angle. Hence the total air resistance increases, and the effect of decreasing the amount of issuing spray just mentioned is amplified.

Tests made in atmospheric air showed that the spray had a much narrower cone angle and penetrated much farther. The increased penetration is shown by the velocity curves at 0 air pressure in Fig. 10.

Conclusions

For the sake of conciseness, the conclusions are summarized in Table 4. The headings at the top of the table are the variables of the test conditions, while those at the side are the observed injection characteristics. The body of the table contains the effects of the test variables, considered as increasing, on the injection characteristics. For example, increasing "Nozzle opening pressure" increases greatly the "Cone angle of spray."

Application of Conclusions

The variables that could be changed in an engine installation are speed, load, and nozzle-opening pressure. These would affect the combustion line of the indicator card only as they changed temperature, turbulence, and spray characteristics. Within the range tested of these operating variables, only opening pressure would change spray characteristics enough to produce a noticeable effect on the combustion. It would also limit the minimum load that the engine could carry. The effects of speed and load on the spray would be negligible compared to their effects on temperature and turbulence. Combustion would be practically free from the effects of changing spray characteristics with a constant nozzle-opening pressure.

Discussion

E. T. Larkin.[2] The paper is an interesting disclosure of spray characteristics with certain equipment. There have been many other papers presented by other investigators over a period of years regarding various spray investigations, and as one interested in engines, the writer has often wondered how this data can be actually applied to engines and combustion-chamber design in combination with the phenomena of combustion.

Investigations of spray characteristics are only a preliminary step in the determination of oil-engine performance. Combustion is influenced by the air conditions, principally those of temperature and air motion in combination with the shape of the air envelope surrounding the spray or sprays. The air made available to that part of the spray where combustion is first started may cause an acceleration of spray velocity, or a counterflow opposing the spray movement may be formed of sufficient velocity to substantially counteract the movement of a considerable portion of the fuel. It is suggested that more advanced work correlating spray characteristics with combustion characteristics offers a very desirable field of investigation. The work up to date of spray analysis forms a very desirable background for the research which must ultimately be performed to demonstrate the possibilities of developing and controlling high efficiency in oil-engine combustion.

Edgar J. Kates.[3] The writer believes that this paper has much practical value, despite the fact that the tests were conducted in a research laboratory instead of in an actual engine. The tests showed, for one particular make of fuel pump in rather general use, the effect of variations in pump speed, fuel quantity, and nozzle-opening pressure upon such important spray characteristics as velocity of spray, cone angle of spray, and duration of discharge. Many of the conclusions, such as that spray velocity is practically independent of pump speed, are full of meaning for an engine designer and are quite valid, even though there was no combustion or air turbulence.

In actual engines there are so many variables peculiar to the engine design that fuel pump tests on any one engine cannot be used as a basis for predicting results obtainable on another engine design. In the author's tests, these extraneous variables were eliminated by testing upon an apparatus where they did not exist; this now enables an engine designer to make whatever modifications his own engine type entails.

The writer hopes that this valuable research will prove to be the forerunner of others on other makes of fuel pumps, so that engine designers may be able to choose and adapt their fuel pumps to their engines intelligently.

Edward Adams Richardson.[4] The question has been raised regarding the value of tests such as these to the engineer. Exact

information regarding performance characteristics is of great importance. However, the engineer is interested not merely in the characteristics of a piece of equipment when new and in perfect condition. The precision of the performance of the pump system tested by the author and here reported is rather amazing. The writer would like to know just how old, from the standpoint of actual use, the equipment here tested was. He would like to have tests made on the same or similar equipment after a reasonable and definite amount of service. It is very important to know, when dealing with apparatus depending largely on the precision of its construction for satisfactory performance, just how well such apparatus retains its characteristics during service. In other words, the engineer is not so much interested in the maximum performance obtainable under laboratory conditions as in the average good performance which may be expected during a reasonable life. This point has been neglected, and it is of the utmost importance. It is to be regretted that the representatives of the manufacturer saw fit to ignore one or two queries of this nature at the meeting.

Author's Closure

It is true that this paper deals only with a small part of the problem of correctly using the fuel in Diesel engines. The many designs of engine combustion chambers, each with turbulence of the air resulting from the movement of the piston and the movement of the flame front, would make a great number of tests necessary to examine these other factors with our present technique. Incidentally, a knowledge of the spray dispersion in quiet air, together with information on operating dispersion characteristics, such as can be obtained by overloading the engine and observing the soot markings, may give the engine manufacturer qualitative information on his cylinder turbulence. It is hoped to test other designs of injection systems, and loans of additional equipment for this purpose are desired.

The pressures of the air into which the test sprays are injected have little intrinsic meaning. What is desired in dispersion tests is that the density of the air shall be the same as under operating conditions. A pressure of 200 lb per sq in. was used, because at room temperature the density of such air corresponds to that in an engine compressed 14:1. Again, the issue velocity of the oil depends on the pressure difference between the oil-line pressure and the air pressure. Operating conditions may be closely approximated, therefore, simply by changing the pressure of the oil at the nozzle to compensate for the air pressure.

While the author does not know how many hours this particular pump system was operated prior to making these tests, he knows that it is about three years old. This paper does not pretend to deal with all of the important considerations of injection systems, such as wear, cost, etc., but only with the spray characteristics.

PME-55-1

Progress in Petroleum Mechanical Engineering

OIL and its products have become so powerful a factor in transportation the world over that the long-continued depression has had little effect in disturbing the petroleum market. As a result the oil industry gives every indication of leading the world out of its economic slump.[1] Of course, actually, it has affected the volume of business, and it is only because the refiner was supplied with crude contracts at low prices that he was able to maintain a profit on refined products, although even this is not generally true throughout the country. Likewise, the reduction in volume and consequent profit over operating expense and overhead has been partly offset by cuts in salaries and wages, as well as reduction in labor by reason of operation of larger units.

It is in times of depression that the refiner must look to additional economies that may be obtained, and for this reason the forward-looking refiner has continued his research work where it seemed most promising in results.

While it is the one major industry enjoying a sustained and comparatively intact market, the arrest in normal expansion due to the depression has emphasized economic weaknesses particularly during the past year, which have commanded considerable time and thought toward their elimination on the part of leading executives.

To reduce the hazards of unnecessary and dangerous competition in export fields, two conferences of major world petroleum leaders were held, which resulted in establishing a working agreement among British, Dutch, Rumanian, and American interests. The Soviet failed to join.[2] The most obvious effect of the bitterly fought tariff on crude imports to this country that was made a law last June is shown in the readjustment of domestic corporations with foreign concessions and facilities. Organizations mainly interested in the domestic market are selling their foreign holdings to those already well established in export fields. There has been a marked increase in foreign refining capacity in the year, and diversion of South American crude from our shores undoubtedly will provide an added stimulus in this direction.

In our domestic field the industry has failed to take full advantages of the sustained market due primarily to continual disturbance in crude-oil production, which did not balance supply with demand. Control systems have been set up in the various producing states, but either through lack of proper legal authority or weaknesses in the agencies, the attempts to curtail production in line with demand have not been very satisfactory. So serious is this problem that voices of leading executives have been heard at many public gatherings offering plans to curb waste and balance production with demand. Arresting attention, particularly of the engineering profession, is that of Mr. W. S. Farish, presenting "A Rational Program for the Oil Industry."[3] Briefly, his program of balancing supply with demand recognizes a compelling right of the public to a proper supply of oil and its products at reasonable prices; it recognizes the right of the public to an intelligent conduct of the oil business to insure security of employment both for the dollar and for the man; it demands the protection of the small independent operator as well as the large integrated unit; and it demands the application of sound engineering principles. Improvement toward stabilization through present efforts at control is evident and will be more so when the industry adopts some such broad program.

A disturbing factor to the domestic market is due to the ease with which taxes may be collected on motor fuels and lubricants. The ever-widening margin between retail sales price and superimposed tax is producing an additive stimulus to illicit production. Through the bootlegger, the state not only loses the taxes, but is responsible for subjecting a law-abiding industry, in which it has a direct interest, to a severe and punitive competition.

To aid in relieving general distress, the oil industry is rapidly adopting the "share the work movement," and many of the larger units are now operating on schedules of a five-day week.

The year has been marked by mergers, notably the Standard Oil Company of New York and the Vacuum Oil Company in Socony-Vacuum Company;[4] Sinclair and Prairie in the Consolidated Oil Company,[5] with rumors of a combination of the Standards of New Jersey, California, Ohio, and Kentucky afoot.[6] Meanwhile the Consolidated and Standard of California are bidding for Richfield, and the Standard of Indiana has sold its Pan-American foreign holdings, including a refinery on the island of Aruba, D. W. I., to the Standard Oil Company of New Jersey.[7] Three major refining organizations, in cooperation with a large equipment manufacturer, have pooled their patent interests in the formation of the Petroleum Distillate Corporation. The Standard Oil Development Company (of New Jersey), The Atlantic Refining Company, the Standard Oil Company of Indiana, and the Foster-Wheeler Corporation are the organizations involved, the latter acting as exclusive licensing agent for the pooled patent interests. The Southwestern Engineering Corporation has been appointed agent for the Donnelly and Jenkins processes.

Refining

"Continuing failure to reduce refining operations to accord with market demand has added to economic difficulties of the industry. Blame is in part due to distress crude seeking a market at any price and in part to a competition for gallonage prompted by a surplus refining capacity. As long as refiners are willing to sell gasoline on too wide a margin, expand into new territory, and attract new outlets by further reductions, the present disproportionate distribution costs will continue."[8]

"Flexibility, operating economy, and avoidance of patent

difficulties appear to be the guiding hands in the development and improvement of cracking-plant technology, irrespective of the value and application of cracking to the solution of the problem of maximum yield of gasoline possessing the highest anti-knock properties demanded by the automotive engine.

"The increases in both yield and anti-knock quality in cracked gasoline are attributable to a large number of new developments of the different methods of application of older ideas. A multiple type of cracking furnace, a viscosity-breaker furnace employed to produce clean cracking stock for the main furnace, and transmitting the greater part of the heat energy in radiant rather than the convection bank are some of the characteristics of new stills.

"Quenching the oil after passing the reaction chamber to reduce carbon formation; use of fractionating towers in direct connection with stills; cooking retorts . . . which yield more charging stock; reforming gasoline, naphtha, and cracking kerosene high-pressure and high-temperature operations; reforming lower hydrocarbons to produce heavier molecules of the gasoline range; use of vapor phase condition along with the liquid phase to increase the anti-knock value, are some of the features to attain the desired results in old as well as new installations."[9]

Attracting considerable attention in the industry is the recent commercial introduction of hydrogenated motor fuels and lubricants. These products are manufactured under pressures and temperatures ranging as high as 3500 lb per sq in. and 1000 F, meaning considerable advance in oil technology plant engineering, plant and safety control, and metallurgy.

The industry was skeptical of the practical operation of commercial plants because of the unheard-of advance in pressures and the hazards involved in hydrogen manufacture and handling in the process. Through the development of delicate controls and sensitive automatic safety alarms, commercial runs of one year's operation without shutdowns are cited to show the ruggedness of the catalysts and the workability of the process. Although working with oil-hydrogen mixtures at high temperatures and pressures, no lost-time accidents have occurred due in any way to the process. The commercial equipment is remarkably flexible from the points of view of feed stocks and products derived, the latter running from lubricants to aviation fuel with no coking in the process. Two new products of this process of interest are a high-flash safety fuel for aviation and marine use and high-solvency naphthas.[10] The final test of hydrogenated products, public demand in a competitive market, is now under way.

To meet the increasing demand for cracking capacity, one large Eastern refiner installed and is now operating a "tube and tank" unit of 10,000 bbl capacity. The unit has duplicate furnaces, each of 40,000,000 Btu heat capacity at normal rating, connected to a common fractionating and condensing system. This arrangement not only reduces capital investment but adds to flexibility of operation and ease of repairs to either heater without complete shutdown. The major portion of the heat is absorbed in the radiant section, and the furnace is so designed that the heat-absorption rate at no point exceeds 10,000 Btu per sq ft per hr.

The two soaking drums, designed for a working pressure of 1000 lb at 900 F, are each 70 in. in inside diameter by 40 ft high, with wall thickness of 7 in., and were hot forged and pierced from a single billet of steel—no seams or joints.

The separator is of the vertical type, 11 ft in diameter by 45 ft high, with a wall thickness of $1^3/_8$ in. designed for a working pressure of 150 lb. The fractionating tower is 12 ft in diameter and 90 ft high, weighs 325,000 lb, and has 25 bubble plates. The hot-oil charging pumps are of the crank and flywheel duplex type with outside packed plunger and are run through reducing gears by simplex, double-acting, tandem gas engines. The speed of these engines may be varied from 70 to 140 rpm by a throttling governor automatically maintaining the correct air-gas ratio.

A large mid-continent refiner is completing a 20,000-bbl combination unit for skinning and cracking, said to be the largest unit of its kind to date. This unit is designed to convert 70 per cent of the daily 20,000-bbl run into gasoline with an octane rating of 70. The only by-products of the operation will be the refinery gas and a superior grade of fuel oil having a viscosity of 150 to 200 sec at 122 F furol. Some idea of the size of this unit may be gained from the volume of one of the two furnaces, which is 74,000 cu ft, and the hourly heat energy estimated to be released is approximately 2,000,000 Btu. This unit will perform five operations: (1) Skimming. (2) Heavy virgin gasoline is separated and reformed by cracking to improve the anti-knock value and volatility. (3) Reduced crude is subjected to a viscosity-breaking operation to reduce fuel-oil quantity and provide cleaner cracking stock for the principal cracking operation. (4) The pre-processed fuel-oil charging stock is flashed to separate it into cracked gasoline, clean charging and recycle stock, and fuel oil. The clean charging stock is separately cracked in another operation to give maximum yield of high anti-knock value. (5) The various gasolines are blended and stabilized, the motor-fuel production representing 70 per cent of the mid-continent crude oil originally charged to the unit.

The demand for higher octane gasoline, calling for increased cracking capacity, has in turn called for gas- and vapor-recovery systems in economically operated plants. One large Eastern refiner has installed a recovery plant capable of processing 15,000,000 cu ft of gas daily and to recover upward of 50,000 gal of gasoline each 24 hours.[11,12,13] The year has been marked by the more general use of debutanization and stabilization plants.

Equipment manufacturers supplying the industry have kept pace with progress in refining by developing alloys resistant to heat and corrosion; new processes in heat treating and welding of pressure vessels; more sensitive instruments for measuring, controlling, recording, and providing safety in plant operation; and improved pumps and compressors to meet the increasing variety and demand of modern refinery operations.

A notable contribution by an Eastern equipment manufacturer is an improved type of heat exchanger, shown in Fig. 1. A feature is the elimination of tube sheets, so often the cause of leakage troubles, particularly where high temperatures and pressures are involved. Eliminating the tube sheets permits a better tube spacing with a view to increased heat transfer, permits the use of larger tube sizes, and by casing the tube bundle, does away with short circuiting around baffles (reduced efficiency), so often the case in the usual design. Several of these units have been in practical operation on high temperature and pressure work and have not only returned a remarkable increase in efficiency over the usual type, but demonstrated ease of inspection and tube cleaning.[14]

Because of the rapid increase in knowledge of the chemistry and technology of petroleum and its constituents made during the past year, the problem of efficient plant design for a given crude and market demand is becoming increasingly complex. "One thing is clear, however, and that is that technical advancement is fast. The difficulties of refining facilities are numerous. The problem becomes all the more intricate through knowledge

of the fact that what is selected and constructed today will in all possibility be obsolete five or six years hence, for this industry has definitely abandoned its old-fashioned 'hammer and tongs' practices."[15]

The recently issued Recommendations on Refinery Heat Exchangers by the A.S.M.E. should prove a boon to the industry in clarifying difficulties between refiners and equipment manufacturers in an increasingly important phase of development of the modern plant. Other papers of interest contributed under the auspices of the A.S.M.E. during the past year are: "Properties of Hydrocarbon Mixtures at High Pressures," by W. K. Lewis and C. D. Luke, Massachusetts Institute of Technology; "Heat-Transfer Design Data and Alignment Charts," by T. H. Chilton, Allan P. Colburn, Raymond F. Genereaux, and Harcourt C. Vernon, E. I. du Pont de Nemours & Co., and "Flow of Fluids in Closed Conduits," by R. J. S. Pigott, Gulf Oil and Refining Company.

TRANSPORTATION PROGRESS

There has been very little expansion in oil-pipe-line facilities during the year 1932. One reason is that the capacity of pipe lines had been built up to meet the peak requirements for petroleum products of 1930 and 1931. The other important reason is that the only large oil field developed during the last year was the East Texas field, which is near the Gulf Coast, and much of this petroleum was moved over the existing trunk lines or short lines built to the Gulf. The decreased consumption in petroleum products during the last year has resulted in decreased pipe-line runs. Consequently, the pipe-line industry has not expanded to any extent—which has reacted on purchases of pipe machinery and equipment. A very large amount of second-hand equipment was used in the East Texas field. It appears now that there should not be any appreciable expansion of either the gathering systems or trunk lines during the year 1933, because

(1) The existing fields should be able to supply the crude oil requirements for the coming year
(2) The consumption of petroleum products during 1933 will very likely not exceed that of 1930 to 1931, for which the pipe line capacities were built.

An oversupply of crude petroleum has resulted in state control over some of the newer and larger oil fields. This control is generally known in the petroleum industry as "proration." Until about two years ago petroleum was produced from a well to its full capacity. This practice was characterized not only by a waste of natural gas, petroleum, the lifting power of the gas, and a disorderly development of the field, but also by an economic waste in the overexpansion of production, natural gasoline, and pipe-line facilities, which had to be depreciated in a comparatively short time. Proration means that a given field is allowed a certain amount of production, and the wells, with exceptions, are allowed to produce only a prorated amount of oil in a certain period.

From the pipe-line viewpoint there is a distinct advantage of extending the life of an oil field and eliminating the overdevelopment of pipe-line facilities to take care of peak loads. There have been certain disadvantages to pipe lines in operating in oil fields which are prorated; but the orderly development of oil fields over a period of years should result in more economical and better operating conditions. As a measure of conserving the natural petroleum resources some form of proration will probably continue.

Gathering Systems

The last year has marked the further use of the gasoline-motor-driven unit for gathering oil from the many points in a new oil field. This type of unit has definitely replaced the steam pump for this service.

Just as the Diesel engine replaced the steam engine for trunk-line pumps years ago, so the gas- or gasoline-motor driven pumping unit has displaced the steam pump in the gathering system during the last two or three years. The steam pump is obsolete for this service.

Electrical Motor Drive

About the year 1926 the electrical motor came into use for driving reciprocating pumps for field gathering stations and, later in that year and the following year, the use of electrical motors was extended to driving centrifugal pumps as booster units on trunk lines. In 1928 and 1929 the electrical motor came into rather extensive use for driving centrifugal pumps on newly built trunk lines. The electrical motor was also used extensively on trunk lines for driving reciprocating pumps. During that period, pipe-line engineers in general were inclined to favor the use of the electrical induction motor.

The last two years has marked a very decided change of attitude on the part of these engineers as to the use of electrical motors. This change has been brought about by the following reasons:

(1) The rates of the electrical power companies were very complicated, and did not fit into the operating conditions of the pipe-line industry
(2) Electrical-power rates were not in competition with the power developed by the Diesel engine
(3) The electrical motor has a constant-speed motor, lacking in flexibility in operation, which could easily be obtained without penalty through the use of the Diesel engine
(4) The demand charges set up in the rates of the power companies met with considerable disfavor on the part of the pipe-line engineers and executives
(5) The cost of Diesel engines during the years 1929, 1930, and 1931 was sufficiently low to make the power rates too high to compete. The years 1931 and 1932 were marked with substitution of gas- or gasoline-motor-driven pumping units for the electrical motor, and under the existing condition, this trend will very likely continue.

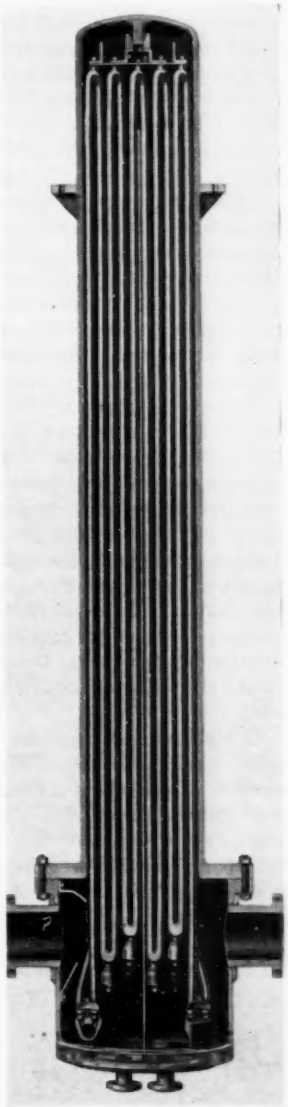

Fig. 1

[15] "The Problems of Technical Progress," *Refiner*, Oct., 1932.

Pipe

Only a small amount of pipe has been purchased by the pipe-line industry during the year 1932, because there has not been any great expansion in the industry and the surplus stock and second-hand supplies have been consumed.

In the future, seamless pipe will undoubtedly be used instead of the lap-welded pipe. In the larger sizes, both seamless and the electrically welded pipe will be used. Lap-welded pipe is almost obsolete in the pipe-line industry.

For years, the 3-in. pipe has been used generally, but it appears now that this is becoming an obsolete size, and it is likely that the industry will use 2-in. and 4-in. pipe, and 3-in. pipe will not be carried in stock after the supplies have been exhausted. Of course, 3-in. fittings will probably become obsolete with the 3-in. pipe.

During recent years there has been a tendency for pipe-line companies to use pipe with a wall thickness less than that which has been used for years. There have been some cases in which the wall thickness has been reduced very materially in the larger sizes of pipe. There has been some pipe laid with $^1/_4$-in. wall thickness, as compared with the $^3/_4$-in. wall thickness for standard pipe. It has even been suggested that $^1/_8$-in. wall thickness be used.

The wall thickness will be reduced, apparently in the 8-, 10-, and 12-in. sizes of pipe, from the standard thickness. It is the author's opinion that it may be reduced by $^1/_{16}$ in., or to the extreme of $^1/_8$ in., but the corrosion factor is of such importance that unless a satisfactory coating is developed, it cannot be reduced much lower than that. Besides the corrosion problem, there are certain mechanical problems involved that limit the reduction of the wall thicknesses of the pipe. It is known that the wall of the pipe fails from corrosion, not so much due to the pressure inside of the pipe, but to the wall being eaten through eventually; the thicker the pipe, the longer the life of it, but of course there is an economical thickness that should be used in the wall.

It has been customary in the construction of new pipe lines to purchase pipe in lengths of 40 ft, plus or minus, but the laws of the various states make it difficult to transport such lengths of pipe over the highways today. There are certain provisions also in the laws of the various states which limit the weight that can be transported on trucks. These regulations will undoubtedly limit the length of the pipe for new trunk lines which are to be built in areas where the state highways traverse the country. It is possible that some special permission could be obtained, but this remains to be worked out.

Fittings

Except in the small sizes, 2 to 4 in., the cast-iron and cast-steel fittings have become obsolete. Forged steel flanges, bends, tees, caps, etc., have come into use extensively, and undoubtedly have made the larger cast fittings obsolete. This class of material has been made obsolete by electric and acetylene welding.

Diesel Engines

Of course, the Diesel engine in the lower speed has been definitely established as the driving unit for trunk-line reciprocating pumps. One of the most important developments in the Diesel engine for pipe-line service has been the trend to the use of the solid-injection engine. This type of unit will undoubtedly be used in the future installations instead of the air-injection method.

Probably the most important development in the use of Diesel engines for pipe-line service has been the installation of some high-speed Diesel engines connected with gear increasers to centrifugal pumps. One large pipe-line company installed a 300-hp, 750-rpm Diesel unit to drive through a gear increaser a centrifugal pump with a capacity of 25,000 bbl at 430 lb pressure. This unit has the desirable features required for field-gathering pumping stations. Such a unit is portable, easily installed, has low investment cost, and has the flexibility of operation which cannot be obtained in the electrical motors. It is very likely that this type of unit will be used in the future for oil-field gathering stations, instead of the electrical motor. Its low operating cost puts the electrical motor out of competition for this service.

The high-speed Diesel-engine unit connected with a 3600-rpm centrifugal pump has brought into use the gear increaser. It looks as though a new field has been developed for gear increasers.

Many pipe-line engineers desire in a Diesel-engine installation for driving oil-pipe-line pumps to have the water-circulating pump driven off the individual unit, rather than having the circulating water supplied from some centralized pumping installation. The installation of the water-circulating pump on each unit gives more assurance that the engine will not be operated without this supply of cooling water. Generally, the pipe-line engineers have been required to figure out a drive for the circulating-water pump, and in many cases it has been driven off the gear of the pump. However, with the development of the closed water system making use of the heat exchangers, there is a desire on the part of pipe-line men to have the water-circulating pump driven off the engine, because the Diesel-engine manufacturer has not paid much attention to this feature, but it is one that is worth considering. In the future, it is likely that the pipe-line engineer will expect the Diesel-engine manufacturer to design a Diesel-engine unit which will come out equipped with a circulating-water pump and a heat exchanger for cooling the water.

Heat Exchangers for Closed Cooling-Water Systems for Diesel Engines

About three years ago the heat exchanger came into use as a part of a closed cooling-water system making use of the crude oil pumped for cooling the water. The use of the heat exchanger for this service has been extended further during the past year, and its use will very likely make the open cooling-water system obsolete. The general practice in the industry for years has been to make use of the open cooling-water system, which involved earthen or concrete reservoirs, spray systems, water towers, and an intricate system of piping. In many places pipe-line stations have inadequate or poor water supplies, and consequently the operating conditions are made difficult on account of this poor water supply or the lack of it. The heat exchanger, making use of the crude oil, has simplified this problem, because only a very small amount of water is required for the closed system, and the oil which is pumped through the trunk line does not reach a temperature much above 80 deg in the summer time, and of course as low as 32 deg in the winter time. One of the worst operating problems encountered with bad weather is cracked cylinder heads. The closed cooling-water system corrects this fault and remedies many others that are encountered, when cooling water is used for Diesel engines.

Most of the installations have been made with the heat exchanger on the suction line to the trunk line or the trunk-line crude-oil pump. Such an installation involves, usually, a booster pump on the suction line to feed the oil through the heat exchanger to the main discharge pump, because there is too much friction loss in the heat exchanger to permit the pumps to fill, if such provision is not made. During this year two installations have been made with the heat exchanger on the discharge line from the crude-oil pump. Such an installation simplified operations, and it is more economical. These heat exchangers

on the discharge lines have proved practicable and serviceable up to this time.

Motor Transport

For years, the slow heavy-duty truck has been used in the pipe-line industry, because their loads were heavy, and as a rule the roads were such that speed could not be made. The last three or four years have marked very important changes in the pipe-line industry, both as to the condition of roads and as to the load which was carried on them. A few years ago repairs in pipe lines were made by a large crew of men, and heavy materials and tools were required. The use of welding, both electrical and acetylene, has changed these methods so that today a comparatively few men are required for a pipe-line crew, and materials that must be transported are much lighter in weight. This change has eliminated the necessity of having the trucks carry a very heavy load. Likewise, during the last three years the expansion of concrete roads and graveled highways has made it possible for pipe-line trucks to make considerable speed along the route of the pipe line. For these reasons, the lighter weight truck with a higher speed is replacing the heavy-duty truck with a slow speed. The truck with a capacity of $1^1/_2$ to 2 tons, and capable of making 45 miles an hour, will replace the trucks of $2^1/_2$ to 3 tons with a speed of 18 or 20 miles an hour. This change has occurred primarily during this year, but it will be very marked within the next year or two.

It is the customary practice of the pipe-line industry to equip their trucks with either a hub or a body winch, with the necessary braking provisions on the winch. This feature should be considered in the design of trucks for pipe-line service.

One feature which is very important to pipe-line trucks is the proper clearance, because much of the time these trucks have to follow the course of the pipe-line right of way, which is not graded, and the necessary clearance must be in these trucks to avoid difficulties.

Welding

Electrical and acetylene welding has become thoroughly established in pipe-line practice. As pointed out in previous reports, welding has revolutionized the methods of constructing and repairing pipe lines. Each year marks an improvement in the welding methods, also extension of its uses. Welding has been speeded up, both in repairing lines and in the constructing of lines. An example of the efficiency of the acetylene welding in pipe-line service can be pointed out. During the last year one large pipe-line company constructed about 370 miles of line in which there were about 49,000 welds made on 8-in., 10-in., and 12-in. pipe. In those 49,000 welds only two small pinhole leaks developed. One of these pinholes in the weld was found while there was no pressure on the line. The other leak developed after oil was put in the line. This is a very interesting example of the efficiency of welding, because the welding was done over a stretch of about 700 miles, and the welds were made by many different welders under all kinds of working conditions.

Although there has been extensive use of both acetylene and electric welding in the pipe-line industry, there still remains a very worth-while field of development. Until recently, most pipe lines were laid with screw joints, and a considerable amount of mileage is buried in the ground with screw joints. These joints leak, and considerable maintenance cost is experienced on account of these leaking couplings. If it were only the leaks and the loss of the oil that the pipe-line companies have to contend with, the fault would not be so serious, but it is now known that when the oil leaks around these couplings and along the pipe lines buried in the ground, a very serious corrosion results within two to three years. Some pipe-line companies believe that 50 to 75 per cent of their underground corrosion problems is caused by the oil leaks from screw couplings. One pipe-line company has welded these couplings, so that they will not have this leakage problem during the years to come; other pipe-line companies have considered it. It remains, however, that leaking couplings develop frequently and that they must be repaired permanently. There is a certain amount of danger in making these welds by hand, because the coupling may spring a leak while it is being welded and a fire may follow. It is believed that the welding companies, either the acetylene or the electrical groups, should develop an automatic method for welding up both sides of pipe-line couplings which are on lines in service.

Automatic Pumping Stations

A few years ago there was considerable work being done by pipe-line engineers on automatic pipe-line pumping stations, and the results of their work were surprising. However, the last two years have marked an oversupply of labor, and consequently the development of automatic equipment has come to a standstill. The group of engineers working on this problem under the sponsorship of The American Society of Mechanical Engineers has felt that, until times change, when more men are required for other work, these automatic pumping stations should be held in abeyance.

Metering of Oil

The regulation of the oil fields by the states has brought into prominence the use of meters for measuring oil from oil-field gathering stations. Thus, the trend to the measuring of oil by meters will probably continue, not because of state regulations, but because of the need for such equipment in the pipe-line industry.

Pipe-Line Bridges

One of the principal maintenance problems in pipe-line work is creek and river crossings. The worst corrosion problems are found in creek crossings. Considerable trouble is experienced also in keeping these pipe-line crossings in place, because of the erosion of the banks and the changing of the channels of the creeks and rivers. To meet this problem pipe-line bridges have come into use, and it is likely that there will be a continued trend in this direction if the bridges can be made and installed at a cost which will be competitive with the replacement of the pipe and the maintaining of the creek banks for safety.

PRODUCTION PRACTICES

It is plainly evident in reviewing the progress in oil-field production and drilling practices that the proration or curtailment of oil production has continued in almost every oil field during the year. During this year, like last year, all producers of crude oil have been compelled to turn their attention to more fundamental and effective methods of attacking problems of economy on account of the low price received for the crude oil. Outward manifestations of progress are less obvious than usual, for the nature of the work accomplished and the improvements in progress have not been of the spectacular sort.

However, among some of the important improvements worthy of discussion are well-pumping equipment and operation, development of bottom-hole pressure gages, use of tapered tubing, and hoisting equipment.

Well-Pumping Equipment

Most of the progress made in this equipment has been confined to perfecting and modifying the existing equipment. Surface installations being generally adopted for heavy wells are steel rig fronts with substantial concrete foundations, rather than the

heavy timbers previously used. Each member is fabricated from structural steel sections, electrically welded or riveted, and supported by suitable concrete foundations. Anti-friction bearings are used where necessary to increase mechanical efficiency. Manufacturers of this type of equipment have responded loyally to the demands of the engineers of the oil industry by substantial improvements in design and material.

Sucker-rod manufacturers are continually improving this equipment for deep-pumping requirements. Special high-tensile alloy steels and careful heat treatment are now employed with marked results. Internal stresses in the metal resulting from the upsetting operation are removed, and the grain structure of the steel is improved by heat treatment. Combination or tapered sucker-rod strings, $^3/_4$ in. and $^7/_8$ in., are used successfully in pumping deep wells. The number of rods of each size for the string is calculated knowing the well load, and provides a more uniform distribution of stress in the rod string.

Improved field practice of thoroughly cleaning and tightening sucker-rod joints has practically eliminated joint failures, and under the most severe conditions sucker-rod service is considerably greater than that obtained several years ago.

Severe demands are made today on oil-well pumps and parts, especially in deep-well operation, and manufacturers are constantly improving or developing new designs of this equipment. Low daily allowable production has greatly furthered the adoption of the insert-type pump by many operators. Pumps of this type save considerable time in replacements or repairs, since the complete pump can be pulled from the well by pulling the sucker rods only. The diameter of the insert pump is limited by the size of tubing through which it must pass; therefore the pumping capacity is somewhat less than that of the common type pump, which is attached as a part of the tubing, and therefore possesses greater inside diameter and greater displacement. Oil-well pumps of small diameters, 1 in. and $1^1/_4$ in. i.d., are rapidly gaining favor for the pumping of wells of small daily production, 50 bbl or less. Small-diameter pumps reduce the load on sucker rods and other pumping equipment; also the maintenance expense and initial investment are considerably less than with pumps of larger diameter. In some cases daily production has been increased by use of the small-diameter pumps by increasing the pumping time, thereby maintaining a low fluid head and obtaining a constant flow of oil from the producing formation.

Vast improvements have been made in design and material of pump-valve cages, valves, and seats, in order to prevent excessive wear, thus materially reducing the number of repair jobs on many wells.

Most oil companies now keep detailed records of pump repairs, so that service obtained from all vital parts of the pump can be checked and improvements made where possible. Analyses of pump-repair costs involve material and labor charges as well as production losses arising from well shutdown time. It is therefore obvious that continuous service in operation with a minimum of shutdown time is very important from an economic standpoint.

Bottom-Hole Pressure Gages

Instruments for measuring the pressure at the bottom of the well bore are rapidly coming into general use in the major oil fields of the country. There are many types of both maximum indicating and recording gages available, some complicated and expensive, and others simple and inexpensive. Probably the simplest in design is that of using a heavy bronze tube equipped with a Schroeder tire valve in one end and an outlet valve in the other end for attaching an indicating test gage. This device, less the gage, is lowered to the bottom of the well and allowed to remain approximately 10 minutes in order to permit pressure inside and outside of the tube to equalize. It is then pulled to the top of the well and the test gage is attached, which indicates the pressure in the tube—the bottom-hole pressure, assuming no leakage has occurred.

The recording type of bottom-hole pressure gage is perhaps the most useful, since a continuous record of pressures may be obtained from the top to the bottom of the hole. There are several of this type available, and involve the use of the Bourdon tube or Sylphon bellows. The recording mechanism consists in most cases of a strip or circular chart, clock operated.

There is only one electric bottom-hole pressure gage known to the writer. This instrument is attached to the bottom of the tubing and gives a continuous reading at the surface by means of an electric cable connected between the gage and a recording apparatus at the well head. The angular deflection of a sealed helix in the instrument sets up a vertical motion, which is transmitted to the surface, of an armature moving in an inductance bridge coil. No field tests have been made with this instrument to date.

Practically all bottom-hole pressure gages are provided with maximum recording thermometers in order that corrections for temperature may be made in the pressure measurements. Petroleum engineers have determined that bottom-hole pressure measurements should be correct within 5 lb to be of most value.

Since the decline of oil and gas production is directly proportional to the decline in pressure in most oil-producing formations, bottom-hole pressure measurements are of considerable value in the study and analysis of flowing and pumping conditions, or production control.

Use of Tapered Tubing

When a well ceases to flow efficiently through 2-in. or larger tubing, conditions are frequently favorable for installing a small tapered string of tubing. The tapered string may consist of tubing as small as $^3/_8$ in. in diameter at bottom, followed by $^1/_2$, $^3/_4$, and 1 in. at the top. A thorough knowledge of the quantity of gas energy available is necessary in the design of the tapered string in order to obtain efficient flow.

The use of small tapered-tubing strings has been used successfully in extending the life of flowing wells, and is particularly adaptable to shallow wells of small production. Much closer study is now being given to the mechanics of flowing gas-oil fluids especially in regard to slippage, friction, and velocity, and it is expected that the use of tapered tubing for flowing small wells will be more widely used in the future.

Hoisting Equipment

When wells are pumped from central power, it is necessary to provide some type of hoisting equipment for removing sucker rods, tubing, or pump from the well in making repairs. Various makes of tractors equipped with winches have been in common use for many years for this purpose. During this year, however, several types of hoisting units mounted on skids or winches on trucks have been offered by manufacturers of this equipment.

Both types of units have been used successfully, and have effected great economies in the repair of wells because of the greater speed in moving from location to location, and thereby covering a larger territory in a shorter period of time than could be accomplished by tractors.

It is expected that during the next year some improvement in the financial status of the oil industry will result from the rigid curtailment of crude-oil production and possible increase in price. Such a condition should bring about expenditures for deeper drilling and development of undrilled acreage. With deeper drilling, the engineers of the oil industry will be confronted with the problem of providing equipment of proper design and material for accomplishing the work economically and efficiently.

PME-55-2

Heat-Transfer Design Data and Alignment Charts

By THOMAS H. CHILTON,[1] ALLAN P. COLBURN,[2] RAYMOND P. GENEREAUX,[3] AND HARCOURT C. VERNON,[4] WILMINGTON, DEL.

A search was made, during a research program on heat transfer, for the best available methods for the prediction of heat-transfer coefficients and for means of simplifying design calculations. The equations selected or developed on film coefficients are given in the paper for gases flowing in turbulent motion inside tubes, for gases flowing across tube banks, for free convection outside horizontal cylinders and at vertical surfaces, and for condensing vapors. Alignment charts are given for the solution of these equations. A simplified method of designing gas-heat exchangers was worked out on the basis of one of the equations for the heat-transfer coefficient, and a chart is also given for pressure-drop calculations made in designing heat-transfer equipment.

IN the course of a research program on heat transfer, a search was made for the best available methods for the prediction of heat-transfer coefficients and for means of simplifying design calculations. Equations developed or selected from the literature for film coefficients are presented in this paper for the following cases: Gases flowing in turbulent motion inside tubes; gases flowing across tube banks; free convection outside horizontal cylinders and at vertical surfaces; and condensing vapors. Alignment charts are given for the solution of these equations in which the properties of the fluids are included. A simplified method of designing gas-heat exchangers was worked out on the basis of one of the equations for the heat-transfer coefficient, and a chart representing this relationship is given. A chart is also given for pressure-drop calculations made in designing heat-transfer equipment.

While alignment charts are not relied upon ordinarily for extreme accuracy, the precision attainable is ample for engineering computations, and they afford an easily obtainable check on the order of magnitude of a given quantity. Most of the charts here presented are a combination of ordinary alignment charts with line-coordinate charts, which have been found convenient for the representation of data on any physical properties for which a straight-line function can be found by a choice of suitable coordinates (12).[5] The units employed are those customary in the chemical industry.

Table of Nomenclature

D = diam, in in.
M = mass velocity, thousands of lb per hr per sq ft of cross-section = $3.6\,G$
G = mass velocity, lb per sec per sq ft of cross-section
m = weight rate, thousands of lb per hr
P = pressure, in atm abs
Δp = pressure drop, lb per sq in.
ΔH = pressure drop, in. of water
f = friction factor in pressure-drop equation
L = length, in ft
Z = viscosity, in centipoises
w = density, lb per cu ft (on pressure-drop chart)
ρ = density, lb per cu ft (on heat-transfer chart)
c_p = specific heat at constant pressure, pcu[6] per lb per deg C = Btu per lb per deg F
h = heat-transfer coefficient, pcu per hr per sq ft per deg C = Btu per hr per sq ft per deg F
Δt = temperature difference, deg C
Δt_{mean} = logarithmic mean-temperature difference, deg C
t = temperature, deg C
N = number of tubes in parallel
k = thermal conductivity, pcu per hr per sq ft per (deg C per ft) = Btu per hr per sq ft per (deg F per ft)
β = coefficient of thermal expansion, per deg C
λ = latent heat of evaporation, pcu per lb = calories per gram = (1/1.8) × Btu per lb

Friction Loss in Pipes

The chart for pressure drop in pipes, Fig. 1, is based on the Fanning equation, which is in the units here employed:

$$\Delta P = \frac{0.0004\,fLM^2}{wD} \quad \ldots\ldots [1]$$

Values for the factor f have been assumed to follow a relation with Reynolds' number expressed by the equation

$$f = 0.034\,(Z/DM)^{0.22} \quad \ldots\ldots [2]$$

over the usual range of turbulent motion, i.e., for moderate velocities of other than highly viscous liquids or highly compressed gases. That this is approximately true can be seen when Equation [2] is plotted, as for instance, on the curve of Mc-

[5] Numbers in parentheses apply to references at the end of the paper.

[6] The symbol pcu = pound-centigrade unit.

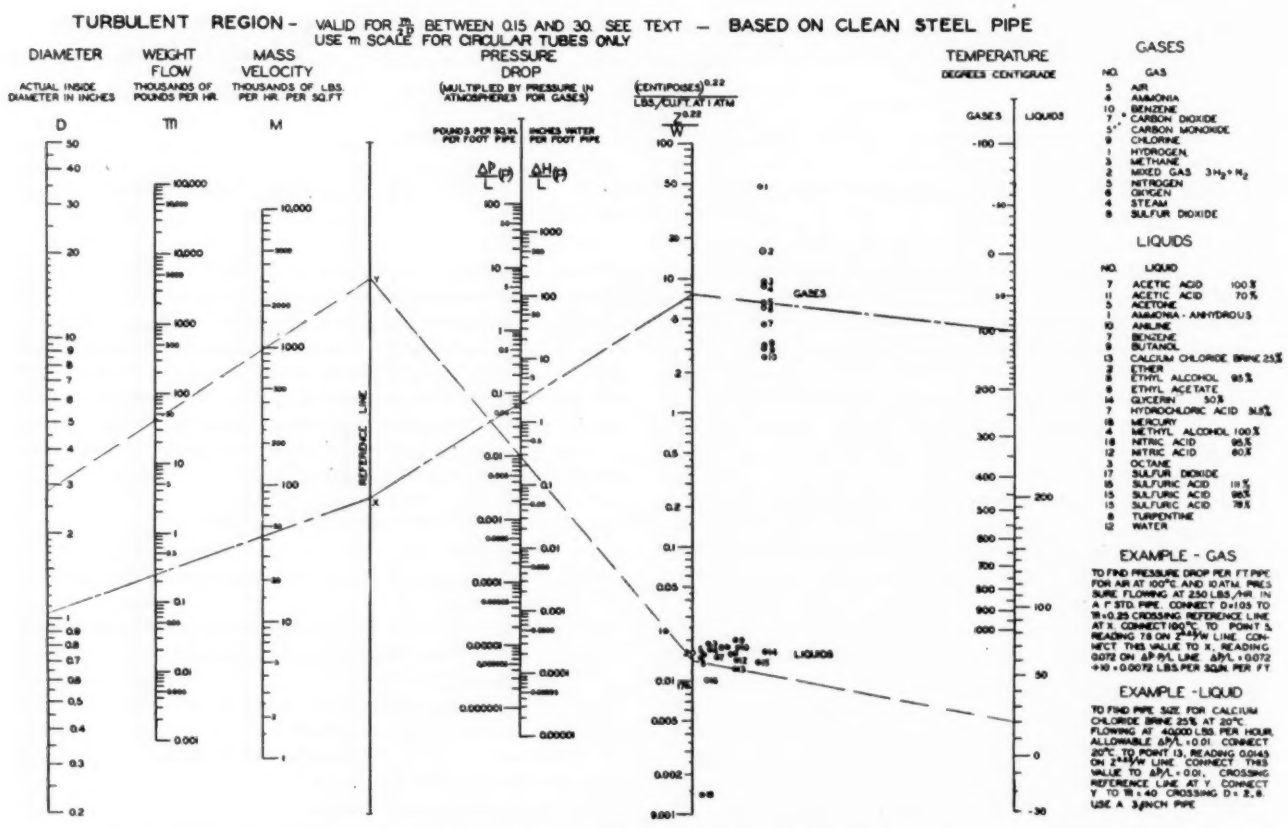

FIG. 1 FLUID FLOW, PIPE FLOW CHART (WEIGHT UNITS)

Adams and Sherwood (7). The chart does not therefore hold for the extreme turbulent region, above $DM/Z = 5500$, where, for commercial pipes, the friction factor appears to assume a constant value of about 0.0053, or for viscous flow, below $DM/Z = 28$. To determine whether the chart is applicable, values of the Reynolds number may be calculated. Alternatively, these extreme cases can be solved directly by the ordinary slide rule, since the equations do not involve fractional exponents:

For viscous flow:

$$\Delta P = \frac{0.0000186\ LZM}{wD^2} \quad \ldots\ldots\ldots\ldots [3]$$

For the extreme turbulent region:

$$\Delta P = \frac{0.0000212\ LM^2}{wD} \quad \ldots\ldots\ldots\ldots [4]$$

Of the results obtained by one or the other of these equations and by the chart, the less favorable should be taken; that is, the higher pressure drop, larger diameter, or lower capacity.

The friction-factor values are for commercial-steel or wrought-iron pipe in good condition. Allowance for roughness can be made, if desired, by adjusting the pressure drop in proportion to the expected friction factor.

It should be noted that for gases the value on the chart is the pressure drop (in lb per sq in. or in in. of water) multiplied by the absolute pressure (in atmospheres), so that to obtain the pressure drop from the scale reading, this product is to be divided by the absolute pressure.

For other than isothermal flow, the temperature to be used is the arithmetic mean temperature of the main body of the fluid. For the absolute pressure, the arithmetic mean of inlet and outlet pressures should be used.

Points can be added for substances not listed on the chart by connecting two values of $Z^{0.22}/w$ with corresponding temperatures and noting where the lines cross.

Notice also that the three left-hand scales are not independent, but may be used to give the third from any two of the values in the equation:

$$m = \frac{\pi}{4}\left(\frac{D}{12}\right)^2 M \quad \ldots\ldots\ldots\ldots [5]$$

This applies, of course, only to circular sections. The chart may be used for other sections by employing the M scale only and substituting for D the "equivalent diameter" (equal to four times the free cross-sectional area divided by the "wetted" perimeter).

HEAT TRANSFER, GASES FLOWING IN TUBES

The equation recommended (2) for predicting heat-transfer coefficients for gases in turbulent flow inside tubes is:

$$h = 13.3\ c_p Z^{0.2}(M^{0.8}/D^{0.2}) \quad \ldots\ldots\ldots\ldots [6]$$

At low velocities, the heat transfer is likely to be determined by free convection. Free convection may be controlling even above the critical velocity (especially at high pressures). In case of doubt for vertical tubes, the free-convection coefficient may be predicted by the chart of Fig. 6 for vertical surfaces and the result used when higher than the values from the chart representing Equation [6]. Equation [6] is for the convection coefficient only and does not include radiation from solid surfaces or gas radiation, which may be appreciable for CO_2, SO_2,

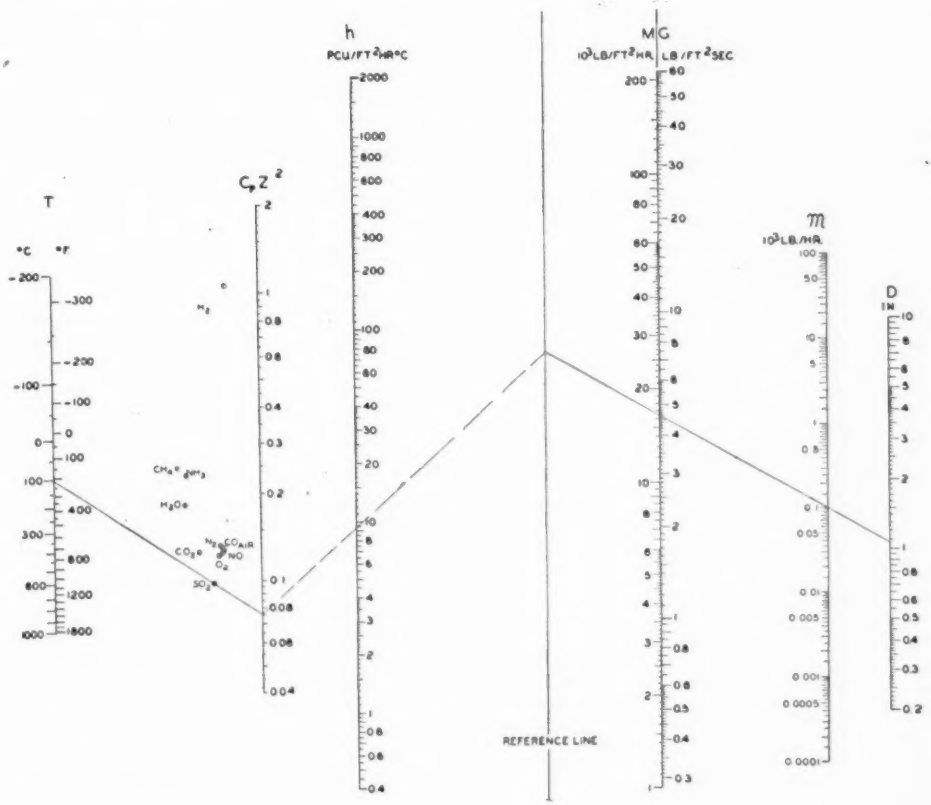

FIG. 2 GASES THROUGH TUBES
[Film coefficient, $h = 13.3\ c_p Z^{0.2}(M^{0.8}/D^{0.2})$. Example: 16,300 lb per sq ft per hr of SO_2 at 100 C average temperature flowing through a tube with 1.06 in. inside diameter. Align 1.06 on D with 16.3 on M to intersect reference line. The crossing at m gives the weight flowing per hour in the tube. Align 100 on T deg C with SO_2 to intersect $cZ^{0.2}$. Connect this with the reference-line intersection. The crossing on the h scale gives the film coefficient, 94 pcu per sq ft per hr deg C.]

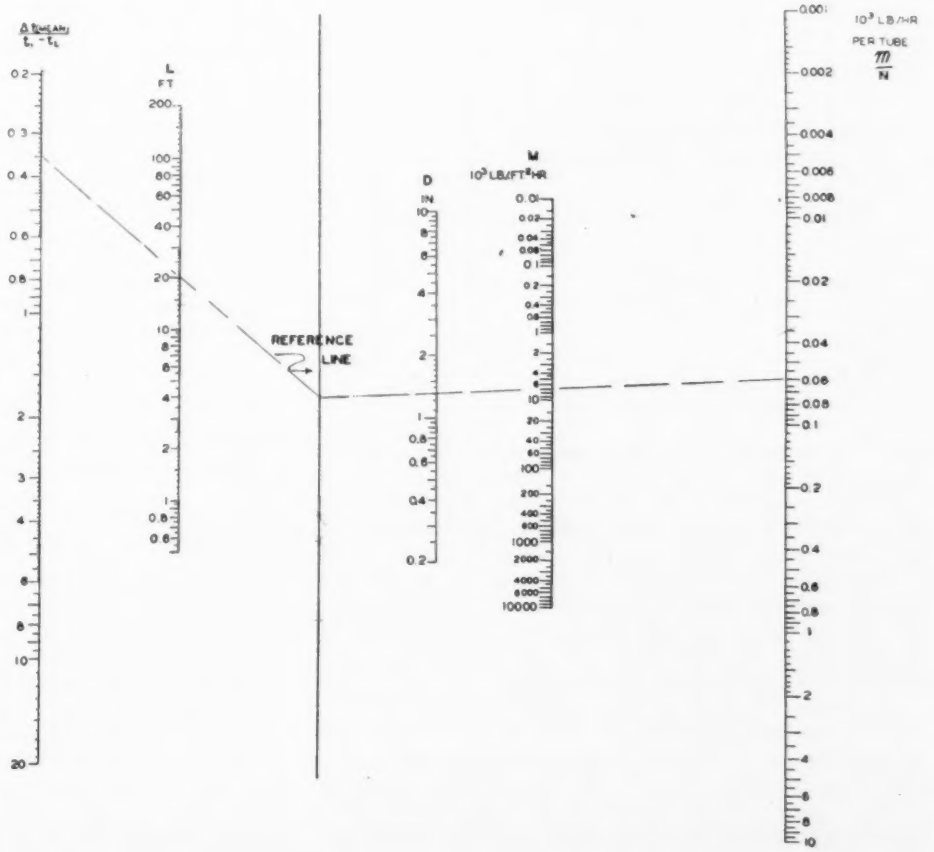

FIG. 3 GASES THROUGH TUBES
[$L(\Delta t\ \text{mean})/(t_1 - t_2) = 9.94\ (m/N)^{0.2} D^{0.8} = 3.51\ M^{0.2} D^{1.2}$, derived from $1000 m c_p (t_1 - t_2) = 5.94\ c_p (M^{0.8}/D^{0.2})\ A\ \Delta t$. Example: Required to heat 600 lb of gas per hr under the following precalculated conditions: Initial temperature 20 C, final 120 C; initial temperature difference to tube 40 C, final 30 C. Then, $\Delta t_{\text{mean}} = (40 - 30)/(\ln 40/30) = 34.9$ and $\Delta t_{\text{mean}}/(t_1 - t_2) = 0.349$. Assume 1.3 in. i.d. tubes; assume economical M about 7. Align 1.3 on D with 7 on M. This gives m/N about 0.06. With $0.06 \times 1000 = 60$ lb per hr per tube, then 10 tubes will be required. Align 0.06 on m/N with 1.3 on D to reference line, thence to 0.349 on $\Delta t_{\text{mean}}/(t_1 - t_2)$. This gives 20.2 on L. The tubes must be 20 ft long.]

NH_3, and H_2O and should be determined from curves of Hottel (5). No allowance has been made for an entrance effect on heat transfer, although an increase may be obtained by unusual entrance conditions.

Equation [6] has a theoretical basis, being derived from the Reynolds analogy equation (18) by substitution of practically the same expression as that given for the friction factor. It is in agreement with data of Nusselt (11) and of a number of other investigators. Data in the literature on the effect of temperature, aside from gas radiation, are very discordant, some being higher and others lower than the effect corresponding to the change in $c_pZ^{0.2}$ with temperature. This latter representation of the temperature effect has a theoretical basis and furthermore checks with that used in Weber's equation (19).

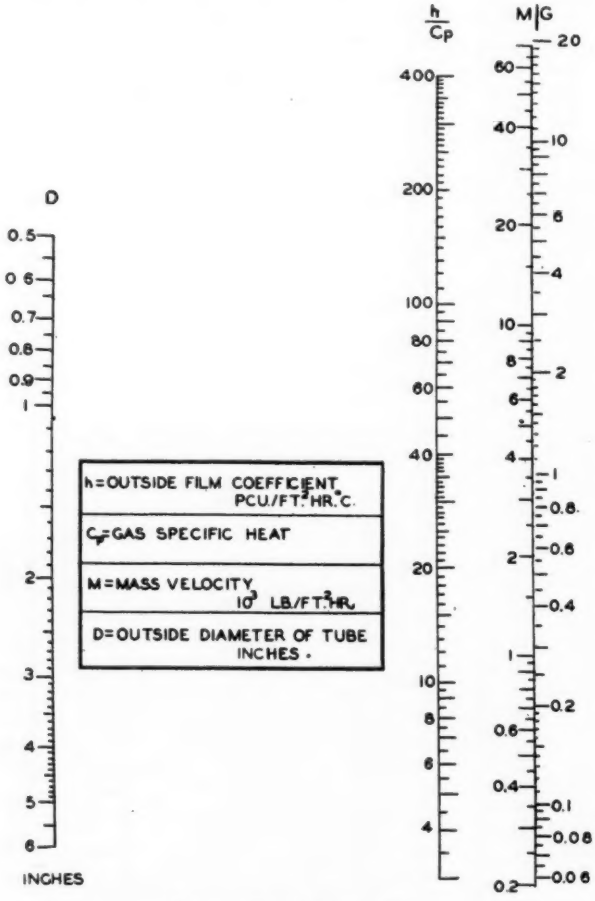

FIG. 4 GASES ACROSS TUBES

The use of the chart, Fig. 2, representing Equation [6], is explained by the example shown thereon. As on the pressure-drop chart, points can be added by joining two values of the function $cZ^{0.2}$ with their respective temperatures for the substance in question. Again as on the former chart, the M, m, and D scales are not independent and the m scale applies only for circular tubes. For other sections the M and D scales can be used, substituting equivalent diameter for D.

If a further simplified equation, originally obtained by F. C. Blake, of the Experimental Station, from some of the same data as was Equation [6], is used for the heat-transfer coefficient, a heat-balance equation can be set up from which the dimensions of an exchanger can be calculated directly in terms of the mean-temperature difference and the temperature rise, on the assumption that the gas film is the controlling resistance. The equation

$$h = 5.94\ c_p(M^{0.8}/D^{0.2}) \quad [7]$$

is equivalent to Equation [6] for air at 20 C ($Z = 0.018$), and should therefore be applicable to other gases consisting chiefly of nitrogen at moderate temperatures; it will be conservative at high temperatures. The heat transferred to or from the gas per hour may be expressed in either of two ways:

$$1000\ M\left(\frac{\pi D^2}{4 \times 144}\right) c_p\ (t_1 - t_2) = h\left(\frac{\pi DL}{12}\right) \Delta t_{mean} \quad [8]$$

Substituting for h by Equation [8], noting that Δt_{mean} refers to the temperature difference from wall to gas, and simplifying, we obtain:

$$3.51\ M^{0.2}\ D^{1.2} = L\ \frac{\Delta t_{mean}}{(t_1 - t_2)} \quad [9]$$

This relationship is represented by the chart, Fig. 3. The example given illustrates the method of making a calculation.

The main advantage of this chart is that it permits the rapid calculation of numerous alternative designs, without separate calculation of the cross-section and surface area of the exchanger at each step. In designing an exchanger, the value of $\Delta t_{mean}/(t_1 - t_2)$ is generally fixed in advance, and the number and dimensions of the tubes are required. The recommended procedure is then to start with a value of M somewhere near the optimum from the standpoint of cost of power for inducing the flow and fixed charges on the exchanger. Formulas for calculating the optimum velocity have been derived by Lewis, Ward, and Voss (6) and by Schack (16). It may be noted that the optimum M increases with the two-thirds power of the density of the gas being handled; for air at atmospheric pressure it ranges from $M = 5$ to $M = 12$. The designs as derived from the chart should be checked for pressure drop by Fig. 1.

An important consideration which can be derived from Equation [9] is that a given ratio of length to diameter will give approximately the same value of $\Delta t_{mean}/(t_1 - t_2)$, influenced only to a small extent by the mass velocity or the actual length.

The three scales D, M, and m/N on this chart are not independent, and apply only for flow inside circular tubes.

GASES FLOWING ACROSS TUBES

The following formula for the heat-transfer coefficient for gases flowing at right angles to tube banks was derived by F. C. Blake from data of Reiher (13) and of Carrier (1):

$$h = 16\ c_p\ M^{0.7}/D^{0.3} \quad [10]$$

The coefficient given applies for more than three rows of staggered tubes. For other arrangements, the following table gives factors by which the predicted coefficient is to be multiplied:

Spacing	Number of rows	Factor
Staggered	>3	1.0
Staggered	3	0.9
Staggered	2	0.8
In line	>3	0.75
In line	2–3	0.7
Single tube	–	0.75

The mass velocity is calculated on the minimum cross-section, or the free area between baffles at the closest approach of the tubes in an average row. The factor for a single tube has been adjusted to conform to the results of Drew and Ryan (4).

The data on which the equation and chart are based are from tests on flow directly at right angles to the axis of the tubes. It is not known what factors should be applied for a baffled exchanger with a moderate number of rows of tubes;

the gas coming up around the baffle is not always flowing at right angles to the tube, and some allowance should be made for this effect. Equipment manufacturers recommend factors as low as 0.5 to be applied to the calculated coefficient. Natural convection may, for cases of low velocity or high pressures, give rise to higher coefficients than predicted by this equation.

The alignment chart for this equation, Fig. 4, takes the simplest form, of three parallel scales. An example is scarcely necessary.

Free Convection

Coefficients for heat transfer by free or natural convection depend on the properties of the fluid and the temperature difference, and the alignment charts for the equations developed are particularly good examples of the advantages of the method of plotting here employed.

For heat losses from horizontal cylinders the equation:

$$h = 100 \sqrt[4]{\frac{\beta \rho^2 k^3 c_p \Delta t}{ZD}}. \quad [11]$$

agrees with data cited by Rice (14) and Nusselt (11) for tubes of ordinary diameters (not for fine wires).

It is of importance to notice, since h varies as the square root of the density, that gases at high pressures give high coefficients by natural convection, as shown by the example given on the chart, Fig. 5.

To illustrate the use of the chart for liquids, the following values may be used as a check: water, at 40 C, $\Delta t_m = 20$ C, $D = 1.4$ in.; $\Delta t_m/D = 1.43$; $h = 105$.

No allowance has been made for scale and dirt films, which may offer considerable resistance in stagnant or slowly moving liquids. No allowance, likewise, has been made for the effect on the coefficient of placing tubes in a vertical row as in a cooling coil in a tank of water; a somewhat lower coefficient will probably be obtained than predicted by this equation. Perhaps, as below, the sum of the diameters in the vertical row should be used instead of the diameter of a single tube.

The coefficient for heat transfer by natural convection at vertical surfaces may be represented by an equation somewhat similar in form, proposed by Colburn and Hougen (3):

$$h = 71 \sqrt[3]{\frac{\beta \rho^2 k^3 c_p \Delta t}{Z}} \quad \ldots\ldots\ldots\ldots\ldots\ldots [12]$$

For air, this equation agrees with that of Rice (15).

A similar alignment chart, Fig. 6, is given for estimation of the coefficient for a number of common fluids. In addition to the example shown, the following may be used as a check (compare with the example in Fig. 5): ammonia at 200 C, $\Delta t_m = 100$, $P = 10$ atm; $P^2 \Delta t_m = 10{,}000$; $h = 5.2$. Note that at 1 atm the coefficient would be only 1.1.

No scale is shown on the reference line on these two charts, since it can be seen that the function is complicated. For adding other points, the equation is best solved for two temperatures, using the appropriate properties of the substance in question, and noting where the lines cross which connect the values of h so obtained with the respective temperatures.

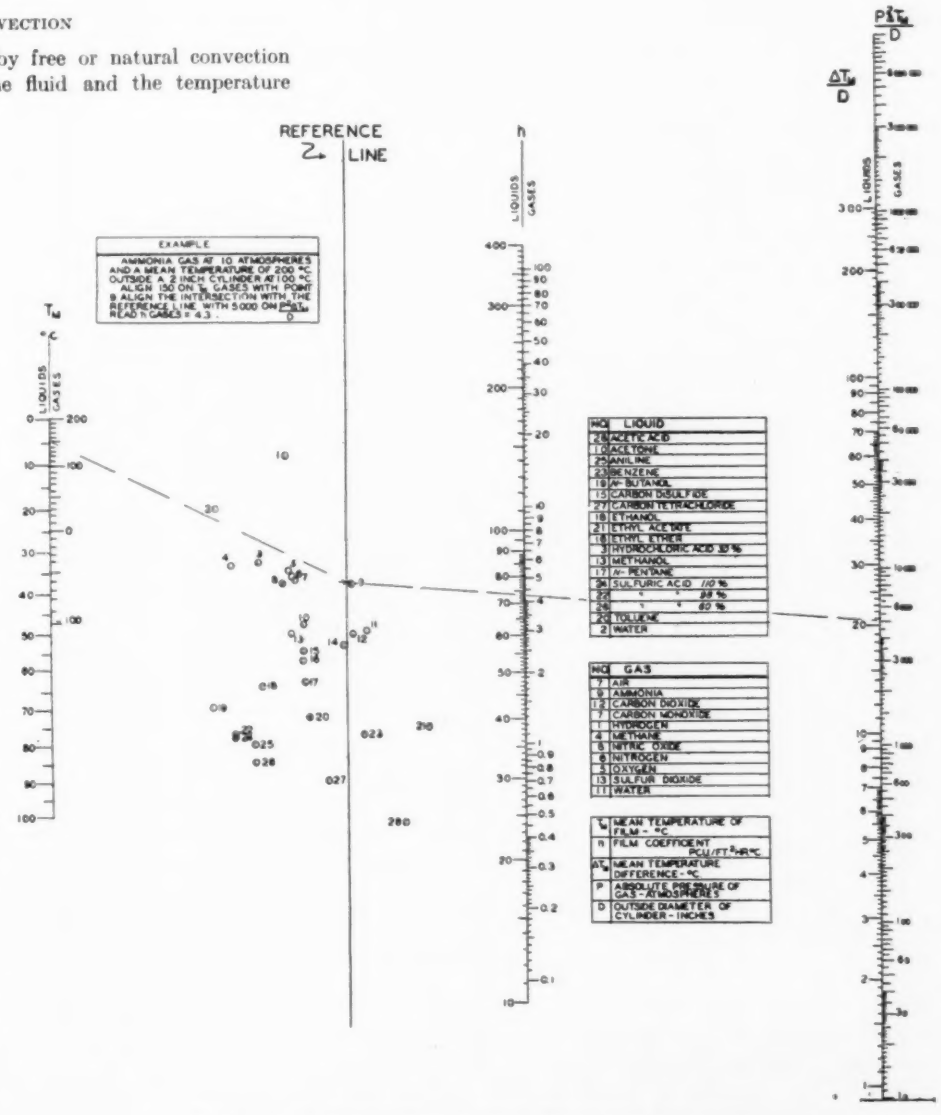

Fig. 5 Free Convection, Outside Horizontal Cylinders
[Film coefficient of heat transfer, $h = 100(\beta \rho^2 k^3 c_p/Z)^{1/4}(\Delta t/D)^{1/4}$.]

Neither of these equations includes radiation from the solid body or from polyatomic gases.

Condensing Vapors

Coefficients for the condensation or pure vapors are ordinarily high in relation to those for other resistances in heat exchangers. The following equations, due to Nusselt (10), give minimum values to be used as a guide. These equations are based on the

resistance to the passage of heat offered by the layer of condensate forming on the surface and flowing in viscous motion under the influence of gravity; they are, therefore, different for horizontal and for vertical surfaces.

For vertical surfaces:

$$h = 105 \sqrt[4]{\frac{\lambda \rho^2 k^3}{ZL\,\Delta t}} \quad \ldots\ldots\ldots\ldots\ldots [13]$$

For horizontal tubes:

$$h = 152 \sqrt[4]{\frac{\lambda \rho^2 k^3}{ZD\,\Delta t}} \quad \ldots\ldots\ldots\ldots\ldots [14]$$

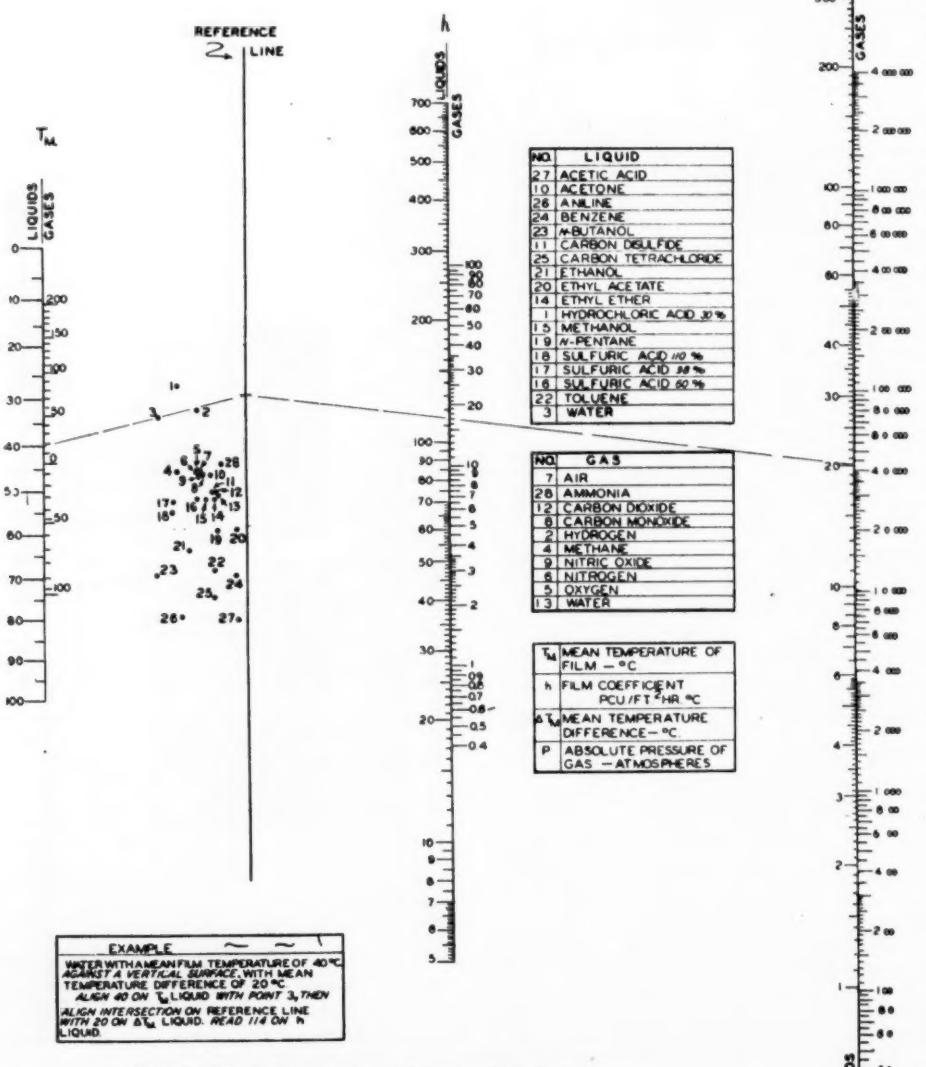

FIG. 6 FREE CONVECTION, VERTICAL SURFACES

[Film coefficient of heat transfer, $h = 71(\beta\rho^3k^2c_p/Z)^{1/3}(\Delta t)^{1/3}$.]

The value of Δt to be substituted in these equations will generally have to be estimated or obtained by trial and error, in consideration of the other resistances in series; it represents the temperature drop across the film, from saturated vapor to wall surface. The height of vertical surface, in feet, is represented by L; and the diameter of the tube, in inches, or the sum of the diameters of tubes in a vertical row, by D; the temperature called for is the average film temperature.

These equations are solved graphically on the chart, Fig. 7. An important conclusion obtained by inspection of the chart is that steam and ammonia give high coefficients, but most organic vapors give very much lower values.

Four properties are combined in the substance points on the chart. Points for other substances can be located by solving the equations for two temperatures where the properties are known.

There is evidence that these equations give conservative values for pure vapors moving at high velocity, or condensing on vertical surfaces of such height that turbulence is induced in the condensate film, though quantitative expressions for these effects are not available (8). Condensation of water on oily surfaces, forming drops instead of a continuous film, also gives high values (17).

The presence of even small percentages of non-condensing gas, however, reduces the coefficients markedly. With increasing concentrations of non-condensing gas, the resistance as calculated for the condensate layer soon becomes negligible, and the problem calls for solution on the basis of diffusion. For a theoretical treatment of this problem and empirical equations for air-steam mixtures, reference is made to the work of Colburn and Hougen (3).

ACKNOWLEDGMENT

The advice of Prof. W. H. McAdams in the selection of equations, the construction of the charts, and the preparation of this paper is gratefully acknowledged.

Discussion

W. W. KRAFT.[7] The authors have made a worth-while contribution to the design engineer in the charts. Work of this character has a double value. It reduces the labor involved in the calculation of optimum design of heat-transfer equipment and it simplifies the correlation of test data with sound theoretical equations. With such correlation, problems in design of heat-transfer equipment can be attacked with increasing confidence, and real advance in design should result.

W. S. PATTERSON.[8] The authors have prepared a very interesting paper and several simple and time-saving alignment charts. They refer to the equations and the charts as representing the "best available methods" for prediction of heat-transfer coefficients to be used in the design of commercial heat exchangers, but do not qualify this statement with data obtained on such apparatus. The conditions under which such equipment must operate and be tested are much different from those conditions under which most of the data were obtained from which the authors' equations and charts were developed. One of the biggest problems always facing the designer of commercial heat exchangers is to use the equations developed from data obtained in a scientific laboratory and at the same time to allow for the different conditions such as shape, size, length, material, and cleanliness of the heat transfer tubes or elements, combination of transverse and longitudinal fluid flow, combination of con-

[7] The Lummus Company, New York, N. Y.

[8] Air Heater Engineer, Combustion Engineering Corporation, New York, N. Y. Mem. A.S.M.E.

duction, radiation and convection heat transfer, presence of variable and perhaps unknown amounts of foreign material or vapors in heating or heated gases, and so on almost indefinitely.

Tests conducted by the writer's company on plate-type air preheaters with plates spaced $^1/_2$ in. and 1.0 in. apart showed that the friction loss between the plates does not vary with the mass velocity to the same power as does the pressure drop caused by entrance to and exit from the heater elements. An equation was developed, from these test results and application of the principle of dimensions, which agrees in form and gives practically the same results as the equation which would result from substitution of the authors' Equation [2] for f in their Equation [1], with the exception that the spacing between the plates was used directly in the equation instead of equivalent diameter. The end losses, however, vary directly as the square of the mass velocity and may amount to a large portion of the total pressure loss, depending on the length of the passages and the abruptness of the entrance to and exit from them. In the case of short tubes rolled into tube sheets or projecting through glands the end losses may be greater than the friction loss through the tube, which is the only portion that can be determined from the authors' equation or chart. Substituting Equation [2] for f in Equation [1], it will be found that the pressure drop due to friction varies inversely as the 1.22 power of the diameter of the tube. In an exchanger with $^1/_2$ in. internal diameter tubes or with plates spaced $^1/_2$ in. apart the accumulation of $^1/_{32}$ in. of scale or soot would therefore increase the friction pressure drop about 50 per cent. This example shows the importance of allowing for roughness and the accumulation of scale or other deposit.

The authors' Fig. 2 chart checks very closely with total transfer rates obtained on air heaters with 1-in. plate spacing, but gives values too high for the closer spacings. This is due to the fact that transfer rates on plate-type heaters as measured by the writer's company have been found to be independent of the spacing between the limits of $^1/_2$ in. and $1^1/_4$ in., which may be due to the fact that the radiation effect, though small, decreases with the spacing and tends to neutralize the effect of the spacing on the convection transfer rate.

In connection with the use of Equation [10] and the Fig. 4 chart the writer does not believe that such a method can be used for various tube spacings without applying some factor to take care of the variable ratio of tube diameter to tube spacing. This chart gives heat-transfer coefficients which are too high for economizers or boilers, in which equipment the tubes are generally not less than 2 in. in diameter and spaced not closer than 1.75 diameters, center to center.

Wherever the writer has mentioned air preheaters in the foregoing discussion, this refers to the power-plant type handling flue gas and air at temperatures not in the average case exceeding 800 F.

Authors' Closure

The authors appreciate Mr. Patterson's remarks with regard to allowance for accumulation of dirt, soot, scale, etc., on heating surfaces, and for other losses in pressure than that due to friction. These allowances will of course have to be made by the experienced engineer for the particular conditions encountered.

With regard to effect of the ratio of tube spacing to tube diameter, correlations of test data of several investigators, which we hope shortly to publish, afford a substantial check on the validity of Equation [10] for ratios of clearance between tubes to tube diameter of from about 1:6 to 4:1, a range of twenty-fourfold. We trust that Mr. Patterson will find opportunity to publish the original tests referred to on economizers, and also those on plate-type heaters with variable spacings.

PME-55-3

Semi-Luminous Flame Obtained With Heavy Domestic Fuel Oil in a Specially Designed Furnace

By P. L. MIKESKA,[1] SCHENECTADY, N. Y.

Some advantages of the semi-luminous flame for oil-burning furnaces are taken up in the early part of the paper. To assist in understanding some of the mechanics involved in obtaining the semi-luminous flame, the diagrammatic sketch, Fig. 2, labels a few of the happenings shown in Fig. 1. Fig. 2 shows four main branches, A, B, C, and D, coming off from the flame. Each of these branches has in it several blocks labeled with some of the factors involved. Branch A deals with oil atomization, primary air, and initial chemical reactions. Branch B deals with secondary combustion air, final chemical reactions, etc. Branch C explains the thermal setting for proper flame temperature. Branch D takes up the specially designed steel boiler made necessary to coordinate properly the many factors involved (such as proper size and correct proportion of the combustion chamber) to obtain the clean, quiet, efficient semi-luminous flame.

A FULLY LUMINOUS FLAME has dense gases or carbon particles in suspension, so there is danger of sooting wherever these gases or particles come into contact with relatively cool boiler surfaces; but such a flame gives off considerable heat by radiation. A non-luminous flame, on the other hand, permits the combustion reactions to be more nearly completed before the gases reach the combustion-chamber outlet; but this flame has very small capacity for giving off heat by radiation.

It was desired to incorporate in oil-burning furnaces the non-sooting characteristics of the non-luminous flame and the good radiation characteristics of the luminous flame. The semi-luminous flame, pictured in the section through the oil furnace (Fig. 1), does this. Since the flame has good radiation characteristics, less secondary heating surface is required and the boiler is lighter as well as less expensive.

An inspection of the flame will tell different stories to different people. Many will think of nothing more than oil, air, and the flame they see. Some, of course, think of the many problems that were involved in the development of such a flame. Then, too, there is the group that has considered the fundamental importance of the combustion efficiency of the sources that provide for our human comforts; but they, perhaps, have given little thought to the problems involved. To assist in understanding some of the mechanics involved in obtaining the semi-luminous flame, the diagrammatic sketch (Fig. 2) labels a few of the happenings shown in Fig. 1. Fig. 2 shows four main branches, *A*, *B*, *C*, and *D*, coming off from the flame. Each of these branches has in it several blocks labeled with some of the factors involved. Branch *A* deals with oil atomization, primary air, and initial chemical reactions. Branch *B* deals with secondary combustion air, final chemical reactions, etc. Branch *C* explains the thermal setting for proper flame temperature. Branch *D* takes up the specially designed steel boiler made necessary to coordinate properly the many factors involved (such as proper size and correct proportion of the combustion chamber) to obtain the clean, quiet, efficient semi-luminous flame.

Some Advantages of the Semi-Luminous Flame

Reference has been made to the facts that the semi-luminous flame is non-sooting and is of good radiation characteristics. With a luminous flame there is the probability of a combustion roar if all the combustion air is admitted through a nozzle along with the oil; non-luminous and semi-luminous flames, if properly handled, can be burned with quietness. This quiet flame is further possible because of the symmetry, which does not permit pockets in the combustion chamber where small explosions might take place, resulting in noisy as well as inefficient combustion.

Progressive combustion, symmetry of the whole arrangement, and proper coordination of the various design factors make possible not only a clean, quiet flame, but one that is highly efficient, for it becomes possible to control many of the different variables that enter into combustion, even the combustion air. Such things as draft variations and the like do not materially affect the operation. Some of the well-known requirements of proper combustion are:

1 Enough air should be admitted to assure sufficient oxygen for complete combustion.

2 The combustible should be admitted in as finely divided a state as practicable, and should be admitted at the proper time and place.

3 Complete combustion should be obtained with a minimum of excess air.

4 Air should be admitted at the proper time and in such a way that the oxygen of the air comes into intimate contact with the combustible.

[1] Air-Conditioning Department, General Electric Company. Jun. A.S.M.E. P. Lawrence Mikeska was born in Beeville, Texas, July 28, 1904, and after graduating from the Beeville High School, he attended the University of Texas. During his junior year he was elected to membership of Tau Beta Pi, and in 1928 was graduated from the university with a B.S. in M.E. In September of that year he entered the test and general course given by the General Electric Company at Lynn and Schenectady. After about a year on test, he was transferred to the engineering general department, Schenectady, where he became associated with that group of men from this and other departments responsible for the development of the company's domestic oil furnace. As the development neared completion, Mr. Mikeska was transferred to the works laboratory, and when the air-conditioning department was organized he was taken into that department.

Contributed by the Utilization Committee of the Petroleum Division and presented at a meeting, New York, N. Y., March 15, 1933, of the Metropolitan Section of The American Society of Mechanical Engineers.

Note: Statements and opinions advanced in papers are to be understood as individual expressions of their authors, and not those of the Society.

5 The gaseous mixture must be maintained at or above its ignition point until combustion is complete, by making use of the proper thermal setting.

6 Combustion space of adequate size and proper shape must be provided so that the gases can expand in the proper fashion during the combustion period.

An examination of these various points will reveal that there are many ways to burn oil. Knowing what had been done in a general way with oil combustion, effort was concentrated on trying hundreds of arrangements to burn oil. Finally the semi-luminous flame, employing the impact-expansion principle in two main stages, together with progressive combustion, was adopted.

Fuel oil must have its area enormously increased or be in a gaseous form in order to burn. This can be checked by throwing a lighted match into a small open vessel of the heavier domestic fuel oil; the oil will extinguish the match flame. If the same oil is broken into particles with a small atomizer, however, it can be ignited with a match.

Atomization, Primary Air, and Initial Chemical Reaction

Of the four main branches shown in Fig. 2, branch *A*, which deals with oil atomization, primary air, and initial chemical reaction, will be taken up first.

Motor Compressor. The oil-burner mechanism consists of a motor compressor and burner head, as shown in Fig. 3. A section of this mechanism is shown in Fig. 4. The whole unit is mounted on top of the boiler with a single nut, as shown in Fig. 1.

The driving power for the motor compressor, Fig. 5, is furnished by a quiet induction-type motor. The motor, with hardened and ground shaft, drives a multi-vane fan, the oil pump, and the air compressor without employing any intermediary gears or belts. The small eccentric pump near the lower end of the shaft is an oil pump; the larger eccentric pump just above it is the air compressor. The air compressor takes a small part of the air drawn in by the blower and compresses it for use in the nozzle; this will be taken up in more detail later. The lower part of the motor compressor forms a pressure chamber which contains both oil and air under the pressure necessary to force them through the burner head for atomization. Within this chamber is a float valve which automatically maintains the correct level of the oil in the chamber. Near the motor-compressor oil outlet to the nozzle is a valve for adjusting the rate of flow of oil to the nozzle. The oil pump was designed to produce sufficient suction for drawing in the oil from a storage tank. The pump is capable of producing sufficient negative pressure (suction) in the oil-supply line to raise the oil 15 ft, and the oil pump is self-priming.

Screen Anti-Siphon Valve and Surge Chamber. Because of the suction produced by the pump in the motor compressor, the oil from the tank is drawn through a screen anti-siphon valve, which is placed between the burner and the oil-storage tank. The screen valve is to prevent the siphoning back of the oil and to remove any dirt that may be in the oil. After passing the screen valve, the oil is drawn through the supply line to the motor compressor until it reaches a surge chamber located just ahead of the entrance of the oil line into the motor compressor. This chamber absorbs any shocks caused by pulsation that might come from variations in the flow of oil in the supply line, thus eliminating any noise from this source.

Some of the Main Parts and Functions of the Motor Compressor. Referring to Fig. 5, the oil after passing through the surge chamber enters the motor compressor unit and is conveyed from that point through a tube within the pressure chamber to the oil pump. Only a small part of the oil passing through the oil pump comes from the suction line, since a bypass valve is used on the intake side of the pump. This bypass valve, which is float controlled, regulates the proportion of oil taken from the pressure chamber and the supply line. The major part of the

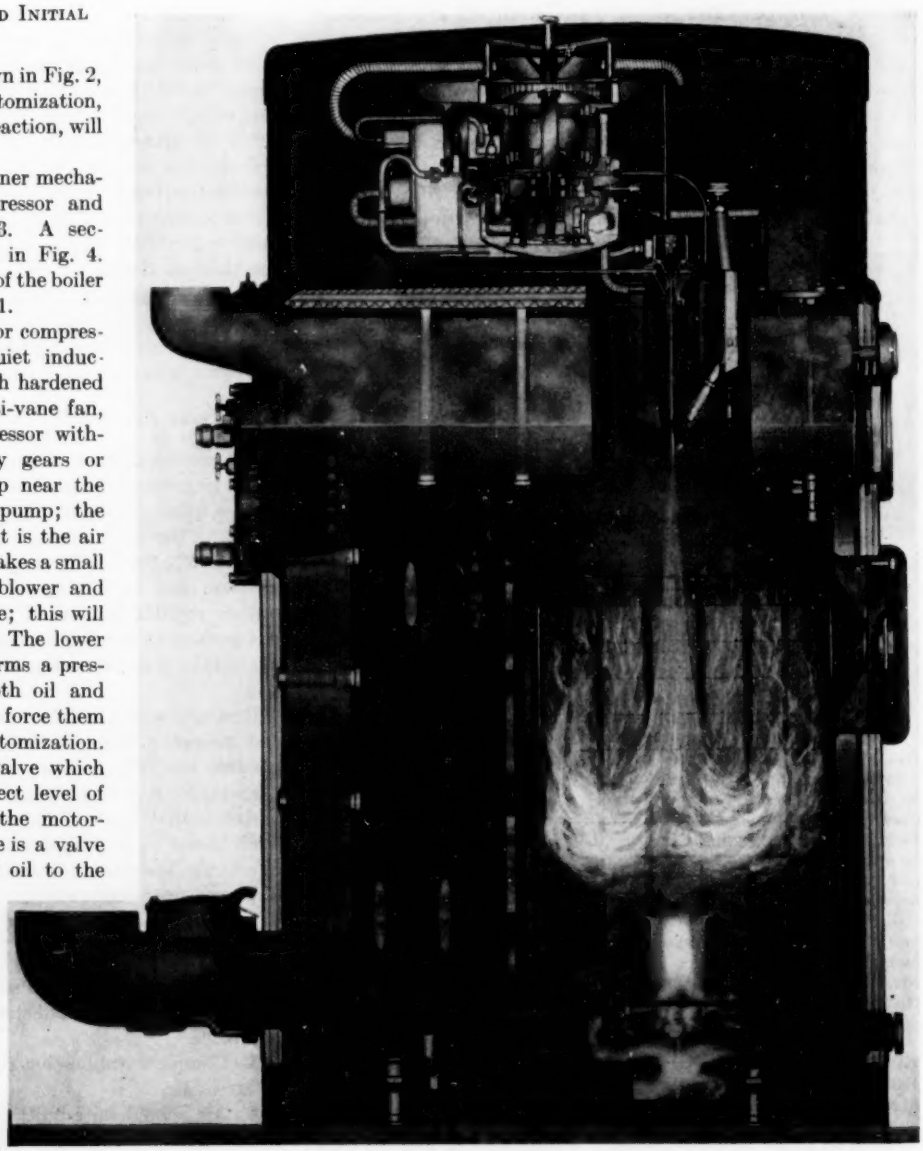

Fig. 1 Section Through Oil-Burning Heating Furnace, Showing Semi-Luminous Flame

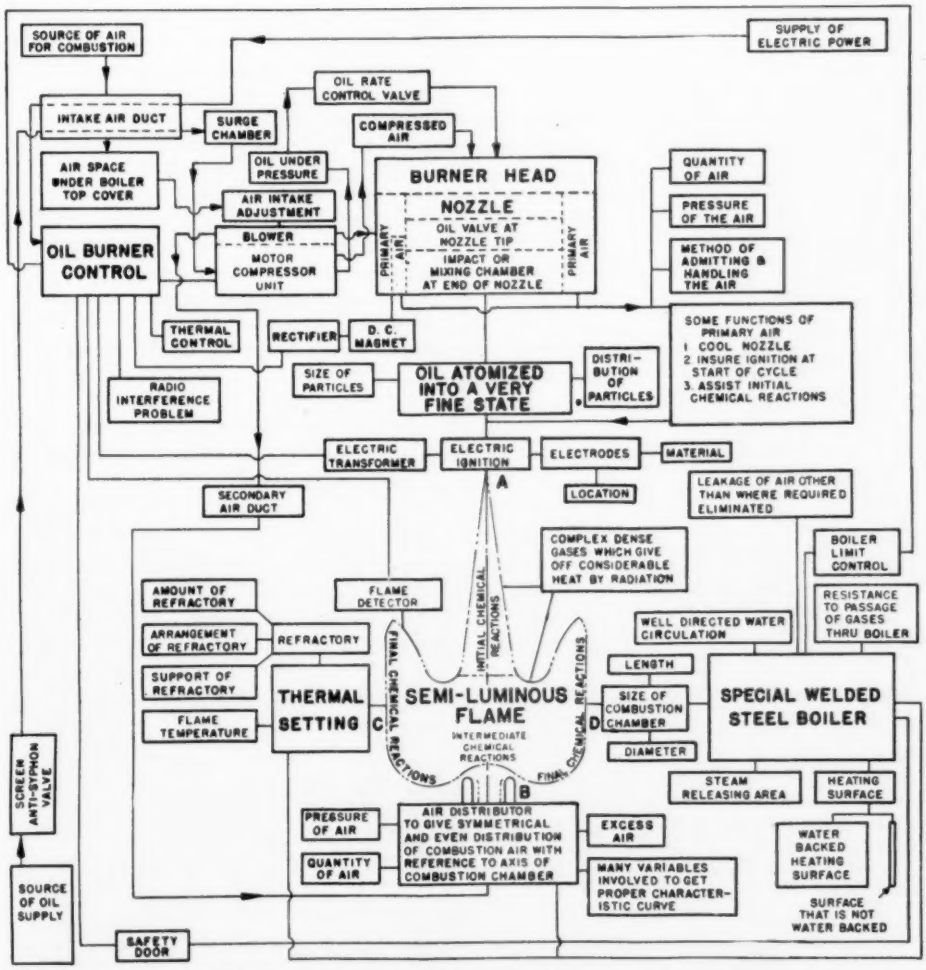

FIG. 2 DIAGRAMMATIC SKETCH OF THE SEMI-LUMINOUS FLAME
(Obtained with heavy domestic fuel oil in a specially designed furnace.)

oil is taken from within the screen of large area mounted below the oil pump in the pressure chamber. The oil is pumped out through an exhaust check valve to the main part of the pressure chamber outside the screen.

The check valve or exhaust valve is of the spring-loaded diaphragm type, which is simple in construction, reliable in operation, and designed to operate at 2 lb per sq in. gage. The two main functions of the check valve are to prevent air from being forced back to the oil pump, which would reduce the priming ability of the pump, and to prevent foaming of the oil in the pressure chamber when air is drawn from the supply line and discharged from the pump during priming. If the oil level in the pressure chamber is high enough to cause the float to open the bypass valve, no oil is taken from the supply line and the full capacity of the oil pump is used in circulating oil within the pressure chamber through the large area screen. During steady operation, the float maintains an oil level in the pressure chamber at a point where the oil passing through the pump is divided between that drawn from the supply line and from the pressure chamber, in such a way that the oil from the supply line equals the amount delivered to the nozzle.

The air compressor previously mentioned discharges into the space in the pressure chamber above the oil. Hence a uniform pressure exists throughout the pressure chamber, and it is by means of this pressure that the oil and compressed air are forced to the nozzle of the burner head.

The oil that feeds to the burner nozzle flows through a tube which extends below the level of the oil in the pressure chamber, as shown in Fig. 5. This tube leads into a valve by which the rate of flow of oil to burner nozzle is regulated. The oil then flows through a hole drilled in the main casting, and thence outward to the copper tube which leads to the burner nozzle.

Air Vent in Oil Line. In the vertical path of the oil just beyond the oil valve is a small vent hole. This vent leads to the chamber under the motor and serves to remove any included air from the oil after it passes the oil-rate adjusting valve. A small amount of oil also flows out through the vent, but this oil serves as a seal and lubricates the air compressor.

Lubrication of Motor Compressor. In fact, the fuel oil is used to lubricate all the parts of this mechanism automatically—it can be seen that oil is supplied to the bearings under pressure. Further examination of Fig. 5 will show that the shaft on which the rotating parts are mounted has a hole drilled up the center. Since the lower end of the shaft ex-

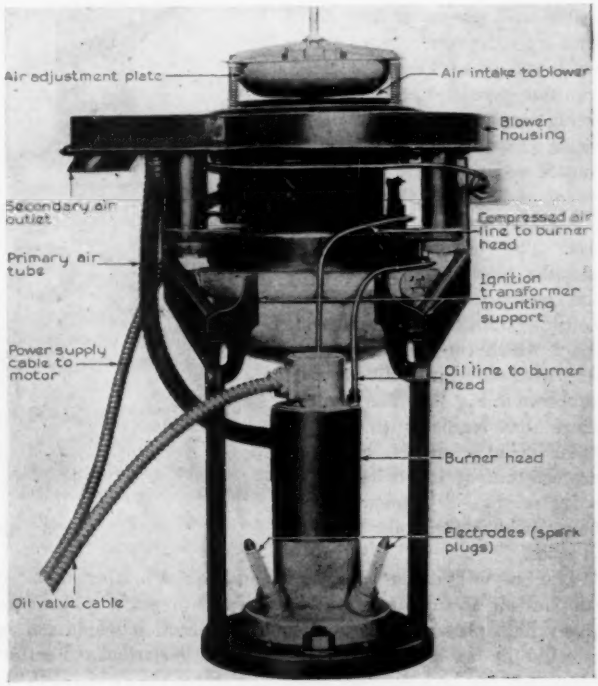

FIG. 3 OIL BURNER, FRONT VIEW

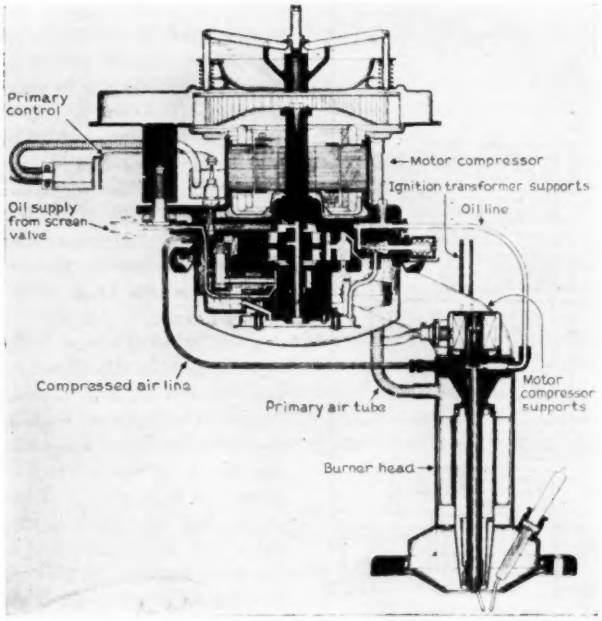

FIG. 4 OIL BURNER, SECTIONAL VIEW

tends below the oil level in the pressure chamber, oil is forced through this hole by the pressure in the chamber. This serves to lubricate under pressure all the bearings, and the air compressor through radial holes drilled in the shaft.

Intake Air Duct. The air used for combustion enters through louvers in the right-hand air duct at the side of the boiler and passes up the air duct into the space under the boiler top cover (Fig. 6). The resulting circulation of the entering air maintains a cool ambient temperature for the oil burner and the control shown on top of the boiler (Fig. 1).

Adjustment of Combustion Air. The combustion air enters the blower at the top of the motor-compressor blower housing through an annular space which can be varied in size by an air-adjustment plate, as shown in Fig. 3. The small shaft that regulates this annular opening to the blower projects out of the boiler top cover so that adjustment can be made with the boiler cover in place.

the unit by the natural draft of the chimney when the oil furnace is shut down. Thus the loss of stored heat in the boiler is very low during "off" periods. This, of course, is highly desirable where a boiler may be used periodically—as, for instance, in heating domestic hot water and the like.

As shown in Fig. 2, the blower supplies air through two separate paths. The smaller part of the two volumes, called primary air, blows through a flexible metal hose connecting the blower housing and the burner-head housing. Less than 10 per cent of the air used for combustion goes through this path.

The rest of the air supplied by the blower is conveyed through the secondary air duct to the air distributor located in the center line of the combustion chamber, as shown in Fig. 6. The details of the air distributor will be covered in the description of branch *B*.

The main functions of the primary air are to cool the nozzle, to supply enough oxygen so that the oil can be ignited, and to take part in the initial chemical reactions. More detailed information on these items appears later.

The air regulator (Fig. 3) at the blower intake controls both the primary and the secondary air in the correct proportion, regardless of what the oil rate may be set for in gallons per hour.

Air Supply for Air Compressor. In addition to the primary and secondary air which leaves the blower directly, there is a small amount taken from under the blower housing and drawn

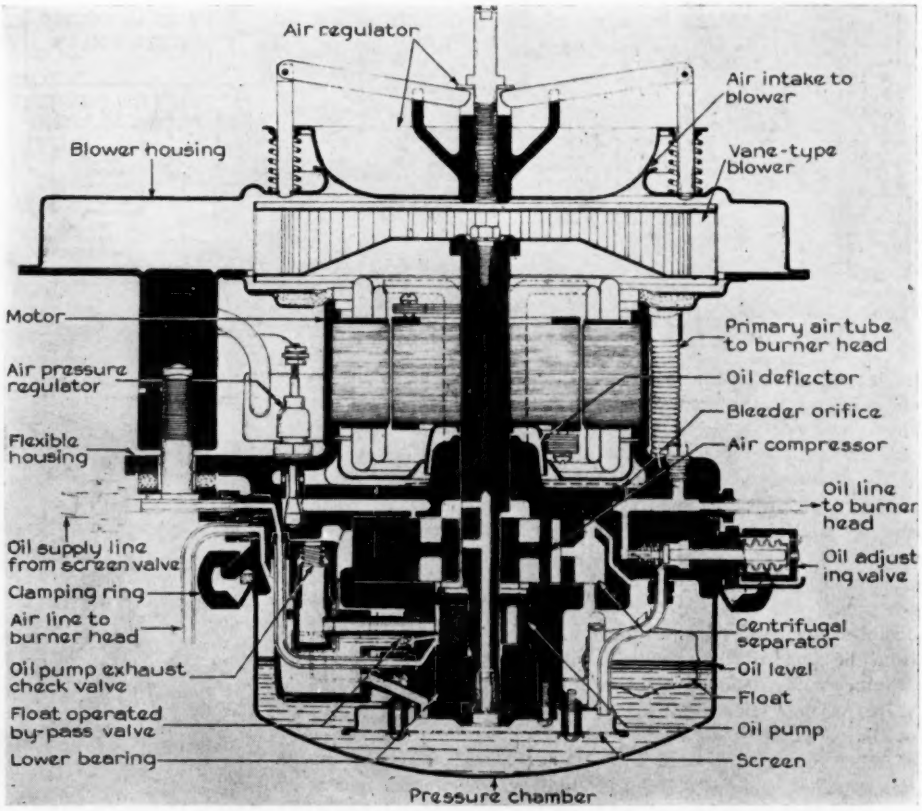

FIG. 5 SECTIONAL VIEW OF OIL-BURNER MOTOR COMPRESSOR

The blower is of the vane type, and is quiet in operation. It supplies air at from 1.5 to 1.75 in. water pressure. This relatively high pressure was used so that operation would not be affected by such things as slight draft variations. Further, because of the high pressure required to force the air through the system, only very small quantities of air can be drawn through

down through the motor stator and rotor to the air-compressor intake. The intake to the air compressor is located in the space immediately below the motor winding, and is so arranged that the oil passing through the upper motor bearing, as well as the oil which passes through the vent in the oil-feed line, is taken into the air compressor and delivered back into the pressure chamber

along with the air. The purpose of the vent, as previously mentioned, is to remove air from the oil line. The air compressor is of the rotary eccentric type (Fig. 5). A view of it on its shaft is shown in Fig. 7.

Centrifugal Oil and Air Separator. The air compressor discharges the mixture of oil and air into a centrifugal separator (see Fig. 5), which is located in the cylinder (housing) of the air-compressor eccentric pump. The high velocity of the air and oil leaving the air compressor sets up a rapid swirling motion of the discharge into the separator, effectively separating the oil from the air. The oil naturally flows out through a small opening in the bottom of the separator, and the air goes through an opening in the top of the separator. The main object in using the centrifugal separator is to prevent an accumulation of oil in the air passages through the nozzle, which might result in erratic operation of the burner. The discharge of air from the separator is directly into the pressure chamber. The compressed air in the pressure chamber is carried to the nozzle in the burner head (see Fig. 4) by means of a small copper tube.

Compressed Air Used for Atomization. The pressure of the compressed air varies with the oil rate. For a given oil rate the pressure is kept substantially constant by a simple pressure regulator. The compressed air line is taken from the top of the pressure chamber to the burner head by a small copper tube shown in Fig. 4. Before the nozzle valve in the burner head opens, 8 to 10 lb per sq in. gage is the pressure in the pressure chamber. After the nozzle valve opens, the compressed-air pressure is approximately 12 lb per sq in. gage for the 1¼ gal oil rate and 15 lb per sq in. gage (approximately) for the higher oil rate, around 2 gal per hour.

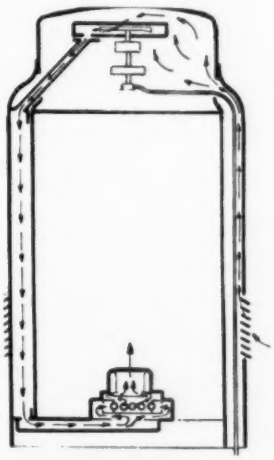

FIG. 6 DUCTS FOR CONVEYING AIR

Atomization of Oil in the Nozzle. The paths of the oil and air through the motor compressor have been traced through up to the nozzle. The purpose of atomization in the combustion of a hydrocarbon oil is to increase enormously the surface area of a given quantity of oil, thereby accelerating the change of the liquid into the gaseous stage. The radiant-heat energy from the flame playing upon the enormously increased surface of the small particles of oil later vaporizes it and changes it into a gasous stage.

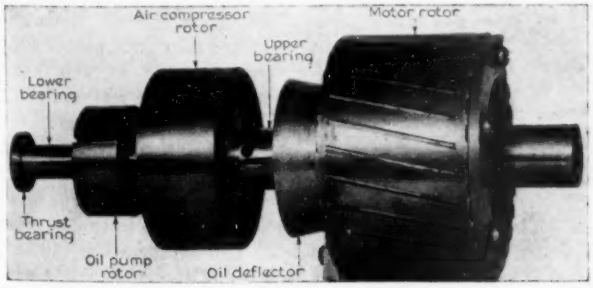

FIG. 7 AIR-COMPRESSOR OIL PUMP AND MOTOR ROTORS
(Mounted on the same shaft.)

Oil Valve at Nozzle Tip Operated by D-C Magnet. The burner head which houses the nozzle is shown in Fig. 8. Some of the things which will be noticed are the oil valve within the nozzle which is used for shutting off the oil when the burner is stopped. The oil valve shuts the oil off right at the nozzle tip, so that oil dribble is eliminated. Oil dribble, resulting in drops of oil adhering to the nozzle, will frequently (because of heat from the flame which causes the nozzle to operate at too high a temperature) break down and form a carbon deposit, which will upset the performance of the nozzle. An enlarged view of the end of the nozzle (Fig. 9) shows that, after the oil is shut off at the end of the oil orifice, compressed air continues to flow, because of the flywheel effect of the motor compressor. This compressed air blows off the small amount of oil that may have remained. When the burner is shut down, a spring keeps the oil valve closed. However, when the control (see wiring diagram Fig. 10) calls for burner operation, the magnet lifts the oil valve against the action of the spring. Hence, a power failure would immediately

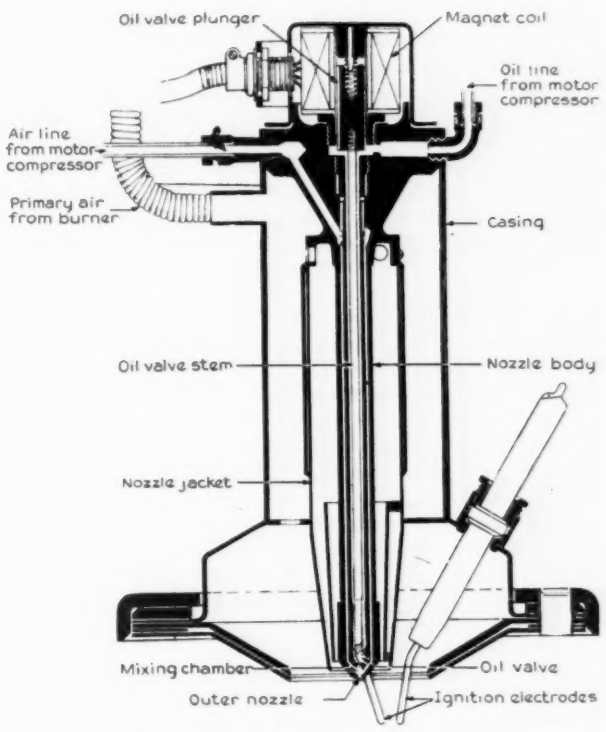

FIG. 8 SECTIONAL VIEW OF OIL-BURNER HEAD

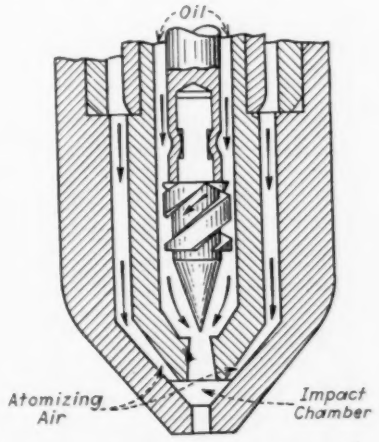

FIG. 9 ENLARGED VIEW OF LOWER PART OF NOZZLE

shut the burner off right at the nozzle tip and not permit any of the oil to dribble, which might cause carbonizing at the nozzle and "after fire" in the combustion chamber.

Impact Chamber Located Near the End of the Nozzle. The oil entering the nozzle passes down along the valve stem until it comes to the valve-stem guide, which has a spiral groove on it to give the oil a rotating motion. A much enlarged view of the end of the nozzle is shown in Fig. 9. The rotating stream of oil then passes out through the oil nozzle into a small impact or mixing chamber. Compressed air enters the mixing or impact chamber, as shown in Fig. 9. Thus the compressed air (the air is also at a high velocity) impacts or bombards the small stream of oil. This provides complete mixing of the oil and air, as well as breaking the oil into small particles.

The mixture of oil and air leaves the mixing chamber, discharging through the final nozzle orifice, which is approximately 50 times as large as the conventional small nozzle orifices of about 8 mils diameter.

Discharging of the compressed air in the manner described results in an exceedingly fine atomization.

Further, the air passage that supplies the compressed air to the impact chamber is so arranged that a whirling motion is given to the air as it mixes with the oil, so that centrifugal force resulting from the high speed of rotation of the mixture leaving the final orifice aids still further in breaking up the oil.

Oil Atomized Into a Very Fine State. Laboratory tests were made by observing these small oil particles by scattered light and measuring the rate of fall in still air. From the rate of fall the diameter of the drop was then calculated by means of Stokes's law. It was found that a drop of oil no larger than the head of a match that passed through this nozzle was broken up into millions of particles. A microphotograph of some of these particles coming from the nozzle is shown in Fig. 11.

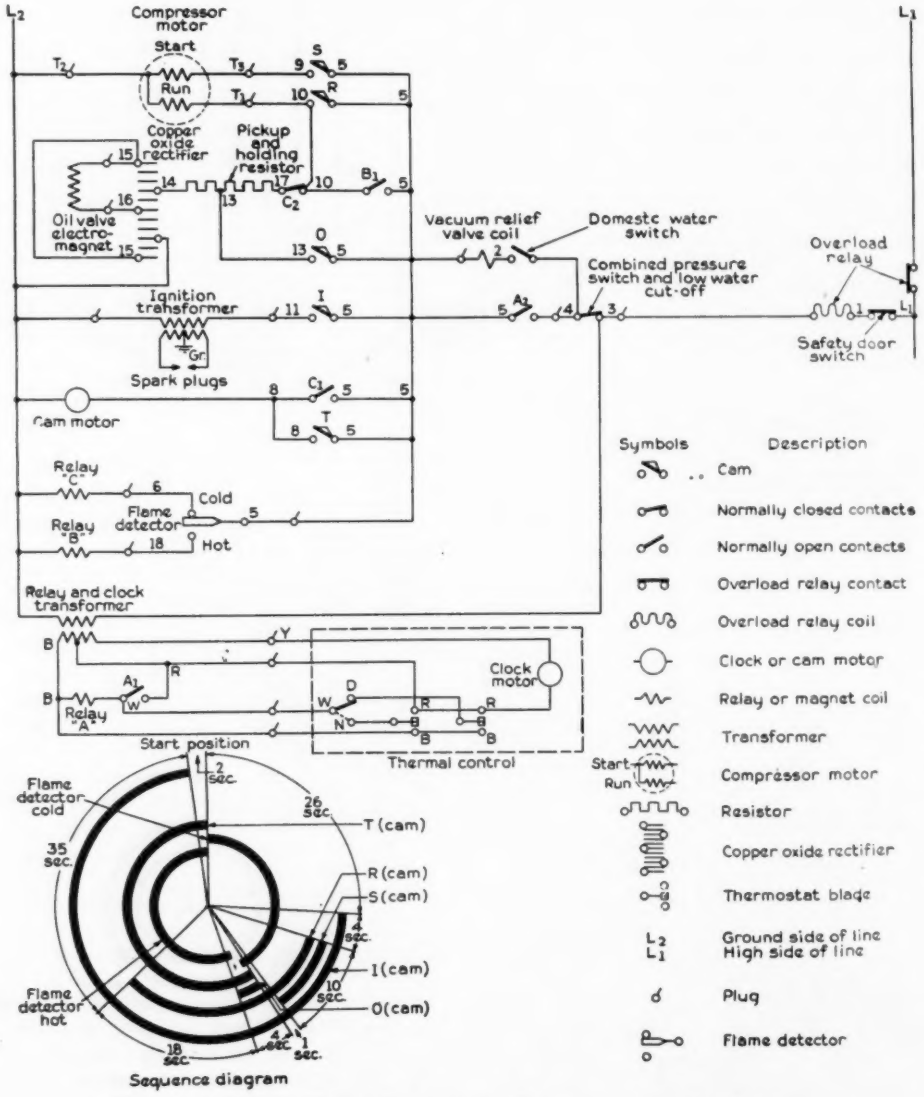

FIG. 10 SCHEMATIC WIRING DIAGRAM FOR CONTROLLING THE OIL FURNACE

Motion-Picture Study of Atomization During Development. At one stage of the development there were several designs of nozzles which were reasonably good. In order to be able to study the problem under little better conditions than being in a room filled with oil vapor and having to breathe it, a slow-motion-picture study was made of the nozzle performance without flame. Later it was possible to study these without the aforementioned handicap.

Electric Ignition of Oil and Initial Chemical Reactions. The finely atomized oil and air jets sweep past the ignition electrodes, which are placed just out of the path of the jets previously mentioned. The ignition spark is supplied by a 12,000-volt transformer which is grounded at the mid-point, and ignition is held on for 72 sec at the start of each cycle. The details of the wiring diagram of the control are given in Fig. 10. Ignition is made possible by the primary air which is blown downward around the nozzle, part of which passes inside of the nozzle jacket and the rest on the outside of the nozzle jacket.

Atomization, as mentioned previously, enormously increases the surface area of the oil. The heat produced by the spark from the electrodes is sufficiently intense and at a high enough temperature (1000 to 1500 F is necessary) to vaporize some of the small particles of atomized oil in the immediate vicinity of the spark and thereby initiate combustion. The moment that this has occurred, the few ignited particles of oil produce sufficient heat to vaporize the neighboring particles of oil and raise the temperature to a sufficiently high value to ignite them, which is possible because of the oxygen present in the primary air. Progressively, the flame burns downward slowly in what might be termed the ini-

FIG. 11 MICROPHOTOGRAPH OF SOME OIL PARTICLES COMING FROM OIL-BURNER NOZZLE

(These were sprayed on a ruled-glass slide, the squares being 0.004 in. on each side.)

tial chemical reaction, since the primary air contains only a very small percentage of the air necessary to burn the oil completely.

Cooling of Nozzle. Aside from making ignition positive, the primary air keeps the nozzle cool. Later this primary air takes part in the initial chemical reaction of combustion.

The design of the nozzle should be such that its maximum operating temperature is considerably lower than the temperature at which carbonizing takes place. The nozzle in question was so designed that during maximum load, as well as during shutdown (while the refractory is red hot), the temperature of the nozzle will at no time be anywhere near the point at which the oil breaks down and leaves a carbon deposit.

Method of Admitting Primary Air. The primary air is distributed symmetrically and evenly with reference to the axis of the combustion chamber and must be admitted correctly to get the proper initial chemical reaction to obtain the quiet, semi-luminous flame. Unsymmetrical admission of primary air would cause a deflection of the oil and air jets, which would produce inefficient combustion and a noisy flame. The primary air unites with the atomized oil and air jets and is ignited by the heat from the spark (previously described), combustion then starts, and a visible flame is produced.

SECONDARY COMBUSTION AIR FOR INTERMEDIATE AND FINAL CHEMICAL REACTIONS

Next in order is branch *B* of Fig. 2, which deals with secondary combustion air for the intermediate and final chemical reactions.

Secondary Air Duct. The secondary combustion air makes its way from the oil-burner blower to the bottom of the boiler, as shown in Fig. 6. Before the air enters the combustion chamber it has to pass through an air distributor, the location of which with reference to the boiler is shown in Fig. 1. Some of the necessary factors are the symmetrical and even distribution of air with reference to the axis of the combustion chamber.

Characteristic Curve of Air Distributor. Exploring with a pitot tube across the air distributor (refractory nozzle removed) gave the curve shown in Fig. 12. Exploring with the same tube at right angles to the first path gave readings such that only one curve had to be plotted—the other would be superimposed on the one shown. The curve demonstrates how the air distributor handles the air.

Design of Air Distributor. Such a curve is obtained by allowing the air to distribute in two directions as it enters the air-distributor housing, after which it passes through 12 holes into another annular chamber. A second time the air is made to pass through 12 holes placed out of phase with reference to the first set, so that the air strikes a metal strip and is deflected in two directions before entering the last set of holes. It then rises vertically through an orifice 4 in. in diameter and hits a circular plate. This plate deflects the air through an annular opening. The air then travels laterally through a number of vanes which give it a slight whirl, after which it passes out through the final orifice of the air distributor. The air then goes through a refractory nozzle before it is available for combustion purposes.

The foregoing may seem an intricate way of handling the air, but it is necessary in order to obtain the best performance.

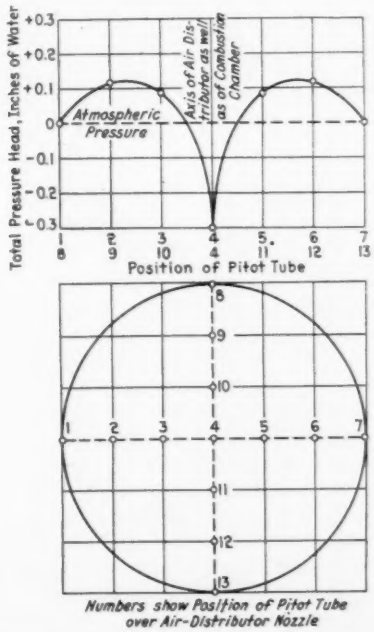

FIG. 12 CHARACTERISTIC SECONDARY-AIR PRESSURE CURVE

(For air distributor without refractory nozzle. This shows the symmetrical distribution of the air with reference to the axis of the combustion chamber.)

Aside from the problem of getting the air evenly distributed, there were many variables involved which complicated the problem, such as the angle and depth of the vanes and the diameter of the final orifice in the air distributor. Then placing the refractory nozzle brought in two more variables: the nozzle height and the shape of the end of the refractory nozzle.

The characteristic curve shown in Fig. 12 is necessary in order to obtain the semi-luminous flame at its best. All the aforementioned variables play their part in determining this curve.

With the refractory nozzle located on top of the air distributor, the characteristic curve is flattened out somewhat.

For purposes of discussion, three stages of combustion were selected, and these were designated as initial, intermediate and final chemical reactions. However, the mere symmetry of the whole thing will indicate that the combustion is progressive, and only for convenience during discussion were the three stages selected.

The nitrogen remaining from the air brought in to supply oxygen for combustion has many things to its discredit; however, there may be one thing to its credit—it possibly acts as a cushion which helps in securing a quiet flame.

Intermediate and Final Chemical Reactions. The secondary air impacts with the vaporized oil, air, etc. that had just previously

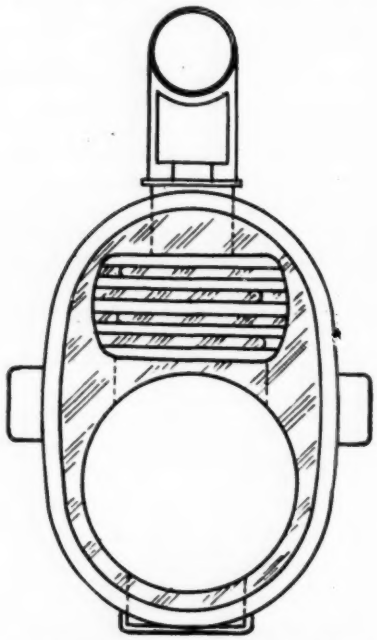

FIG. 13 COMBUSTION CHAMBER AND TUBE DRUM
(Surrounded by water on top, sides, and bottom.)

entered into its initial stages of combustion. This mixture now, at the proper time and place, meets the oxygen it needs to complete the combustion. The air supplying the oxygen as previously described is symmetrically and correctly distributed.

The exit of the combustion gases is out near the top of the combustion chamber; the primary air and atomized oil feed along the axis of combustion chamber at the top; the secondary air feeds from the bottom of the boiler, also symmetrically with reference to the axis of the combustion chamber. The products of combustion therefore rise nicely up the sides of the combustion chamber to exit out of the lateral pass. The mixture in rising up the combustion chamber wall obtains enough oxygen, well controlled, to complete the final chemical reactions. These chemical reactions are taking place under ideal thermal setting, which will be taken up in the description of branch *C* of Fig. 2.

THERMAL SETTING

The thermal setting of all this progressive combustion is an important point; hence, branch *C* logically follows.

Flame Temperature. For many reasons it is desirable to get as high a flame temperature as is practicable, since a larger amount of heat can be picked up in the combustion chamber because of the well-known Stefan-Boltzmann law. Aside from that, the higher flame temperature aids immensely in supporting the various chemical reactions and is of greatest importance to the final ones.

To carry out the final chemical reactions as they take place along the sides of the combustion chamber, such a temperature must be maintained that the rising oxygen can be practically all used and combustion made complete.

Refractory Bricks and Their Support. The proper flame temperature can be obtained by the use of the right amount of refractory. There is a practical limit to the amount of refractory necessary, which can best be determined by experiment. Refractory, especially in large pieces, has a tendency to crack or break when subjected to thermal abuse, so the refractory was made into small bricks and placed on supporting rods like beads on a string, as shown in Fig. 1. The expansions and contractions are small, and the bricks have ample freedom. These rods supporting the bricks are suspended from a refractory supporting ring welded to the upper end of the combustion chamber. The rods are of stainless iron with a high percentage of chrome. The refractory bricks in reality float as a sort of a sheet, leaving a space between the bricks and the water-backed combustion chamber wall. This general arrangement is highly desirable from a heat-transfer standpoint, since a large amount of the radiant heat can strike the water-backed walls from directly back of the strings of bricks. The refractory bricks very quickly become red hot and, in turn, radiate a great amount of heat to the water-backed combustion chamber. As a matter of fact, tests that have been made indicate that approximately 75 per cent of the heat is picked up in the combustion chamber. Of further interest is the fact that the combustion chamber has only 30.2 per cent of the total heating surface in the boiler.

This refractory arrangement makes it possible for the final combustion reaction to take place while the flame is rising up the side of the combustion chamber, thus giving at all times ample thermal support.

SPECIAL WELDED STEEL BOILER

The nature of the three branches, *A*, *B*, and *C* of Fig. 2, and the symmetry of the whole unit show why a special boiler, explained in branch *D*, is needed.

General. For a furnace that is to give quiet, complete, and highly efficient combustion, the size and shape of the combustion chamber are of great importance. The two main dimensions are the diameter and the length of the combustion chamber. Next in the order of importance is the matter of resistances to which the gases are subjected in their travel through the boiler.

The boiler with down draft was finally adopted because of its better adaptability to the many factors involved. The downdraft boiler is inherently less affected by draft variation than the other types.

In the construction of the boiler, use was made of the well-known and efficient counterflow principle as used in power-plant boilers; that is, hot gases from the combustion chamber pass into the top of the tube drum where the water is the hottest and then passes downward over the water tubes (adiators), becoming cooler as they come in contact with surfaces backed by the cooler return water at the bottom of the boiler.

The vertical section through the boiler is shown in Fig. 1, and a horizontal section through the boiler is shown in Fig. 13. The boiler proper is of arc-welded heavy steel plate, and upon completion is essentially one piece.

The amount of heating surface, the steam-releasing area, etc. are some of the simpler problems involved.

Boiler Output and the Amount of Heating Surface Used. The boiler (Fig. 14) has a nozzle output of 257,000 Btu per hour, or 7.68 bhp. The total heating surface of the boiler is 60 sq ft,

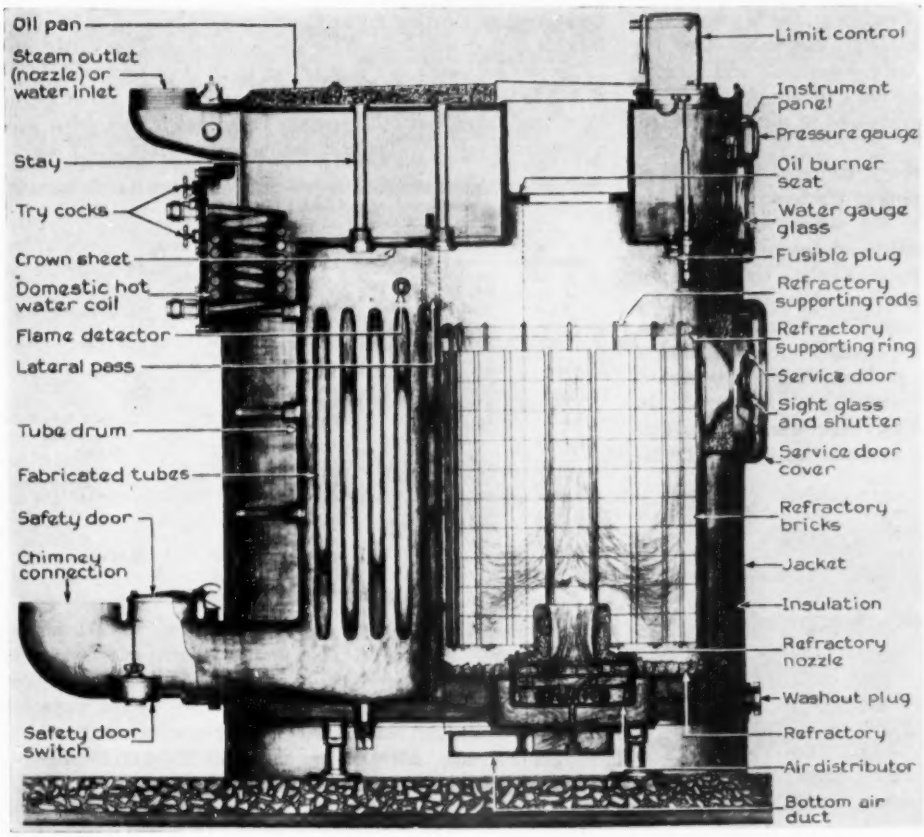

FIG. 14 SECTIONAL VIEW OF BOILER

of which 57.6 sq ft, or 96 per cent of the heating surfaces exposed to the combustion gases, is water backed. The volume of the combustion chamber (less volume occupied by refractory) is 5.2 cu ft. Hence this means a heat release of over 60,000 Btu per cubic foot of combustion space per hour.

Combustion Chamber and Tube Drum. The two main parts of the boiler are the combustion chamber and the tube drum. These are surrounded by an outer shell, together with the top and bottom of the boiler. The boiler was made elliptical (slightly modified) for convenience in handling in close quarters and for beauty. The width is such that it can be carried through an ordinary doorway.

A seat is provided for the burner head at the top of the combustion chamber, and the air distributor is at the bottom of the combustion chamber, as shown in Fig. 14. The refractory bricks are installed through a service door on the front of the boiler and are held within the combustion chamber by a refractory supporting ring which is welded to the upper end of the combustion chamber, as shown in Fig. 14.

The tube drum contains four fabricated tubes or "adiators" (see Fig. 1). Easy access is gained to the tubes for purposes of cleaning through a clean-out door opening. At the bottom of the tube drum is a rake-out door. The chimney connection with safety door (shown in Fig. 14) is attached to the back of the boiler at the bottom of the tube drum. If this door is open for any reason, it operates a switch which shuts down the burner. If a combination of failures should occur which would cause a "puff" or pressure to build up in the combustion passages, this door will open to relieve the pressure and at the same time shut off the power to the burner.

Boiler Accessories and Control. There are the usual little fixtures that go to complete a boiler, such as the fusible plug, water gage, steam gage, low-water cutoff (a part of the boiler-limit control which protects the crown sheet), etc.

It may be of interest to show how the low-water cutoff operates. The limit control which contains the low-water cutoff has a bulb containing turpentine, which is inserted into a well and which projects a little above the crown sheet. If the boiler-water level drops to a certain point above the crown sheets, the water quickly evaporates out of this well and causes the temperature of the bulb to rise. Expansion of the liquid in the tube causes a sylphon to expand and to break the main circuit. As soon as water is added to the boiler, the well is again filled with water, which cools the liquid in the bulb. This cooling causes the sylphon to contract and to make contact so that the burner can again operate. The arrangement of the low-water cutoff in the control circuit is shown in Fig. 10. The location of the limit control on top of the boiler is shown in Fig. 15. The water-gage glass, of the type used on some locomotives, permits flush mounting of the gage and adds to the appearance of the unit.

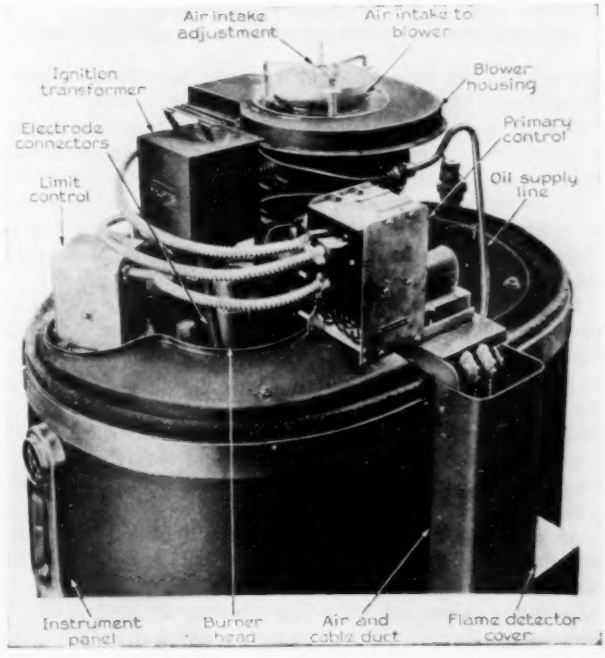

FIG. 15 OIL BURNER AND OIL-BURNER CONTROL ASSEMBLED ON BOILER

The limit control has three main functions: to keep the steam pressure between set limits; to operate the low-water cutoff for protecting the crown sheet, previously described; and to control the boiler water between 170 and 185 F for supplying heat to a domestic hot-water coil which is immersed in the boiler water, as shown in Fig. 1.

Flame Detector. The flame detector is mounted on the side of the boiler so as to permit the cleaning of the secondary heating surfaces without possible injury to the instrument. The element exposed to the products of combustion passes directly over one of the fabricated tubes, and is placed only a short distance beyond the zone where the final chemical reactions take place. The instrument is an extremely sensitive thermal-responsive device which operates on temperature changes in the combustion chamber. It detects the presence of flame during the ignition period, thus permitting continuous operation of the burner. It detects the absence of flame should this occur during operation, stops the flow of oil, and permits a new starting cycle to be inaugurated. The flame detector is so sensitive that it responds within two or three seconds, depending on the oil rate.

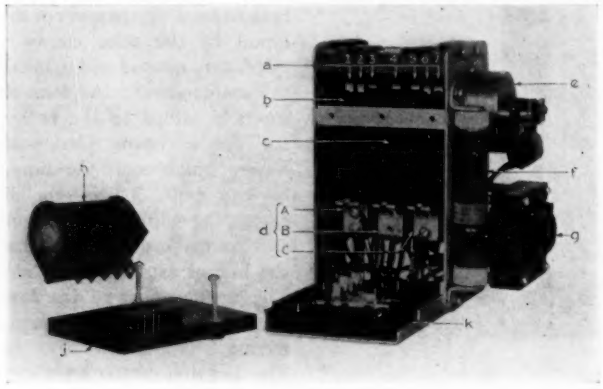

FIG. 16 PRIMARY CONTROL
(Showing oil-valve rectifier and rectifier plug board and cover.)

The flame detector is a nichrome tube within which is placed a quartz rod. The quartz has a negligible expansion with temperature changes; the nichrome has a decided expansion. The relative motion between the rod and the tube actuates contacts when the tube is subjected to heat from the combustion gases. The flame detector contacts control relays, as shown in the control circuit (Fig. 10).

If the oil does not ignite at the first try, the timing mechanism keeps on running after the flame detector has shut down the burner and repeats the cycle. Again, the condition may not be proper for combustion, and the flame detector will shut down the burner. The timing mechanism will continue running and repeating the cycle a number of times, but if combustion has not been established, the unit will shut down and no further action on the part of the burner is possible until a reset button is manually pressed.

Air and Cable Ducts. The intake-air and cable duct and the secondary-air ducts, the former on the right-hand side of the furnace and the latter on the left, are shown in Fig. 6. The intake-air and cable duct, aside from covering the electric and oil lines, has another function in that it conveys the air, which enters through louvers in the bottom of the duct, into the space under the boiler top cover. The cover, together with this duct, also acts as a sonic filter; that is, small mechanical noises originating under the cover are muffled.

Boiler Destruction Test Made for the A.S.M.E. Boiler Code Committee. The boiler was made to conform with the A.S.M.E. Low-Pressure Heating Boiler Construction Code. For some information that was wanted for the Boiler Code Committee, the boiler was subjected to a destruction test. At a hydrostatic test of 275 lb per sq in. gage, a small leak was formed in one of the fabricated tubes, but otherwise the boiler was in fine shape with no apparent injury. The test results are shown in Table 1.

TABLE 1 DESTRUCTION TEST OF OIL FURNACE BOILER (BOILER NO. 6)

Pressure, lb per sq in. gage	Deflection in mils				Space between two center adiators, in.	Remarks

OIL-BURNER CONTROL

The first application of the semi-luminous flame was in a domestic oil furnace. Hence, it is only proper to bring in a few words about the general control used. At several points, references have been made to various control parts such as the flame detector and boiler limit control, with further reference to the wiring diagram (Fig. 10). Mention was also made of the ignition spark, together with the manner in which the oil valve at the nozzle tip is operated.

Primary Control. By referring to Fig. 15 it will be seen how the primary control (Fig. 16) is mounted with reference to the oil burner and boiler. The primary control unit controls the sequence of operation of the various parts composing the complete oil burner. In this particular case, a thermal control (a wall-type clock thermostat with day and night control) and the boiler limit control take care of starting and stopping the oil burner, opening and closing the circuit to the oil valve and ignition transformer at the proper point in the starting cycle. The primary control also responds to the signals given by the flame detector, which indicates whether the flame is on or off. The primary control has a motor which causes the camshaft to make one revolution in 100 sec and which operates the contacts in the time sequence as shown in the wiring diagram (Fig. 10).

The cams and cam contacts control the following circuits: Referring to Fig. 16 and reading from left to right, they are: (1) Oil burner motor-starting winding. (2) Snap contact for motor-starting and running windings. (3) Oil-burner motor-running winding. (4) Ignition transformer. (5) Camshaft motor. (6) Snap contacts for cam motor and oil valve. (7) Oil valve. Also reading from left to right, the relays control the following circuits: Relay A: Left contact, A-1 (normally open), holding contact for thermal control circuit; right contacts, A-2 (normally open), main line contacts. Relay B: Right contact, B-1 (normally open), motor-running winding and oil-valve contacts. Relay C: Left contact, C-2 (normally closed), oil-valve contacts; right contact, C-1 (normally open), camshaft motor contacts.

Plug receptacles are used in the primary control for the copper-oxide rectifier, flame detector, thermal control leads, and for the oil-valve cable. The plug-in type arrangement is characteristic of the whole control. For instance, referring to Fig. 15, the ignition transformer can be lifted from its position merely by pulling out one plug and lifting directly by the case. The burner and

control, shown in Fig. 15, can be removed from the top of the boiler and placed back in position in less than 10 min, assuming that the burner was operating at the start of this test and is again running at the end of this test.

As mentioned under the head of atomization in branch *A*, Fig. 2, sometimes the flame does not ignite the first time. Hence the control was worked out for the "repeat start" system of control. During the five starts for which the control is mechanically adjusted, the flame must ignite or else the control must be reset manually.

The very sensitive flame detector makes it possible to reduce the oil-flow period during the starting operation, and use of the "repeat start" system of control eliminates the danger of ignition "puff."

PME-55-4

Some Problems in the Lubrication of Vertical Journal Bearings

By A. I. PONOMAREFF[1] and E. D. HOWE,[2] BERKELEY, CALIF.

A. I. Ponomareff

In deep-well pumping a motor at the surface drives a pump runner at the water level through a long vertical shaft supported at the top by a thrust bearing and guided at intervals of its length by journal bearings. For effective design the power absorbed by the journal bearings should be known approximately. The preponderance of horizontal shafts in various kinds of machinery has resulted in an extensive literature on their lubrication, but there is little that bears on the lubrication of such vertical shafts as are used in pumps, hydraulic turbines, a few steam turbines, cream separators, and centrifuges. The friction loss in these is small, but in the deep-well pump the loss may be as great as 5 per cent of the power input. The paper relates the details of an investigation to establish some of the basic facts underlying the lubrication of vertical journal bearings such as are used in deep-well pumps.

E. D. Howe

THE CONVENTIONAL deep-well pump installation consists of a motor at the ground elevation driving a pump runner at the water level (often several hundred feet below the ground surface). The power is transmitted from the motor to the pump through a long vertical shaft supported at the upper end by a thrust bearing and guided at intervals of from 3 to 10 ft by journal bearings. The power absorbed by the vertical journal bearings must be known approximately for effective design. However, a survey of the current engineering literature revealed that no data were available for this computation. The reason for the lack of information in the current literature probably lies in the preponderance of horizontal shafts in various kinds of machinery. Vertical shafts are used in comparatively few machines, some of which are pumps, hydraulic turbines, a few steam turbines, cream separators, and centrifuges. In all of these except the deep-well pump the loss in the vertical guide bearings is a very small part of the total bearing friction loss, as the major part of the bearing loss occurs in the thrust bearing. Since in the deep-well pump the total journal-bearing loss may be as great as 5 per cent of the power input, the design of these bearings becomes important. The following investigation was therefore made for the purpose of establishing some of the more basic facts underlying the lubrication of vertical journal bearings such as are used in deep-well pumps.

The experiments described were performed upon a vertical-bearing model designed by the authors and built by the Byron Jackson Company of Berkeley, Calif. The experimental work was done in the Mechanical Engineering Laboratories of the University of California at Berkeley. The authors gratefully acknowledge the many helpful suggestions given by Mr. A. Hollander, of the Byron Jackson Company, and the mechanical assistance given by the hydraulic laboratory of the university.

The theory for the lubrication of bearings for horizontal shafts is not applicable to the lubrication of vertical bearings because there exists in the former case a radial load which is lacking in the latter case. The theory of the lubrication of the vertical bearing is therefore developed independently from the equations of fluid motion, which apply only to those cases in which the fluid films are complete. The equations of motion[3] are:

$$\rho \frac{Du}{Dt} = \rho X - \frac{\partial p}{\partial x} + \frac{1}{3}\mu \frac{\partial \phi}{\partial x} + \mu \nabla^2 u$$

$$\rho \frac{Dv}{Dt} = \rho Y - \frac{\partial p}{\partial y} + \frac{1}{3}\mu \frac{\partial \phi}{\partial y} + \mu \nabla^2 v$$

$$\rho \frac{Dw}{Dt} = \rho Z - \frac{\partial p}{\partial z} + \frac{1}{3}\mu \frac{\partial \phi}{\partial z} + \mu \Delta^2 w$$

Let x = distance measured along the journal in the direction of motion, but referred to a point fixed in space (see Fig. 1)

y = distance measured perpendicular to the journal surface

z = distance measured axially from the end of the bearing sleeve

[3] "The Mechanical Properties of Fluids," a collective work, 1924, D. van Nostrand Company, New York, p. 92.

$y_{max} = h$ = width of clearance space
u, v, w = the velocity components parallel to the axes at the point (x, y, z)
X, Y, Z = the external force components per unit mass
ρ = the mass density
μ = the coefficient of viscosity
p = the pressure at (x, y, z)
$\frac{D}{Dt} = \frac{\partial}{\partial t} + u\frac{\partial}{\partial x} + v\frac{\partial}{\partial y} + w\frac{\partial}{\partial z}$
$\phi = \frac{\partial u}{\partial x} + \frac{\partial v}{\partial y} + \frac{\partial w}{\partial z}$
$\nabla^2 = \frac{\partial^2}{\partial x^2} + \frac{\partial^2}{\partial y^2} + \frac{\partial^2}{\partial z^2}$
N = speed of rotation in rpm
F = force.

The following assumptions are made:

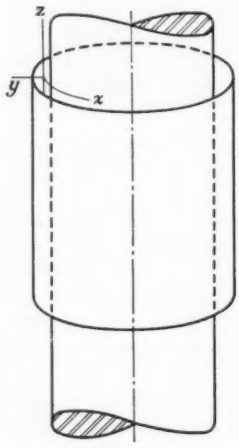

FIG. 1

(1) Reynolds' number $vl\rho/\mu$, computed from the journal velocity, the radial clearance, and the oil viscosity is so small that the flow is free of eddies.

(2) The forces due to weight and inertia of the fluid are so small that they may be neglected in comparison with the viscous forces.

(3) Since the fluid is a liquid under low pressures, all terms depending upon compressibility may be neglected.

(4) Because of the thinness of the oil film as compared with its length πd, the curvature of the film may be neglected.

(5) The axial flow is so small that it may be neglected and the problem may be treated as one of flow in two dimensions.

(6) The radial load is zero at all times.

The consequences of the above assumptions are:

(*a*) From (2) $\frac{Du}{Dt} \to 0$, $\frac{Dv}{Dt} \to 0$, $\frac{Dw}{Dt} \to 0$, $X, Y, Z \to 0$

(*b*) From (3) $\phi = 0$

(*c*) From (5) $w \to 0$

(*d*) From (6) $\frac{\partial p}{\partial x} = 0$, $\frac{\partial p}{\partial y} = 0$

Two cases arise in practice when the journal and sleeve surface elements are parallel: the first one is that in which the journal and bearing sleeve are concentric, and the second one that in which they are eccentric.

Case 1 (*Journal and Bearing Sleeve Concentric*). Since the shaft is concentric, $v = 0$, and there is no acceleration in the x-direction; so that $\frac{\partial^2 u}{\partial x^2} = 0$. Therefore Euler's equations reduce to:

$$\frac{\partial^2 u}{\partial y^2} = 0 \quad \text{or} \quad u = C_1 y + C_2$$

The constants can be evaluated from the boundary conditions, which are: when $y = 0$, $u = V$, and when $y = h$, $u = 0$. Inserting these values, $C_1 = -V/h$ and $C_2 = V$.

Hence $u = V(1 - (y/h))$.

From the definition of the coefficient of viscosity:

$$F_x = -\mu \frac{\partial u}{\partial y} \cdot A = \mu \frac{V}{h} A = \text{force tangential to shaft.}$$

The torque is:

$$F_x \cdot r = \mu \frac{V}{h} \frac{d}{2} \pi dl$$

or

$$T = F_x \cdot r = \mu \frac{V}{h} \frac{d}{2} \pi dl$$

where $A = \pi dl$

V may be expressed as $V = (\pi dN/60)$, so that:

$$T = \mu \frac{\pi^2 d^3 lN}{120\, h}$$

The power necessary to produce this torque is:

$$L_c = \frac{2\pi TN}{33{,}000} = \frac{\mu \pi^3 d^3 lN^2}{1{,}980{,}000\, h} \text{ (hp)} \ldots\ldots\ldots\ldots [1]$$

d = diameter of journal in feet
l = length of sleeve in feet
N = speed in rpm
h = clearance (radial) in feet
μ = viscosity in lb × sec per sq ft

or

$$L_c = 6.12 \times 10^{-10} \frac{\eta \pi^3 D^3 LN^2}{H} \ldots\ldots\ldots\ldots [1a]$$

where η = coefficient of viscosity in poises
D = diameter in inches
L = sleeve length in inches
N = speed in rpm
H = radial clearance in thousandths of inches.

That this equation is similar to that for the power loss in a pipe line may be seen by rearranging the factors:

$$L_c = K\eta D \left(\frac{L}{H}\right) V^2 = K'\eta D V^2 \ldots\ldots\ldots\ldots [a]$$

where K is a pure number.

The power is thus proportional to the product of shaft diameter and the square of the linear speed.

The power loss due to pipe friction is

$$L_f = \frac{Qjh_L}{550} = \frac{Avj}{550} \times f \frac{L}{D} \frac{v^2}{2g}$$

for viscous flow $f = \frac{64}{\frac{vd\rho}{\mu}}$, so that:

$$L_f = \frac{64}{550} A\mu \frac{L}{D^2} v^2$$

$$L_f = K_1 \mu l v^2 \ldots\ldots\ldots\ldots [b]$$

In both of these Equations [*a*] and [*b*], the power loss is proportional to the product of a length and the square of the speed, thus illustrating the analogy between pipe friction and bearing friction.

Case 2 (*Journal and Bearing Sleeve Eccentric*). In this case the change of speed of the particle is rather small, so that all of the assumptions for case 1 are valid. The effect of the eccentricity is to render the tangential force dependent upon the angle through the relation:

$$dF = \mu \frac{V}{h} dA$$

in which $h = f(\theta)$; θ = angle of radius vector; $dA = lrd\theta$, so that $dF = \mu lr \frac{V}{h} d\theta$.

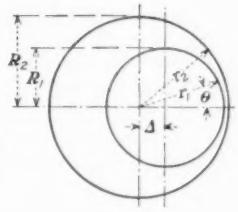

FIG. 2

To find $h = f(\theta)$, consider the figure shown. The equations of the two circles (see Fig. 2) in cylindrical coordinates are:

large circle $r_2 = R_2$

small circle $r_1^2 - 2r_1 \Delta \cos\theta + \Delta^2 = R_1^2$

Solving the latter equation for r_1, gives:

$$r_1 = \frac{2\Delta\cos\theta \pm \sqrt{4\Delta^2\cos^2\theta + 4(R_1^2 - \Delta^2)}}{2}$$

Since the two radii are nearly equal, the clearance h is given by:

$$h = r_2 - r_1 = R_2 - [\Delta\cos\theta \pm \sqrt{\Delta^2\cos^2\theta + (R_1^2 - \Delta^2)}]$$

Hence:

$$dF = \frac{\mu l R_1 V d\theta}{R_2 - [\Delta\cos\theta \pm \sqrt{\Delta^2\cos^2\theta + (R_1^2 - \Delta^2)}]}$$

or

$$F = \mu l V R_1 \cdot 2 \int_0^{\pi} \frac{d\theta}{R_2 - [\Delta\cos\theta \pm \sqrt{\Delta^2\cos^2\theta + (R_1^2 - \Delta^2)}]}$$

To evaluate the integral, note that the radical may be reduced, since $\Delta^2(1 - \cos^2\theta)$ is negligible in comparison with R_1^2. The integral therefore becomes:

$$2\int_0^{\pi} \frac{d\theta}{R_2 - R_1 - \Delta\cos\theta}$$

which can be evaluated by Equation [234], page 46, Hudson's "The Engineering Manual," as:

$$= \frac{4}{\sqrt{(R_2 - R_1)^2 - \Delta^2}} \tan^{-1}\left(\frac{\sqrt{R_2 - R_1 - \Delta}}{\sqrt{R_2 - R_1 + \Delta}} \tan\frac{\theta}{2}\right)\Bigg]_0^{\pi}$$

$$= \frac{2\pi}{\sqrt{(R_2 - R_1)^2 - \Delta^2}}$$

Inserting this value in the foregoing equation gives:

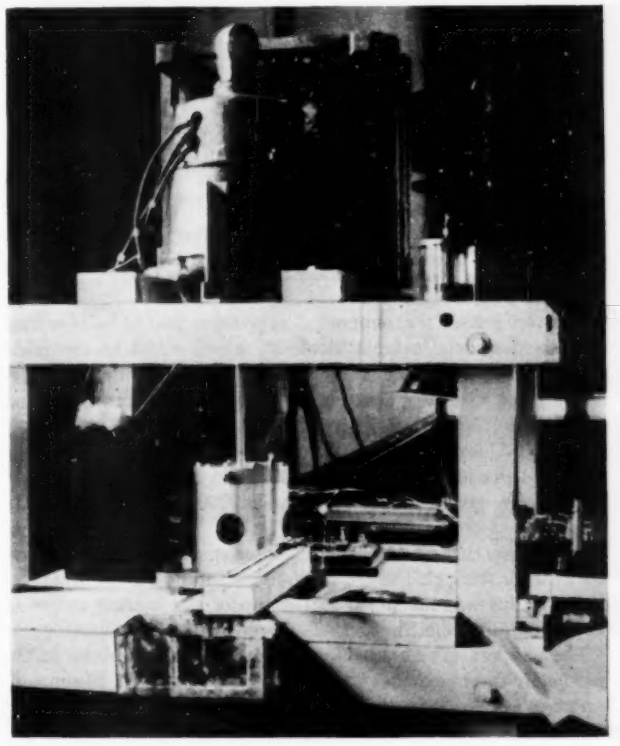
$$F = \mu l V R_1 \frac{2\pi}{\sqrt{(R_2 - R_1)^2 - \Delta^2}}$$

The power necessary in this case is:

$$L_c = \frac{2\pi N R_1}{33{,}000} \times \frac{\pi d_1 N}{60} \cdot R_1 \mu l \frac{2\pi}{\sqrt{(R_2 - R_1)^2 - \Delta^2}} \quad \ldots\ldots [2]$$

$$= \frac{\mu\pi^2 d_1^3 N^2 l}{1{,}980{,}000\, h_c} \times \frac{1}{\sqrt{1 - k^2}} = \frac{L_c}{\sqrt{1 - k^2}}$$

d = diameter of journal in feet
h_c = difference in radii in feet
Δ = eccentricity in feet



$$k = \frac{\Delta}{R_2 - R_1}$$

Other symbols as before.

DESCRIPTION OF THE APPARATUS

To verify experimentally the theoretical relations established by Equations [1] and [2], the test apparatus was designed to permit (1) the setting of a given journal centrally in the bearing sleeve and (2) the movement of the journal laterally in the bearing sleeve to obtain a desired amount of eccentricity. The apparatus station used in the tests is shown in Fig. 3, and a cross-section of the test bearing showing the arrangement of the principal working parts in Fig. 4.

In Fig. 4 the brass bearing sleeve E, 2.4415 in. inside diameter by $5^1/_2$ in. long, is shown supported centrally by the two ball bearings B, which are in turn pressed into the steel housing P. The sleeve is free to rotate in either direction, being limited in angular motion only by the lever L, which strikes the sides of the

FIG. 3 APPARATUS USED IN THE TESTS

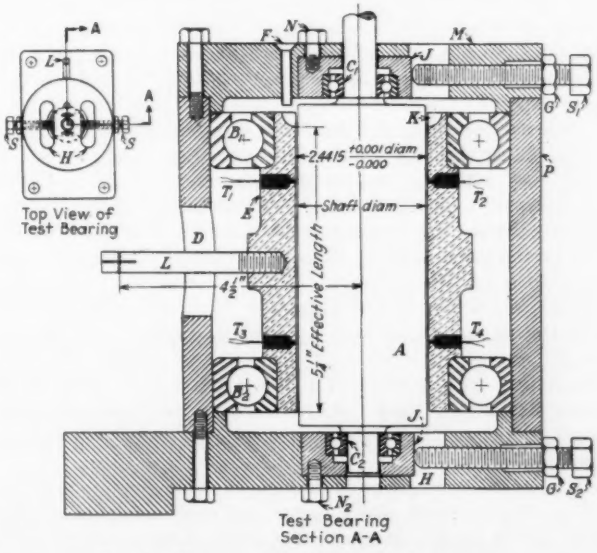


FIG. 4 WORKING PARTS OF TEST APPARATUS

hole D. In order to insure parallelism of the axes of the sleeve and the journal, the steel housing was bored and faced in a single lathe set-up, and the housing cover and base M were provided with spigot joints, which were machined in the same set-ups used for the boring operations upon them. Four slots in the cover and base of the housing were so placed that, without removing either cover or base, the clearances could be measured with an ordinary feeler gage.

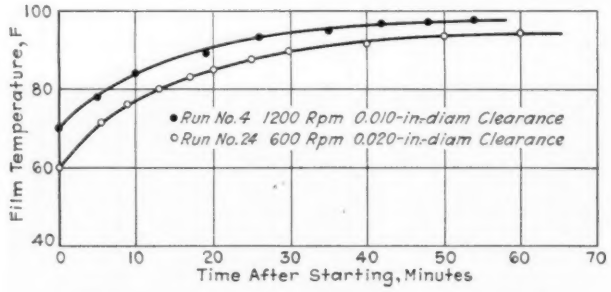

FIG. 5 ESTABLISHMENT OF EQUILIBRIUM CONDITIONS
(Change of film temperature with time. Vertical bearing tests, bearing $2^{7}/_{16}$ in. in diameter by $5^{1}/_{4}$ in. long.)

The test journal was supported by another pair of ball bearings C, pressed into adjustable blocks J, which could be moved in guides by adjusting screws S. Thus the journal could be placed centrally or with any desired eccentricity in the bearing sleeve by means of the adjusting screws, and then locked in position by bolts N and lock nuts G. Change in average clearance was made by using three journals, 2.4405, 2.4400, and 2.4395 in. in diameter, respectively, giving 0.010, 0.015, and 0.020 in. clearance on diameter.

The lubricating oil was supplied from an oil cup located above the bearing through the $^{3}/_{16}$-in.-in-diam tubing F. A groove of $^{1}/_{8}$-in. radius was machined in the top of the bearing sleeve to insure uniform distribution of oil around the journal.

The temperature of the oil was measured at four places on the bearing by thermocouples T. No. 30 copper and No. 30 constantan wires were used for thermocouples. The method of attaching the thermocouples was as follows: The wires were first arranged in pairs, wrapped together with thread, coated with bakelite varnish and then baked. Holes $^{1}/_{16}$ in. were then drilled through the sleeve and counterbored with a diameter of about $^{1}/_{4}$ in., as shown in the sketch. The insulation was then scraped from the ends of the wires, and the wires were placed in the center of the hole projecting beyond the bearing surface far enough so that their exposed portions extended about $^{1}/_{32}$ in. back into the hole. Woods metal, melting at about 200 F, was then poured around the wires, filling the hole. The wires and excess metal were then filed flush with the surface. The thermocouple junction was thus formed by the Woods metal immediately adjacent to the bearing surface. The temperature of the junction should therefore be the temperature of the bearing surface, which approaches that of the oil. One advantage of this construction was that the surface was not warped by heating as would have been the case had the thermocouples been soldered in place. Each thermocouple was calibrated after attachment to the bearing sleeve by comparison with a standard thermometer over a temperature range of from 60 to 150 F. A Brown Instrument Company potentiometer was used for measuring the voltage generated at the hot junction.

The journal was connected through a flexible coupling to a 1-hp 110-v direct-current shunt motor mounted vertically on the table above the test bearing. The speed of the motor could be varied from 300 to 1350 rpm by means of rheostats. (For the tests at 3600 rpm a $^{1}/_{3}$-hp alternating-current motor was used.) The speed of the motor was measured by means of a Horn type tachometer directly connected to the end of the motor shaft.

To measure the rotative effort on the main bearing sleeve produced by the rotating journal a lever arm L was projected through a 2-in. hole in the bearing housing. The torque was measured by a spring scale attached to the lever arm at a radius of $4^{1}/_{2}$ in.

EXPERIMENTAL PROCEDURE

The procedure followed in the final tests was adopted after a number of trial runs. The oil cup was adjusted to supply oil at a rate sufficiently great to keep the groove on top of the bearing sleeve filled, thereby assuring a uniform flow into the clearance space. The motor was then started and constant speed was maintained until the torque and film temperature became constant. More than one hour was required to establish thermal equilibrium, as may be seen from Fig. 5, a curve showing the change of oil-film temperature with time. To obtain a wide range of viscosities three different oils were used in the tests. The curves in Fig. 6 show the variation with temperature of the oil viscosities.

Some difficulty was experienced in maintaining a complete film with the apparatus as described, so that a second series of tests was made with the bearing sleeve completely immersed in oil. For this purpose the four holes, through one of which the torque arm extended, were closed by means of plates. Leakage was allowed to occur around the torque arm, thus providing a continuous flow through the apparatus. The procedure followed in this series was the same as in the series with the sleeve not immersed.

After thermal equilibrium of the oil film and the bearing had been established, the torque, speed, and oil-film temperature were measured. The theoretical power required to drive the journal

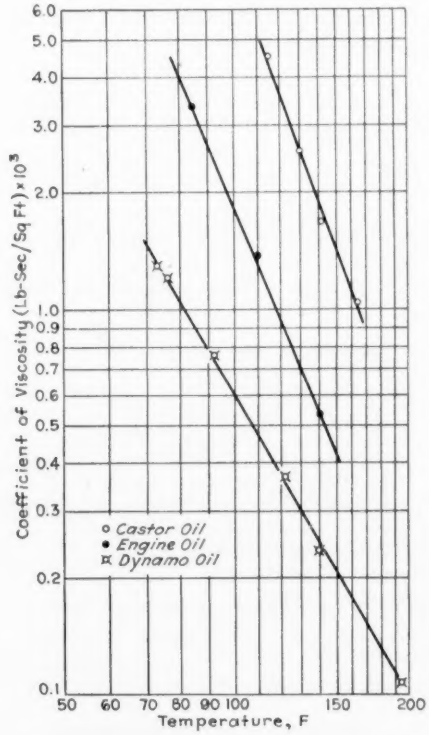

FIG. 6 VISCOSITIES OF OILS USED IN TESTS
(Data obtained with Saybolt viscometer. Vertical bearing tests, bearing $2^{7}/_{16}$ in. in diameter by $5^{1}/_{4}$ in. long.)

was calculated from Equations [1] and [2], and the actual power from:

$$L_a = \frac{2\pi PLN}{33{,}000} \text{ hp} \quad \ldots\ldots\ldots\ldots\ldots\ldots [3]$$

where P = pull on spring scale in pounds
L = length of lever arm in feet
N = speed in revolutions per minute.

Results Obtained

The results of the tests made on the 2.4405- and 2.4395-in.-in-diam. journals located centrally in the bearing sleeve with diametral clearances of 0.010 and 0.020 in., respectively, are shown graphically in Fig. 7. The solid lines give the theoretical power required to drive the journals as computed from Equation [1], using a viscosity of 1.00×10^{-3} (lb-sec/sq ft) (47.9 centipoises). The experimental points were obtained with various viscosities ranging from 0.3×10^{-3} to 6.9×10^{-3} (lb-sec/sq ft). (The film temperatures ranged from 70 F to 160 F.) The measured power was then divided by (the viscosity $\times$ 1000) in order to reduce all values to a common basis. The resulting points were then plotted in Fig. 7. (Note that for viscosities greater than 1.00×10^{-3} it was necessary to immerse the bearing sleeve to insure a complete film.) The plotted experimental values are seen to agree very well with the theoretical curve, the maximum deviation being less than 8 per cent, in agreement with the computed probable error. (See the Appendix.)

The numerous runs made by the authors seem to indicate conclusively that for oils having, under the operating conditions which obtained, viscosities less than approximately 0.7×10^{-3} (lb-sec/sq ft), a positive hydrostatic head on the oil in the clearance is necessary to maintain a complete film. Without such a head the oil is apparently wiped off the journal, thus reducing the effective area and consequently the amount of power

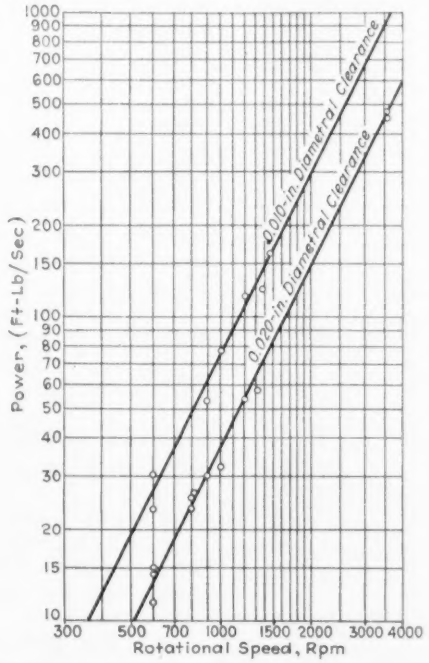

Fig. 7 Comparison of Theoretical and Measured Power

[Journal and sleeve concentric. Solid lines: Power = $\frac{\mu\pi^3 d^3 l^3 n^2}{3600\ h}$ (μ = 100 $\times 10^{-3}$). Plotted points: Power = $\frac{2\pi PLN}{60\mu \times 10^{-3}}$. Vertical bearing tests, bearing $2^7/_{16}$ in. in diameter by $5^1/_4$ in. long.]

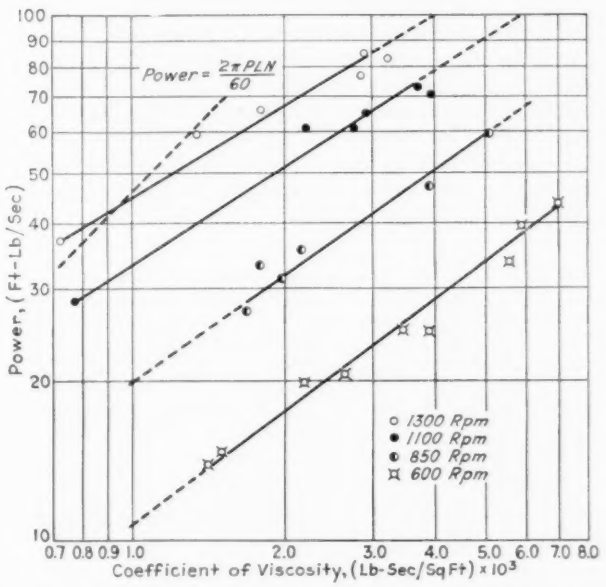

Fig. 8 Effect of Oil Viscosity Upon the Power Required for Lubrication

(Bearing sleeve open to the air. Vertical bearing tests, bearing $2^7/_{16}$ in. in diameter by $5^1/_4$ in. long; 0.020 in.-in-diameter clearance; 0.002-in. eccentricity.)

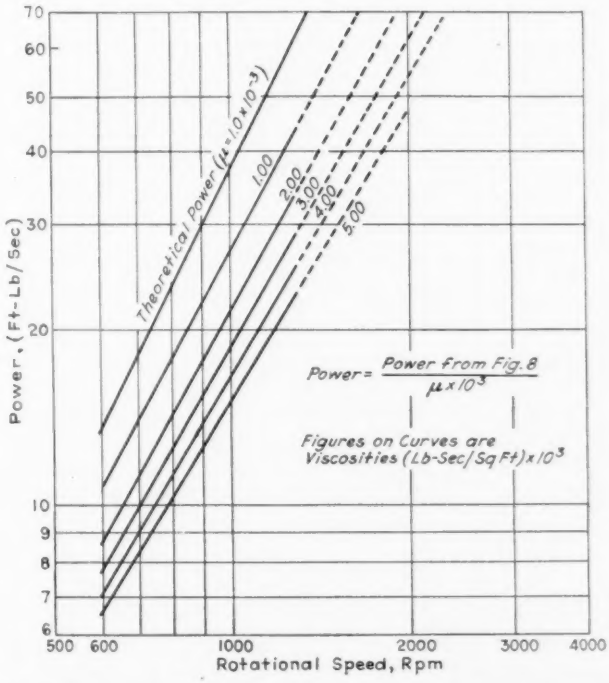

Fig. 9 Effect of Oil Viscosity Upon the Power Required for Lubrication

(Cross-plotted from Fig. 8. Vertical bearing tests, bearing $2^7/_{16}$ in. in diameter by $5^1/_4$ in. long; 0.020-in.-in-diameter clearance; 0.002-in. eccentricity.)

required to drive the shaft. Carrying this to the extreme, one might be led to the erroneous conclusion that the most desirable state would be one in which no film existed, thus reducing the power to a minimum. The fallacy of this will be apparent if it is borne in mind that the purpose of the oil film is to preserve the alignment of the shaft with respect to the housing. Absence of an oil film in a deep-well pump bearing would probably re-

sult in an enormous increase in power required due to the solid friction during rubbing of the journal over the bearing surface.

With the oil cup adjusted to feed 3 drops per minute, as in the actual deep-well pump installations, the reduction of the active oil-film area might produce a decrease of power of as much as 50 per cent. This effect was noticed most definitely when running with cold oil; that is, when the viscosity was large. The reduction of power necessary to drive the journal due to the reduction of the effective oil-film area is shown in Figs. 8 and 9.

The solid curves in Fig. 8 are drawn through the experimental values and show the variation of power required with viscosity at several different speeds. According to Equation [1] these curves should have slopes the same as that of the dotted curve. The reduction in slope is from 1.00 (theoretical) to about 0.60 (actual) for 1100 rpm. This change in slope suggests that possibly the degree of completeness of the oil film is dependent upon the viscosity.

The curves in Fig. 9 are cross-plotted from those in Fig. 8, after reducing all values to a viscosity of 1.00×10^{-3} (lb-sec/sq ft). This curve indicates that for large viscosities (cold oil) a complete film is not maintained, and the power required to drive a journal under such conditions is considerably smaller than computed from Equation [1]. As the viscosity is decreased, it becomes easier to maintain a complete oil film, so that the theory given is more nearly applicable.

The tests made to ascertain the effect of eccentricity of the journal show that for a small eccentricity the effect is negligible, as indicated by Equation [2]. For instance, an eccentricity of 0.003 in. when the average radial clearance is 0.010 in. would produce an increase in power of only 5 per cent, an amount less than the error in the work. For greater eccentricities the measured power was less than the theoretical, from which it is assumed that the film was incomplete due to the reduced minimum clearance.

The results indicate rather definitely that the power actually required by a vertical bearing can be computed directly from Equation [1], when conditions are such that a complete film is maintained.

Under these conditions the power may be obtained from Fig. 10, which was drawn from computations using Equation [1].

The tests previously described have been concerned with the absorption of power by vertical bearings under a small range of conditions. In addition to the factors studied there are others which should be investigated. Some of these factors are:

(*a*) The effect of grooves running the full length of the sleeve

(*b*) The effect of grooves running part way down the sleeve

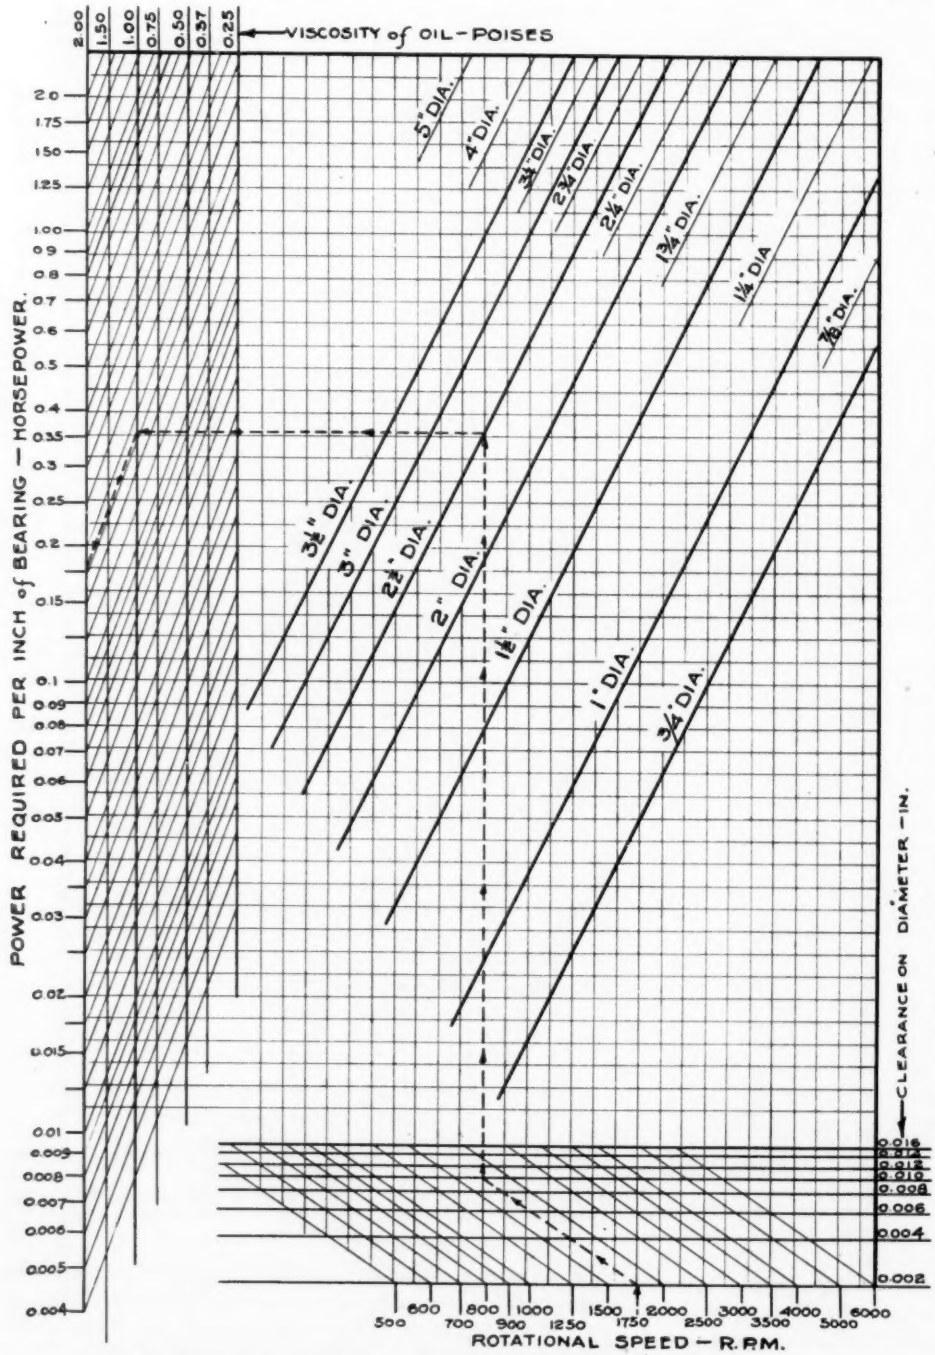

FIG. 10 POWER REQUIRED BY A VERTICAL JOURNAL BEARING PER INCH OF LENGTH

(Based on the equation: Horsepower $= 6.12 \times 10^{-10} \frac{\eta \pi^3 L D^3 N^3}{H}$; where η = viscosity in poises, D = diameter in inches, L = length in inches, N = rpm, H = radial clearance in thousandths of an inch.)

(c) The effect of greater pressures on the oil.

The result of perfect workmanship in the construction of a deep-well pump would be a pump in which the journals and bearing sleeves were concentric and parallel. This is the aim of the manufacturer and is the condition to which the results derived in this work apply directly. Fig. 10 makes it possible for one to obtain immediately the power absorbed by a vertical bearing, assuming that a complete film exists. If the film is incomplete, Fig. 9 gives an approximate idea of the deviation from the case of the complete film.

That these results are dependable is evidenced by the agreement between the actual and theoretical values as shown in Fig. 7. It is to be hoped that these results may point the way to the more effective design of vertical journal bearings in practice and to further research on a problem vital to one of the industries.

Appendix

SAMPLE CALCULATIONS FOR RUN 19-4

1 Theoretical power from Equation [1]:

$$L_c = \frac{\mu\pi^3 d^3 l N^2}{3600\, h}$$

$$= \frac{1.15 \times 10^{-3}}{3600}\,\pi^2\left(\frac{2.44}{12}\right)^3 \times \frac{5.25}{12} \times \frac{12}{0.010} \times 800^2 = 27.9 \text{ ft-lb per sec.}$$

2 Actual power:

$$L_a = \frac{2\pi LPN}{60}$$

where P = pull on scale
L = length of lever arm
N = speed in rpm

$$L_a = \frac{2\pi \times 14.0 \times 4.50 \times 800}{60 \times 12 \times 16}$$

27.5 ft-lb per sec.

3 Actual power based upon viscosity 1.00×10^{-3} lb-sec per sq ft where

$$L_a' = L_a \times \frac{\mu_{st}}{\mu_a}$$

μ_{st} = standard viscosity = 1.00×10^{-3}
μ_a = observed viscosity

$$L_a' = 27.5 \times \frac{1.00 \times 10^{3}}{1.15 \times 10^{-3}} = 23.9 \text{ ft-lb per sec.}$$

4 Accuracy of the results:

The errors involved in the determination of the measured and computed power are of two kinds: accidental errors of observation and systematic and constant errors due to the instruments and methods used.

Systematic and constant errors are evidenced by a greater departure from the theoretical value than the accidental errors would indicate. In the work described, the instruments and methods used were, with one exception, standard. The exception was that of the film temperature measurement, which was accomplished with the thermocouples already described. The results, as will be shown, fall within the computed accidental error, which is an indication that the systematic and constant errors must be of small magnitude.

The measurements were made by means of the instruments named in the table at the foot of the page.

The accidental errors of the results can be computed from the relation:[4]

$$M_{La}^2 = \left(\frac{\partial L_a}{\partial p} \cdot M_p\right)^2 + \left(\frac{\partial L_a}{\partial L} \cdot M_L\right)^2 + \left(\frac{\partial L_a}{\partial N} \cdot M_N\right)^2$$

where M_{La} = mean square error in L_a
M_p = mean square error in p, etc.
$\frac{\partial L_a}{\partial p}, \frac{\partial L_a}{\partial L}, \frac{\partial L_a}{\partial N}$ = partial derivatives.

To determine the mean square errors of the individual measurements, note these data as given for run 19-4:

Time	Speed, rpm	Film temperature—Upper	Lower	Mean	Pull, oz	Viscosity, lb-sec/sq ft
4:15 pm	800	116.5	115.3	116.0	13.8	.....
4:20 pm	800	116.5	115.8	116.1	13.8	.....
4:25 pm	800	116.5	115.8	116.1	14.0	.....
4:30 pm	800	116.5	115.8	116.1	14.0	.....
Average	800	116.5	...	116.1	13.9	1.07×10

Since the data show no appreciable variation from the mean, it is assumed that the mean square error of each quantity is equal to the sluggishness of the instrument. The partial derivatives are obtained from the equations used in calculations. For example:

$$\frac{\partial L_a}{\partial p} = \frac{2\pi LN}{60} = \frac{2\pi \times 4.50 \times 800}{60 \times 12 \times 16} = 1.96$$

Evaluating the other partial derivatives and substituting, the mean square error in the actual power is:

$$M_{La}^2 = \overline{1.96^2} \times \overline{0.3^2} + \overline{6.06^2} \times \overline{0.02^2} + \overline{0.0364^2} \times \overline{3^2}$$
$$= 0.35 + 0.015 + 0.012 = 0.377$$

or $M_{La} = 0.6$ and $L_a = 2.75 \pm 0.61$ ft-lb per sec.

A similar computation for the theoretical power gives:

$L_c = (27.9 \pm 1.9)$
$= (28 \pm 2)$ ft-lb per sec.

In this case the greatest error lies in the determination of h, the mean radial clearance, which is assumed measurable to the nearest 0.0005 in. due to the effects of thermal expansion.

Examination of the curves in Fig. 7 shows that the deviation of the experimental points from the curves is in all cases less than 10 per cent, which compares favorably with the 7 per cent error as heretofore computed.

Quantity	Instrument: Name	Least count	Calibration: Sluggishness	Standard	Conditions
N = speed	Tachometer	10 rpm	3 rpm	Stop-watch rev. counter	Direct-connected vert. shaft
t = film temp.	Thermocouples, potentiometer	0.01 mv	0.5 F	B. of S. thermometer	Bearing shell immersed in oil
P = force	Spring balance	0.5 oz	0.3 oz	Dead weights	Horizontal position
h = clearance	Feeler gage	0.0005 in.			
d = diameter	Micrometer calipers	0.0005 in.			
Viscosity	Saybolt viscometer	0.2 sec, 1 F			
Lever arm	Scale	1.64 in.			

Discussion

BURT L. NEWKIRK.[5] The authors have studied the losses due to fluid friction of a journal constrained to rotate centrally or with a definite eccentricity in a vertical sleeve. In the course of experimental studies published[6] some time ago it was noted that

oil films in journal bearings have, under some circumstances, a tendency to cause the journal to whirl in its bearing. Thus a vertical shaft running in a sleeve bearing so that it is free to move within its clearance may not run centrally or with any fixed eccentricity, but it may move over to a very eccentric position and then travel around in the clearance at a rate equal to half the rotation speed. This tendency may be overcome[7] by any force of moderate magnitude tending to hold the journal to one side of its clearance. It is possible that the bearings of the long shafts of deep-well pumps are sufficiently out of line to supply such a radial force for each bearing and so prevent the whirling, but it is well to keep in mind this whirling tendency of the oil film in any discussion of vertical shafting carrying no radial loading. It seems likely that in bearings having the large clearances used in the experimental apparatus of the authors (0.010 to 0.020 in.) the journals would run in very eccentric positions or whirl.

M. D. HERSEY.[8] The formula for friction of a concentric full journal bearing has been known for many years. A formula for eccentric bearings was published in the Journal of the Washington Academy of Sciences, November 19, 1914, which is exactly equivalent to that of the paper, but only regarded as an approximation. The useful features of the paper are those relating to the apparatus itself, and its application to the eccentric case, and might be more thoroughly investigated when possible.

C. G. WILLIAMS.[9] It is regrettable that there is so little information on vertical bearings. The writer has had experience with deep-well pumps north of Antoneda, Colo., which is irrigated from wells driven from 350 to 950 ft. The pumps were operated by electric motors, and in the deepest wells the frictional resistance in the vertical guide bearings and the thrust bearings amounted to 15 per cent of the input of power when the installation was new. The pumps were multiple-stage centrifugal pumps in 12- to 14-in. tubing. The flow of water from the well was through a 6- or 8-in. pipe. The drive shaft occupied the center of the pipe, and at every joint, of from 16 to 18 ft, a guide bearing was located. In the original installations these guide bearings were of a soft bronze, and in some replacements of soft stick brass, such as for bushings on railroads, the repair work being generally done in the local railroad shop.

These bronze or brass bushings lasted not more than one season of approximately 8 months. The cause of the cutting out of the bearing and part of the cause for the cutting of the shaft was the presence of a layer of fine white quartz sand, such as would pass through 100-mesh screen. The thrust bearing was at the bottom of the motor shaft, which is the poorest location. The housing contained over 2 in. of metal all around the bearing. This allowed the bearing to be made 2 in. larger in diameter. A thrust bearing, somewhat like the Kingsbury thrust bearing, was installed. Rubber bushings or bearings were installed at all points along the shaft. There was a large supply of old feedwater-pump rubber valves 1 in. thick, three of these making a bearing. A fluted punch cut out the center of the rubber disk to allow free water flow through the bearing around the shaft, thus lubricating the bearing. The repairs were made in 1912 in one week's time, and when the writer was in that country in 1922, he found that every pump so repaired was running in good condition, except one pump where the runner had been cut out by the quartz sand. In 1923 the same type of bearing was installed in a multiple-stage centrifugal pump operating in a 24-in. tubing at a depth of 225 ft.

The power losses on the pumps in Colorado were cut from the figures given above to less than 0.25 per cent, while the pump in Arizona, which had had a power loss of 25 per cent in a 200-hp motor, had the losses reduced to 0.15 per cent after the installation of new thrust bearings and soft rubber guide bearings.

Because of the torsional effect of the power on the long shaft, there is a tendency for all of the wear to come on one side of the shaft, rather than on the entire circumference. This stress has the effect of causing the bearing and shaft to assume the features of a stationary shaft and moving bearing that we sometimes have in horizontal-bearing combinations. This effect will, naturally, have an effect on lubrication of the bearing quite different from

[7] Except where the rotor speed is more than twice the critical speed.

[8] Vacuum Oil Company, Inc., Paulsboro, N. J.

[9] Consulting Mechanical Engineer, Rockford, Ill.

that in machine tools; however, where this effect is present, more care must be applied to the manner in which the lubricant is delivered to the bearing.

ALEXEY J. STEPANOFF.[10] The knowledge of the power lost in bearing friction of deep-well pumps is of much more importance than that of any other type of centrifugal pump. Short units can be guaranteed within close margin, since they are tested in the shop under the same conditions as they are operated in the field. Deep-well pumps are sold on the basis of pump over-all efficiency covering hydraulic losses (as a rule the velocity head at discharge is considered a loss) and bearing losses of the column sometimes several hundred feet long, while the manufacturers' facilities usually provide for testing deep-well pumps with short columns only. Byron Jackson Company has built a tower for testing deep-well pumps with columns up to 135 ft long.

The predetermination of the field performance of deep-well pumps involves the following steps: (1) Add to the given static head hydraulic losses in the column; (2) for the head thus obtained and capacity specified the proper pump is selected from the factory test data and "shop bhp" is calculated; (3) add to the shop bhp the power absorbed by the column shaft for field bhp. The power consumed by the thrust bearing is usually provided for in the factory test; however, if the factory tests are run with ball thrust bearings and a Kingsbury bearing is used, the power to drive this bearing should be added to the shop bhp; (4) by dividing the water hp based on the field head by the field bhp from (3), the field pump efficiency is obtained; (5) with the motor efficiency, the plant efficiency can be calculated.

It is seen that the knowledge of the power lost in the column-shaft friction is necessary, not only for effective design, but for every-day routine work. The column bearings of deep-well pumps vary in size and operate at different speed—some of them on oil, others on water. Thus the effect of clearance, speed, diameter, and viscosity of lubricant should be known. The laws of lubrication of vertical bearings were not always understood, and experimental data were scarce and haphazard.

The work accomplished by the authors is the first and necessary step toward the solution of this problem. By the study of an isolated bearing the authors were able to trace the effects of the eccentricity, incompleteness of film, and temperature and thus prepare the future investigator of the long shafts with many bearings for the difficulties he may encounter in the work of this nature.

The writer wishes to call attention to several points not sufficiently stressed. The Euler's equation in its final form applied to the flow similar to that found in the vertical bearings

$$u = V(1 - y/h)$$

means that the velocity of the liquid contained between two surfaces, one moving and the other stationary, is proportional to its distance from the stationary wall and that velocity distribution is a linear function of that distance. Thus the average velocity of the film is equal to one-half that of the moving wall and is independent of the clearance. This is true as long as the flow is viscous. An interesting application of this is found in centrifugal-pump practice. Since the impeller of a pump revolves in a stationary case, the pressure in the clearance between the impeller shroud and the case wall is less than the pressure in the volute proper by the amount of the centrifugal head created within this clearance. The latter depends upon the velocity of rotation of water in that space. From the foregoing it is seen that the average velocity in the clearance should be equal to one-half of the impeller speed if the flow is in the viscous region. The measurements of the pressure distribution in that space by the writer and calculation of the average velocity show that this is approximately true in practice. Displacement of the impeller from its central position did not show material difference in the pressure distribution in the pump case as long as the discharge from the impeller did not hit the side walls of the volute, which is indicated by the vibration of the rotating element.

It is possible to combine the authors' Equations [1], [1*a*], and [2] into a single equation by substituting into Equation [2] for k its value in terms of clearance and eccentricity:

$$P = K \frac{\mu l N^2 d^3}{\sqrt{(c^2 - e^2)}}$$

The writer purposely uses a notation slightly different from that of the authors, as follows:

P = power in hp; this symbol is used rather than L_e because in the paper L stands for length; P is the A.S.M.E. symbol for power

c = clearance radial, used instead of h because on the same page h_L is used for head lost, which is more common notation.

e = eccentricity; preferable to Δ, as that has an established meaning of "increment" used in connection with some other letter; e for eccentricity is also A.S.M.E. symbol

$K = 1.9 \times 10^{-8}$ if μ is in poises, d and l in inches, and c and e in thousandths of an inch

$K = 1.565 \times 10^{-5}$ if μ is in lb-sec per sq ft and d, l, c, and e are in feet.

The advantages of this form of equation are that (1) the necessity of dual notation is eliminated, the system of units affecting the value of the constant only, and (2) it covers both cases with shaft concentric and eccentric—in the first case $e = 0$.

From the inspection of the equation it is seen that the power absorbed by the bearing is proportional to the absolute viscosity, length of the bearing, and square of the speed and cube of the diameter, and inversely proportional to the radial clearance for concentric bearing. For eccentric bearing $\sqrt{(c^2 - e^2)}$ stands for the radial clearance, which is a side of a right triangle constructed on c as a hypotenuse and e as the other side.

The increase in power with the decrease of radial clearance will be easily visualized if one would keep in mind a model consisting of two rubber blocks of the same size but of different height or thickness. Now, if the bases of both blocks are fixed and forces are applied to the upper surfaces, it is readily seen that to produce the same displacement of the upper surfaces the thin block will require a greater force.

The decrease of power to drive a bearing on account of film incompleteness is very interesting. Similar results were observed with horizontal shaft but to much greater degree. With thin film lubrication the actual decrease in power was observed with an increase of viscosity of lubricant. This is explained by the fact that with low oil viscosity the intermeshing of asperities on the two surfaces takes place (that is how the wear of bearings and shafts occurs), while with increased viscosity the bearing surfaces are separated by a film of oil. It seems that with the apparatus used by the authors the possibility of partial solid friction is excluded.

It should be noticed that Equation [1] is limited in its use by the assumptions upon which it is based. Thus at high velocities or large clearances the inertia forces come into play, and the flow changes from viscous to turbulent. One particular case is of interest—that is when the clearance is equal to infinity or when the shaft is immersed into liquid. The Equation [1] gives zero for friction loss, which is not true in practice.

The writer had some difficulty in using Equations (1) and

[10] Designing Engineer, Byron Jackson Company, Berkeley, Calif. Mem. A.S.M.E.

(1*a*) for calculation of a few examples. The results obtained with the formula (1*a*) are 60 times greater than those using Equation (1). Upon checking, it was found that the constant in Equation (1*a*) is in error. Instead of 3.67×10^{-8}, this constant should be 6.12×10^{-10}. [NOTE: The authors have made this correction in Equation (1*a*) of the paper, and also have inserted a new Fig. 10, to correspond to a correct Equation (1*a*).]

It may be well to mention here the conversion factors for the absolute and kinematic viscosity from metric to English units for convenience, as those are missing in standard reference books:

1 To convert the absolute viscosity μ in poises (dynes-sec/cm²) to metric gravitational (kg-sec/Mt^2), divide by 98.1.

2 To convert μ in poises to English absolute units (poundal-sec/ft²), divide by 14.88.

3 To convert μ in poises into English gravitational (lb-sec/ft²), divide by 478.

4 To change the kinematic viscosity from metric (cm²/sec) to English (ft²/sec), divide by 929.

It has been found on many occasions, especially with very deep oil wells, that the field-pump efficiency is appreciably better than expected from the factory test. In the case of deep oil wells, this is explained by the pumping effect of the gas contained in oil (gas lift); in the case of water deep-well pumps with oil-shaft lubrication, this may be caused by the leaky inner tubing and shaft running on water instead of oil. It takes less power to revolve a shaft totally immersed in water than a shaft enclosed in a tubing and running on oil.

The authors have thrown light on the problem of lubrication of vertical bearings under idealized conditions. In deep-well pump practice with very long shafts and a great number of bearings, deviations from these ideal conditions occur, such as incompleteness of film, eccentricity of shaft, side load due to shaft misalignment and crooked wells, and leaky joints in tubing resulting in water lubrication of some bearings instead of oil, so that it is natural to expect that the calculated shaft friction loss may differ from the actual. Compared with limited and scattered test data with long shafts, it seems that the friction horsepower, as calculated by Equation [1], is somewhat too high. The incompleteness of the oil film is probably the explanation for this. Systematic tests with long shafts under actual operating conditions can indicate the way to correct the theoretical formula, probably by attaching to it a single experimental coefficient.

AUTHORS' CLOSURE

Dr. Newkirk's discussion indicates one of the directions which further experimentation might take. The cause of "shaft whirling" would probably not be the condition of oil supply in the case of deep-well pumps. The mechanical processes involved in producing a long shaft and bearing housing assembled with threaded joints do not allow perfect construction, but probably result in shafts and bearing supports which are slightly bent. The shaft in such a case would probably not run with a fixed eccentricity, but would tend to "whirl" due entirely to mechanical imperfections. The authors would be glad to receive more detailed suggestions as to methods for determining the effect of "shaft whirling" upon the power required for lubrication.

The equation to which Mr. Hersey refers is:

$$f = \frac{\pi^2 \frac{D}{c} \cdot \frac{\mu N}{p}}{\sqrt{\frac{x}{c}\left(2 - \frac{x}{c}\right)}}$$

in which

f = coefficient of bearing friction
D = shaft diameter
c = mean radial clearance
x = minimum film thickness
μ = coefficient of viscosity
N = speed of rotation
p = bearing pressure.

As noted in the paper, the radial load p is zero. Inserting this value of p in the foregoing equation, one obtains $f = \infty$. Inasmuch as the assumptions upon which the equation is based are not stated, one is not entitled to eliminate p algebraically by combination with other equations of the same article. It therefore seems that the original presumption of no previous theoretical treatment is justified.

Mr. Williams cites some of his personal experiences which seem to discredit the lubrication of deep-well pump shafts with oil as a sound practice. He seems to imply that water-lubricated rubber bearings are the best for such service. The pumps to which he refers, built 23 years ago, were of the open-column type in which the bearings and shaft were exposed to the grit in the water. Such construction is no longer used in this country except for special cases in which the presence of oil in the water is objectionable. The accepted practice is to inclose the shaft and bearings in a tube which serves the three purposes of supporting the bearings, distributing the lubricating oil, and protecting the shaft and bearings from grit. Thus the testimony of practice is that the oil-lubricated bearing is preferred to the water-lubricated type. Furthermore, the experiments of Professor Langille, of the University of California, indicate that although the rubber bearing is very durable when exposed to much grit, the shaft in such cases is subjected to extreme wear. Unfortunately Mr. Williams' figures in regard to the friction losses in bearings combine the vertical-guide-bearing loss with the thrust-bearing loss. As the figures quoted are for pumps more than 20 years old, we obtained for comparison the following figures on more modern pumps from the Byron Jackson Company, one of the larger manufacturers of deep-well pumps:

Case 1, 40-hp unit with 250-ft setting, 450-ft total head, 1750 rpm speed. In this case the thrust was about 7000 lb, the thrust-bearing loss 3 hp with Kingsbury thrust and 1 hp with ball-bearing thrust. The estimated guide-bearing loss is $1^1/_2$ hp, making the total loss in two cases $2^1/_2$ and $4^1/_2$ hp. This represents $6^1/_4$ and $11^1/_8$ per cent of the power input.

Case 2, 250-hp unit, 700-ft setting at 1200 rpm. The thrust in this case would be about 14,000 lb, the thrust-bearing losses 5 hp, and the guide-bearing loss 10 hp. The total loss in this case is 15 hp, or about 6 per cent of the input.

From these figures it would seem that the loss quoted by Mr. Williams is too small to account for even the thrust-bearing loss, and, further, these figures indicate the order of importance of the whole investigation. Mr. Williams' other remark concerning the wear on one side of the shaft is very interesting. Probably such behavior is due to a bent shaft, since obviously pure torsion would not deflect the shaft.

Mr. Stepanoff points out certain features of the paper which appear to be very important to one in the pump-manufacturing business. In the interests of brevity the original paper was devoted entirely to the essentials of the experimental problem. However, from Mr. Stepanoff's remarks one can not avoid being impressed with the fact that the subject of shaft lubrication is a vital one to the designer of such machinery.

Two errors in the paper as originally printed have been called to attention. The first one is the value of the constant in Equation (1*a*), which should be 6.12×10^{-10} in place of 3.67×10^{-8}. The second relates to Fig. 10, which has been redrawn to eliminate the errors that appeared in the original.

The questions raised in the discussion should lead to further investigation in the field of deep-well pump lubrication.

RP-55-1

Performance of Cutting Fluids in Drilling Various Metals

Progress Report No. 4 of the Sub-committee on Cutting Fluids[1] of the A.S.M.E. Special Research Committee on the Cutting of Metals

By O. W. BOSTON,[2] ANN ARBOR, MICH., and C. J. OXFORD,[3] DETROIT, MICH.

This paper gives the results of a series of drilling tests on nine different metals using eleven different cutting fluids. Modern twist drills having 30-deg helices, ranging from 1/2 in. to 1 1/2 in. in diameter, were used. The materials consisted of a cast aluminum alloy, free-cutting brass, cast iron, malleable cast iron, S.A.E. 1020 steel, S.A.E. 1035 steel, carbon tool steel, S.A.E. 3150 steel, and S.A.E. 1112 steel. The eleven cutting fluids consisted of dry cutting, borax water, two soluble oils, lard oil, two straight mineral oils, two compounded oils, and two sulphurized oils.

For each material a formula for torque and thrust was developed as a function of variable diameter and variable feed. Constants for these formulas for dry cutting and each of the eleven cutting fluids are determined. The influence of the different cutting fluids on each metal is shown. With the net output power for drilling dry expressed as 100 per cent, the savings made are as follows:

- **33.3 per cent for S.A.E. 1020 steel when using a sulphurized oil**
- **31.7 per cent for aluminum alloy when using a 90 per cent mineral–10 per cent lard oil**
- **26.0 per cent for S.A.E. 1035 steel when using a sulphurized lard-mineral oil**
- **23.0 per cent for S.A.E. 3150 steel when using a sulphurized mineral oil**
- **21.0 per cent for carbon tool steel when using sulphurized mineral oil**
- **17.2 per cent for cast iron when using a mineral oil containing 5 per cent oleic acid**
- **10.5 per cent for malleable cast iron when using any kind of an oil, such as lard, mineral, compounded, or sulphurized**
- **6.8 per cent for S.A.E. 1112 steel when using a sulphurized lard-mineral oil.**

No appreciable difference is made whether free-cutting brass is cut dry or with any kind of a cutting fluid.

In the development of the formulas for torque and thrust, it was found that the same results of the exponents for drill diameter and feed would be obtained regardless of the diameter of the drill used in the variable feed tests and regardless of the feed used in the variable drill diameter tests. The values of these exponents are not influenced by the type of cutting fluid used. The torque and thrust lines as a function of feed or diameter as the variable are merely displaced vertically, if affected at all. The constants of the torque and thrust formulas, however, indicate the cutting characteristics of the cutting fluids.

The torque and thrust formulas for all kinds of steels as covered in the paper are found to be identical except for different values of the constant. Other metals, however, produce formulas apparently characteristic of that metal. In other words, different formulas as summarized in Table 4 are developed for the aluminum alloy, the free-cutting brass, cast iron, malleable iron, and steel.

O. W. Boston

C. J. Oxford

THIS REPORT covers an extension of Progress Report No. 3, "Performance of Cutting Fluids," presented at the Hartford, Conn., meeting of the Society in June, 1931. In that report an attempt was made to determine the characteristics of each of eleven cutting fluids, including dry cutting, when drilling and planing an annealed chrome-nickel steel corresponding to S.A.E. 3150.

The present paper is confined to drilling tests using the same eleven cutting fluids, in which eight additional metals have been cut. These metals were selected to represent various classes,

[1] The personnel of the Sub-committee consists of: C. J. Oxford, Chairman; O. W. Boston; F. C. Spencer, *ex-officio*, Chairman of the Special Research Committee on the Cutting of Metals.

[2] Professor, College of Engineering, University of Michigan. Mem. A.S.M.E. Orlan W. Boston was graduated from the Univerity of Michigan Engineering College in 1913, received a Master's degree in 1917, and the degree of Mechanical Engineer in 1926. After graduation he was engaged at the university as instructor in engineering mechanics and mechanical engineering for four years. In October, 1917, he was commissioned in the U. S. Navy and assigned to duty in the Bureau of Ordnance on design and manufacture of submarine mines used in the North Sea blockade. From 1919 to 1921 he was engaged in industrial engineering work for the Cleveland Tractor Company, in Cleveland, as assistant to the vice-president and works manager. In the fall of 1921, he returned to the University of Michigan, where he is professor of shop practice and director of the department of engineering shop. He is author of many papers dealing with the subject of metal cutting and is serving as an A.S.M.E. representative on the Specifications for Tool Steel Committee of the American Society for Testing Materials.

[3] Chief Engineer, National Twist Drill & Tool Company. Assoc. Mem. A.S.M.E. Carl J. Oxford was born in Norway and came to the United States in 1909. After two years in the engineering department at the University of Michigan, he served as tool draftsman with the Packard Motor Car Company, Dodge Brothers, and Nordyke & Marmon until 1916, when he became designing engineer for the Wilt Twist Drill Company. The following year he became associated with the National Twist Drill & Tool Company.

Contributed by the Special Research Committee on the Cutting of Metals and presented at the session of the Machine Shop Practice Division at the Annual Meeting, New York, N. Y., December 5 to 9, 1932, of The American Society of Mechanical Engineers.

and consist of a cast aluminum alloy, a free-cutting brass, cast iron, malleable cast iron, a free-cutting steel, and low-, medium-, and high-carbon steels.

The tests were confined to power determinations in which drill torque and thrust, as measured on a dynamometer, and input power, as measured on a wattmeter, were determined. Drills ranging from 1/2 in. in diameter to 1 1/4 in. in diameter were used. They were operated at a peripheral speed of 60 fpm and at feeds corresponding to commercial practice for steel for the respective diameters. Formulas representing the torque and thrust are developed for all materials as a function of drill diameter and feed.

The exponents for drill diameter and feed are determined for each of the materials drilled, as well as the constants for each cutting fluid used on each material.

The drill press and the equipment used in the tests are shown in Fig. 1.

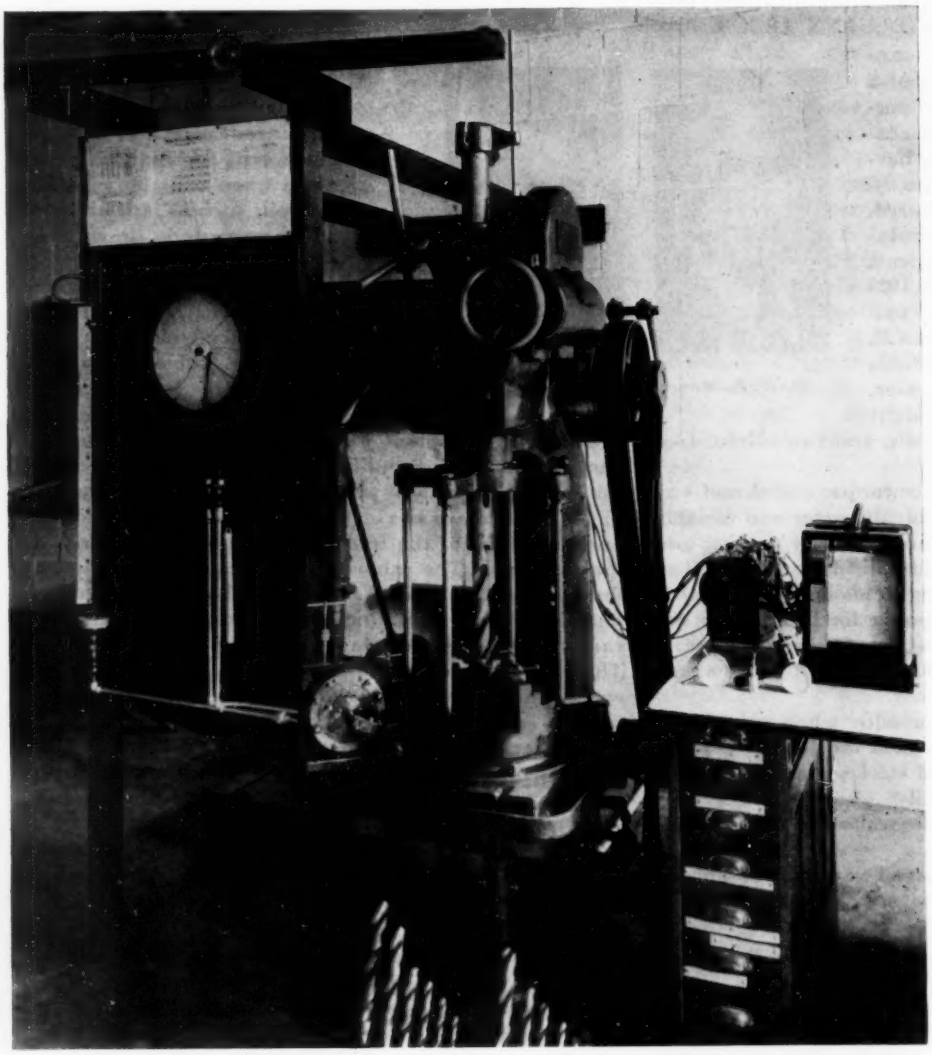

FIG. 1 DRILL PRESS AND EQUIPMENT USED IN TESTS

THE CUTTING FLUIDS

The cutting fluids used in these tests are the same as those used in the previous report. They consist of eleven cutting fluids selected to represent the various classes used commercially. They were described in detail in Report No. 3, but are summarized in Table 1, in which the number, composition, and various properties of each cutting fluid are given.

THE MATERIALS CUT

In Report No. 3, an annealed chrome-nickel steel, corresponding to S.A.E. 3150, was used exclusively. In these tests a limited variety of ferrous and non-ferrous metals were selected to give as good a picture as possible of the performance of the various cutting fluids used. These materials, together with their bar designations, heat treatments, chemical analyses, hardness numbers, and, when available, their physical properties, are listed in Table 2. Photomicrographs at 100 magnifications of all materials used are shown in Figs. 2 to 10, inclusive. These photomicrographs were made from a surface 1/2 in. beneath the outside surface.

The aluminum alloy, corresponding to S.A.E. 33, was selected as that drilled most commonly in this class. It was procured from the University of Michigan foundry in chilled cast bars 1 1/2 in. wide by 2 in. deep and 14 in. long. The bars were dense and uniform, showing no blowholes or other imperfections. The photomicrograph is shown in Fig. 2.

The brass was of the leaded free-cutting variety commonly used for screw-machine work. It was obtained in bars 1 3/4 in. square, extruded to 1 13/16 in. square, and then drawn to finished size. It was sawed to convenient lengths of 14 in. The photomicrograph of this free-cutting brass is shown in Fig. 3.

The soft cast iron tested contained about 1 per cent nickel and 2.62 per cent silicon. It was cast in the University of Michigan foundry in bars 2 in. by 4 in. in section and 14 in. in length. The photomicrograph is shown in Fig. 4.

The malleable cast iron was furnished gratis by the Cadillac Malleable Iron Company in the form of bars 2 in. by 4 in. in section by 14 in. long. The hard iron contained 2.46 per cent total carbon and 1 per cent silicon, and represented a type in common use. The bars were annealed in the front thermocouple pot of the company's No. 2 oven. The annealing cycle was as follows: 40 1/4 hr to heat up to 1550 F, 48 hr at 1550–1625 F, 15 hr cooling to 1500 F, 12 hr cooling to 1400 F, 19 hr cooling to 1300 F, and 18 1/4 hr cooling to 1200 F. To cool from the annealing temperature to 1200 F required 64 1/4 hr. The analysis of the hard

iron, that is, before annealing, is given in Table 2. A photomicrograph of the malleable cast iron is given in Fig. 5.

The annealed chrome-nickel steel, S.A.E. 3150, used in this test is the same as that used in the test for Progress Report No. 3. Certain data from that report are included in this report for purposes of comparison and to make the information contained in this report complete. These bars were furnished in sections 2 in. by 6 in., but for convenience in drilling were cut to 14 in. lengths. The photomicrograph of the S.A.E. 3150 steel is given in Fig. 6.

The low-carbon steels, S.A.E. 1020 and S.A.E. 1035, were furnished as long, annealed, smooth forgings, having a 2 in. by 4 in. cross-section. The carbon contents were 0.22 per cent and 0.38 per cent, respectively. They were selected as being representative of steels commonly used in production work. The carbon tool steel tested had a carbon content of 0.97 per cent and was in an annealed condition. Photomicrographs of the three carbon steels are shown in Figs. 7, 8, and 9, respectively.

A free-cutting high-sulphur steel, corresponding to S.A.E. 1112, also was included in these tests, inasmuch as this type of steel is commonly used in connection with cutting fluids in screw-machine work. It was obtained in the form of cold-drawn bars $1^1/_2$ in. square. A photomicrograph of the S.A.E. 1112 steel is shown in Fig. 10.

THE DRILL PRESS AND THE DYNAMOMETER

The testing equipment used for determining the influence of the cutting fluids in drilling is the same as that described in Progress Report No. 3. The drill press was a No. 2 manufacturing-type Colburn press, driven through a short belt by a 5-hp, 220-v, 3-phase, 60-cycle motor. A gear pump was provided for raising the coolant from the tank at the side of the column to the work and drill. The cutting fluid was supplied in as large quantities as possible and dumped at a low velocity upon the drill just above the work. No drill guide bushing was used.

The testing equipment consisted of a drill dynamometer with gages and recording wattmeter. The drill dynamometer was such that the torque and thrust as developed at the drill point were recorded graphically. The chart of the recording gage was made to rotate so as to register the torque and thrust as a function of the travel of the drill. The method of calibrating the torque and thrust scales is described in detail in an earlier paper entitled, "Power Required to Drill Cast Iron and Steel."[4] Actual cutting speeds were determined during each test, using a speed counter. The wattmeter recorded the tare input power developed by the machine running with the speed and feed gears engaged, but before the drill was cutting, and the gross power input while cutting. The drill point was brought to within $^3/_8$ in. of the surface of the work to be drilled, after which the feed clutch was engaged. The drill press was started and the tare power was recorded on the wattmeter chart while the drill was fed the $^3/_8$ in. to the work. As the drill penetrated the work, the total power also was recorded on the wattmeter chart. The tare power deducted from the gross power gives the net power input. This corresponds to the power output at the drill point, except for the additional frictional load on the gears and bearings of the machine due to the cutting load. This frictional power loss is least for light loads and high speeds and greatest for high loads and low speeds. The efficiency, as determined by dividing the net power output, computed from the torque and thrust by the net power input, determined by the wattmeter, is about 90 per cent for the $^1/_2$-in. drill rotating at 440 rpm and a feed of 0.009 in. per revolution, but is only about 75 per cent for the $1^1/_4$-in. drill at 174 rpm and at a feed of 0.015 in. per revolution.

[4] Trans., A.S.M.E., 1930, MSP-52-2.

THE DRILLS USED

The drills used in these experiments were selected as being representative of the drills corresponding with standard specifications for taper-shank, high-speed-steel twist drills. They were selected in sizes $^1/_2$ in., $^3/_4$ in., 1 in., $1^1/_4$ in., and $1^1/_2$ in. in diameter, and correspond to the "R" drills described in Progress Report No. 3 and a previous paper.[4] The various angles and dimensions of these drills as actually used in the experiments are shown in Table 3. The actual revolutions per minute used for a set-up of approximately 60 fpm linear speed and the feed in inches are shown for each drill size.

RESULTS OF THE DRILLING TESTS

Since the object of this investigation was to determine and compare the characteristics of the various cutting fluids on each of the materials selected, it was thought best to standardize as much as possible on the tests. Therefore, each drill size used was run at a peripheral speed as near as possible to 60 fpm and at a commercial feed as indicated in Table 3.

TABLE 3

Drill Diam.	No.	Web thickness, in.	Helix angle, deg	Point angle, deg	Chisel-edge angle, deg	Clearance at periphery, deg	Actual rpm	Fpm	Feed, in.
$^1/_2$	R	0.081	29	121	129	5–20	449	58.8	0.009
$^3/_4$	R	0.104	31	121	134	5	300	59.0	0.012
1	R	0.141	31	121	136	5	231	60.5	0.013
$1^1/_4$	R	0.180	30	121	138	5	174	57.1	0.015
$1^1/_2$	R	0.213	31–20	121	138	5	151	59.4	0.015

When drilling aluminum and free-cutting brass, however, in order to get values of torque and thrust large enough to measure without an appreciable error, the feeds actually used for each drill size were double those shown in Table 3.

All drills, $^1/_2$ in. to $1^1/_4$ in. in diameter, inclusive, were used in Progress Report No. 3 on the S.A.E. 3150 steel, bar KF, and in this paper on the carbon tool steel, bar GF, which was the first material tested. The results from both of these materials were so uniformly accurate that it was decided, in order to save time, to eliminate the $^3/_4$-in.-diam drill from the tests on the rest of the materials tested. The experimental data presented for cast iron, S.A.E. 1020 steel, and S.A.E. 1035 steel were determined from the $^1/_2$-in., 1-in., and $1^1/_4$-in.-diam drills at their respective speeds and feeds. From these tests, however, it was concluded that the low values of the torque on the $^1/_2$-in. drill made it difficult to read the values with satisfactory accuracy, so that on the rest of the tests, the $^3/_4$-in., 1-in., and $1^1/_4$-in. drills were used, with what the authors believe to be complete satisfaction. The experimental results obtained from each of these materials are discussed separately below and are then finally compared.

Tests on Aluminum

It was found that the formulas for torque and thrust when drilling the S.A.E. 3150 steel, as previously reported, did not hold for aluminum. It was thought desirable, therefore, to determine formulas for aluminum. In Fig. 11 are shown the results of a series of tests to determine correct formulas for aluminum. The variable-feed tests were run with the $1^1/_4$-in.-diam drill, using feeds of 0.015 in., 0.021 in., 0.030 in., and 0.043 in. The values of feed are greater than those generally used on steel in order that the torque and thrust may be sufficiently large to be read with accuracy. The values of feed as used were selected to give approximately equal increments between plotted points on the log-log curve in Fig. 11.

When cutting dry, the torque values, as determined from

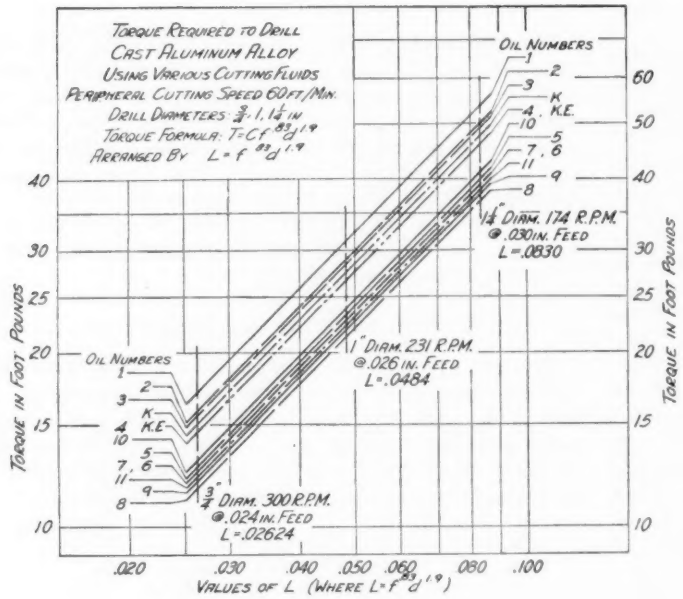

Fig. 12

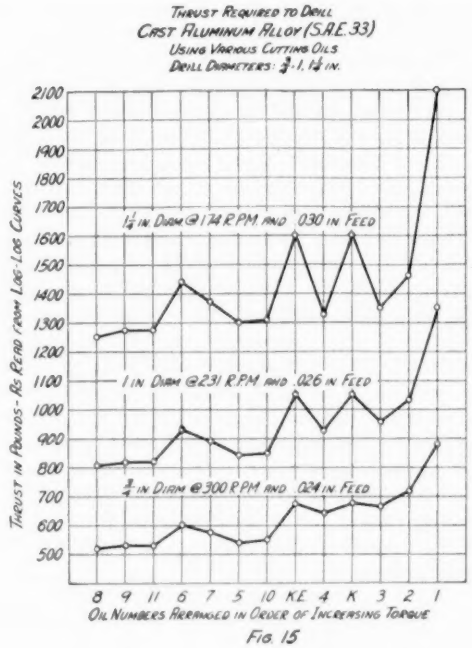

Fig. 15

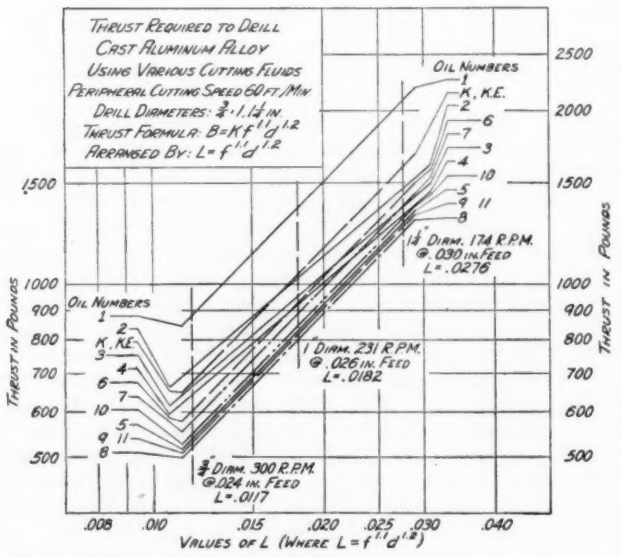

Fig. 13

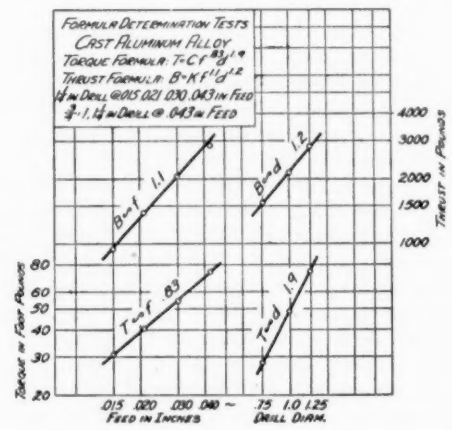

Fig. 11

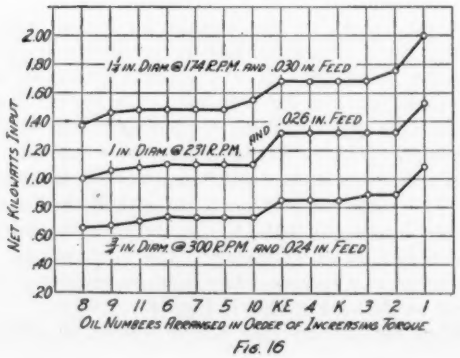

Fig. 16

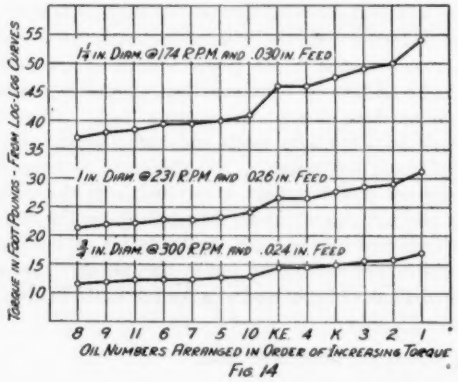

Fig. 14

these tests as a function of the feed, fall very satisfactorily on the straight line indicated, which has a slope with the horizontal of 0.83. The thrust values also indicate a straight line when plotted over the variable-feed values. The slope of this line is 1.1.

For the variable-diameter tests, a feed of 0.043 in. was selected, and both torque and thrust values as plotted over the variable diameter on the log-log paper in Fig. 11 give satisfactory straight lines. The slope of the torque line, as a function of the diameter, is 1.9 and that of the thrust, as a function of the diameter, is 1.2. The torque and thrust equations for aluminum indicated are then as follows:

$$T = C f^{0.83} d^{1.9}$$
$$B = K f^{1.1} d^{1.2}$$

in which T is the torque in foot-pounds developed by the drill; C is a constant depending upon the material drilled, the cutting fluid, and the drills; f is the feed of the drill in inches per revolution; d is the diameter of the drill in inches; B is the thrust in pounds developed by the drill; and K is the constant for thrust corresponding to C in the torque formula.

Tests for the determination of the torque and thrust formulas have been run so often on such a wide variety of materials that the formulas as shown, based on one drill diameter for variable feeds and one feed for variable drill diameters, would maintain had other constant feeds and diameters been selected. The curves shown in Fig. 11 would simply have been raised or lowered with the same slope.

After running the tests to determine formulas, tests were then run to compare, under different cutting conditions, the various cutting fluids. Three separate tests were run for each cutting condition—that is, combination of drill diameter and cutting fluid. If the results did not agree closely, additional check tests were run. Many more, however, were run when cutting dry, inasmuch as the original keenness of the cutting edge was removed by dry cutting, so that uniformity in torque and thrust values could maintain as far as the condition of the cutting point of the drill was concerned. The average of the experimental values of torque, thrust, and power input for the $^{3}/_{4}$-in.-diam drill operating at 0.024 in. feed per revolution, the 1-in.-diam drill operating at 0.026 in. per revolution, and the $1^{1}/_{4}$-in.-diam drill operating at 0.030 in. per revolution are shown plotted in Figs. 12 to 16, inclusive. Results are shown for each of the eleven cutting fluids, as well as one or two in addition.

As in Progress Report No. 3, in order that the torque formulas should give straight lines when plotted on log-log paper for any diameter and feed, the abscissa was selected as a variable L, in which L equals $f^{0.83} d^{1.9}$, as taken from the formula for torque already determined. The averages of the experimental values of torque for the different drills and feeds are shown plotted for each cutting fluid in Fig. 12. Lines drawn through the torque values for a given cutting fluid are straight, but those for one cutting fluid may be above or below those for another, indicating that the only influence of the cutting fluid is to displace the lines vertically and not to change their slope, inasmuch as all of them are parallel.

It is apparent that cutting fluids have a marked influence on the power required to drill aluminum. There appear to be three distinct groups of curves: that for drying cutting (No. 1), the water solution (No. 2), soluble oils (Nos. 3 and 4), and kerosene (K), and the oils.

Pure kerosene (K) and the kerosene-soluble oil mixture (KE), consisting of one part kerosene to four parts of No. 3 soluble oil, were introduced as additional cutting fluids in drilling aluminum, inasmuch as they are used extensively commercially.

From Fig. 12 it is seen that cutting dry requires the greatest power, expressed as torque. It also is seen that, of the water and kerosene group, borax water (No. 2) produces the greatest torque, the 1-to-50 soluble oil (No. 3) produces the next greatest torque, pure kerosene (K) a slightly lower torque, and the 1-to-10 soluble oil (No. 4) and the kerosene-soluble oil (KE) mixture the lowest torque of the second group. The oils, as the third group, produce the lowest torque values, and several tendencies may be noted from their order as indicated. The sulphurized mineral oil (No. 10) requires more power than either of the plain mineral oils (Nos. 6 and 7). Also, the sulphurized lard-mineral oil (No. 11) produces higher torque values than the mineral-lard oil (No. 8). It is interesting, also, to note that the oleic acid-mineral oil (No. 9) produces a torque next to the lowest of all, whereas in cutting S.A.E. 3150 steel, presented in Progress Report No. 3, it produces the highest torque. It appears that sulphur in connection with an oil does more harm than good in a cutting fluid used on aluminum. Also, it appears that the mineral-lard oil (No. 8) and the mineral-oleic acid (No. 9) are better than the straight mineral oils (Nos. 6 and 7) and the lard oil (No. 5).

Values of torque for the various combinations of drill diameter and feed have been taken from the straight-line curves of Fig. 12 for each of the cutting fluids tested. Using the equation for torque as developed for aluminum, the values of the constant C in the torque formula have been computed. On several different occasions the authors have determined drilling formulas for other aluminum alloys. It has been found that no two of these are exactly alike. By changing the composition or the method of producing—that is, whether they are cast, chill cast, or cold drawn—the exponents of the feed and drill diameters are changed. It should therefore be kept in mind that the formulas and constants for the various cutting fluids as presented for this aluminum alloy apply with accuracy only to this one material. Insufficient data are available to show the effect of change in composition, etc. on the characteristics of cutting fluids.

In Fig. 13 are shown plotted on log-log paper the averages of experimental values of thrust over the values of L as abscissa, in which L is equal to $f^{1.1} d^{1.2}$, taken from the equation for thrust as developed for this aluminum. Straight lines are obtained for the thrust as a function of the value of L for each of the thirteen cutting fluids. Two sets of parallel lines, one set having less inclination than the other, are shown. Oils Nos. 2, 3, and 4, which consist of the water compounds, have the less slope. The thrust lines for all of the other cutting fluids, including dry cutting, are parallel, but at a greater inclination. From this fact alone it would appear that, where the value of L is high enough, reaching a value of approximately 0.045, the water solutions and soluble oils would give results comparable to the best cutting oils for thrust only. For this reason the thrust formula as developed for this aluminum does not hold exactly for cutting fluids Nos. 2, 3, and 4, but does hold for dry cutting, under which condition it was determined, as well as for all of the oils, including the kerosene-soluble oil mixture. No explanation of this irregularity can be made at this time.

The thrust values for dry cutting (No. 1) are seen to be considerably higher than those of any other cutting fluids. Kerosene and the kerosene-soluble oil mixture are next in order. In general, the magnitude of the thrust places the oils in much the same order as for torque in Fig. 12, with oils Nos. 8 and 9 at the bottom. The fatty oil (No. 5) and the sulphurized oils (Nos. 10 and 11) also are among the lowest on the thrust scale.

Values of thrust for the various cutting conditions for each of the cutting fluids have been taken from the curves of Fig. 13, and from the equation developed for thrust for aluminum, values for the constant K have been computed.

In arriving at values of C and K as given in Table 4, three

values of torque and thrust were taken from the torque and thrust curves of Figs. 12 and 13, one for the $^3/_4$-in.-diam drill at its speed and feed, a second for the 1-in.-diam drill at its speed and feed, and a third for the $1^1/_4$-in.-diam drill at its speed and feed. Using these values, three values of the constants C and K were obtained. The value shown in Table 5 is an average of these three values. This point is of particular significance in connection with the values of K for cutting fluids Nos. 2, 3, and 4, inasmuch as they do not follow the regular thrust formulas. The value for K, however, as computed for these three fluids, can be used as an average value.

In order to show to better advantage the effect on the torque and thrust values of the various cutting fluids, Figs. 14 and 15 have been prepared. Fig. 14 shows the torque in foot-pounds required for the several drills operating at their respective feeds and speeds, plotted over oil numbers arranged in order of increasing torque. The values plotted are computed and correspond to the values read from the log-log lines in Fig. 12.

Similarly, Fig. 15 shows the thrust in pounds required for the several drills plotted over the oil numbers also in order of increasing torque. If the mineral oils (Nos. 6 and 7) and the two kerosene oils are omitted, the rest give a continuously rising curve from left to right, as do the torque curves. The thrust values for the four oils mentioned are high, in proportion to their torque values. The net power input expressed in kilowatts required for the several drills, when using the thirteen cutting fluids tested, are shown plotted over the oil numbers arranged in order of increasing torque in Fig. 16. These curves correspond favorably to the torque curves of Fig. 14, as might be expected.

Tests on Free-Cutting Brass

As in the case of aluminum, a special series of tests were first run on the free-cutting brass (bar BF) to determine torque and thrust formulas as a function of drill diameter and feed. The results of these tests are shown plotted in Fig. 17. For the variable-feed data, the 1-in.-diam "R" drill was operated at feeds of 0.009, 0.013, 0.029, and 0.042 in., respectively. The cutting was done dry.

The torque and thrust values, as plotted in Fig. 17, give straight lines on the log-log paper. The exponent of the feed in the torque formula was found to be 0.73 and that of the feed in the thrust formula was found to be 0.6. With a constant feed of 0.029 in., additional tests were run with the $^1/_2$-in., $^3/_4$-in., 1-in., $1^1/_4$-in., and $1^1/_2$-in.-diam drills. The torque and thrust for these tests also are plotted in Fig. 17. These values give straight lines from which the exponent of the diameter in the torque formula is found to be 1.9 and that in the thrust formula is found to be 1.0. The drilling formula for the free-cutting brass (bar BF) is therefore as follows:

$$T = C f^{0.73} d^{1.9}$$
$$B = K f^{0.6} d^{1.0}$$

The values of the constants C and K are summarized in Table 4 for all of the cutting fluids, as well as dry cutting.

The average experimental values for torque and thrust are plotted for the different drill diameters and cutting fluids in Fig. 18. It is interesting to note from the torque curves that the cutting fluids have very little influence on the value of the torque when drilling this free-cutting brass. The minimum value of the torque is 49.5 when drilling dry with the $1^1/_4$-in.-diam drill at 0.030 in. feed and a speed of 174 rpm, whereas the highest torque for this same cutting condition is 50.8 for the borax water (No. 2), or an actual difference of 1.3 ft-lb, corresponding to 2.6 per cent. The torque values for all of the cutting fluids fall between the two lines shown, which is a very narrow range.

The values of thrust for the various cutting conditions also

are shown plotted for all the cutting fluids in Fig. 18. Again the divergence of results for the different cutting fluids is very small. Dry cutting, as opposed to the torque, gives the highest thrust values, whereas the light mineral oil (No. 6) and the light mineral oil containing oleic acid (No. 9) give the lowest values of thrust. The sulphurized lard-mineral oil is next to the lowest, immediately above which are the equal thrust values for cutting fluids Nos. 2, 4, 5, 8, and 10. It seems strange that next to the highest thrust values when drilling this free-cutting brass are obtained with the 50-to-1 soluble oil (No. 3) and the heavy mineral oil (No. 7). These two cutting fluids give the same results in thrust. It also is interesting to note that the heavy mineral oil (No. 7) gives next to the highest in thrust values, whereas the light mineral oil (No. 6) gives the lowest thrust values.

From values of torque and thrust taken from the curves of Fig. 18, and using the torque and thrust equations, average values for the constants C and K have been computed as given in Table 4.

Tests on Cast Iron

Preliminary drilling tests were first run on the cast iron, cutting dry, to develop suitable formulas for torque and thrust as a function of the feed and drill diameter. The variable-feed tests were run with the $1^1/_4$-in.-diam drill, with feeds of 0.011, 0.015, 0.021, and 0.029 in. per revolution. The variable-diameter tests with the $^1/_2$-in., 1-in., and $1^1/_4$-in.-diam drills were made with a constant feed of 0.021 in. per revolution. These tests all were run dry.

The results of these tests are shown plotted in Fig. 19. The exponent of the feed as a function of torque is found to be 0.6, and that as a function of thrust 0.73. The exponent for the drill diameter as a function of torque is found to be 1.7, and that as a function of the thrust was found to be indeterminate. By cut-and-try methods, the thrust values, as a function of drill diameter, were replotted and the web thickness of the drill was taken into consideration. It was found that, when the thrust was plotted over $(d/5 + w/d)$, a straight line was obtained on log-log paper, the slope of which was 1.9. The formulas for torque and thrust were then obtained as follows:

$$T = C f^{0.6} d^{1.7}$$
$$B = K f^{0.73} (d/5 + w/d)^{1.9}$$

The values of w for different drill sizes are given under the column of web thickness of the drill in Table 3.

In a previous paper, "Power Required to Drill Cast Iron and Steel,"[4] a formula was developed for a soft cast iron for torque, as follows:

$$T = C f^{0.6} d^2$$

The present formula gives the exponent of d of only 1.7. This difference apparently is due to the difference in cast irons, as the cast iron used in this paper contained 1 per cent nickel. The exponents of the feed, however, are the same in the two formulas. It appears from this that, for cast iron, no one set of formulas will hold for various analyses.

The results of a series of experiments to determine comparative values illustrating the influence of various cutting fluids on the cast iron are shown plotted in Figs. 20 to 24, inclusive. The averages of experimental values of torque are plotted on log-log paper in Fig. 20 for each of the eleven cutting fluids used. The torque values for the different drill sizes operating at their proper speeds and feeds are plotted over a variable L, in which L equals $f^{0.6} d^{1.7}$, as taken from the torque formula.

The lines in Fig. 20 illustrate that the greatest torque values are obtained when cutting dry (No. 1). It is interesting to note the close values obtained with cutting fluids 4, 2, 5, 7, 3, 6, 11, and 8, inasmuch as No. 2 is a borax water, Nos. 4 and 3 are soluble oils, No. 5 is a lard oil, Nos. 7 and 6, which give the same values as No. 3, are heavy and light mineral oils, respectively, No. 11 is a sulphurized lard-mineral oil, and No. 8 is a mineral-lard oil. The sulphurized mineral oil (No. 10) gives torque values lower than all those mentioned, while the mineral oil containing 5 per cent oleic acid gives the lowest results of all. Values of torque have been taken from the curves of Fig. 20 in order to compute the constant C for torque from the torque formula. The values of these constants for the eleven cutting fluids are shown in Table 4.

The torque for the $1^1/_4$-in.-diam drill operating at 0.015-in. feed and at a speed of 174 rpm is 43.6 for dry cutting (No. 1). This is the highest of all torque values. The torque value for cutting fluid No. 9 for this drill diameter is the lowest and is 35.9 ft-lb. This shows that the torque for cutting cast iron dry is 21.5 per cent higher than when cutting with oil No. 9.

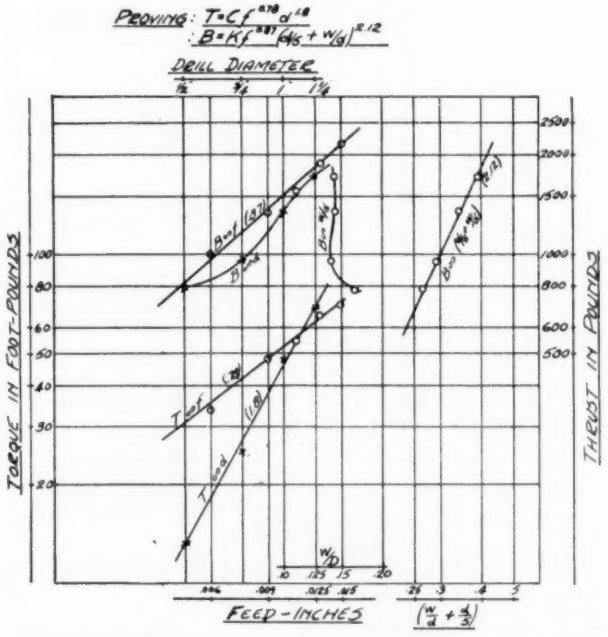

Fig. 29 Torque and Thrust Required to Drill S.A.E. 3150 Steel Using Oil No. 3

(Constant feed, 0.009 in., variable diameter; constant diameter, 1 in., variable feed.)

The average of experimental values of thrust when drilling cast iron also are shown plotted over the variable L in Fig. 21, in which L equals $f^{0.73} (d/5 + w/d)^{1.9}$. Here again straight lines are obtained representing thrust values for the various drill diameters at their respective feeds and speeds. The thrust is greatest when cutting dry (No. 1) and with the heavy mineral oil (No. 7). It is less for the light mineral oil (No. 6) and the mineral-oleic acid oil (No. 9). The conditions seem to be the reverse of what might be expected, inasmuch as the two sulphurized oils (Nos. 10 and 11) give thrust values near the top. Lard oil is in the middle, and the water compound and soluble oils are below the mean values.

The value of the constant K for the thrust formula for each of the cutting fluids, as computed from the curves of Fig. 21, are shown in Table 4.

Values of torque from Fig. 20 are shown plotted for the various drill diameters operating at their respective speeds and feeds over the oil numbers as abscissa in Fig. 22. The oil numbers are arranged in order of increasing torque. The computed

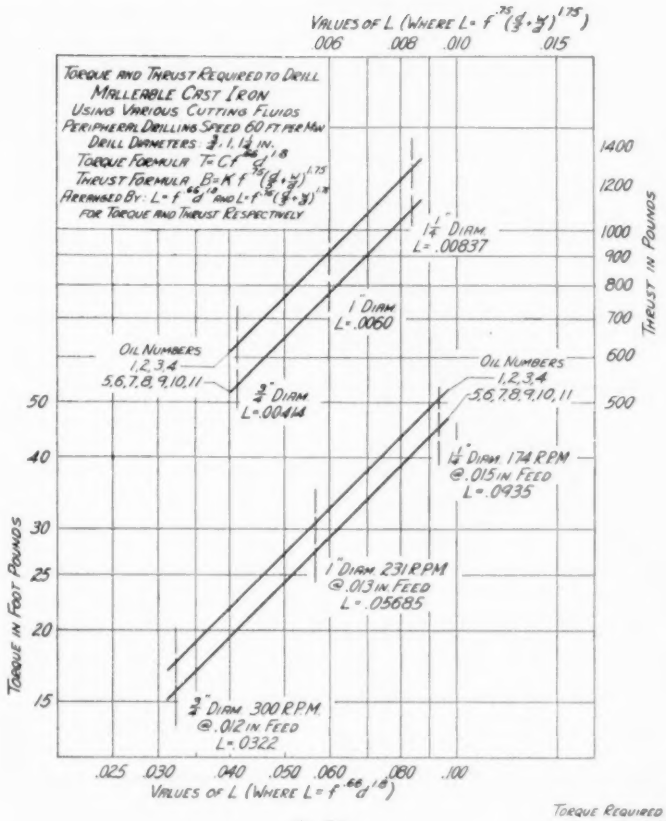

Fig. 26

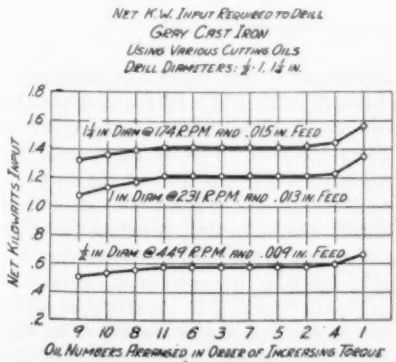

Fig. 24

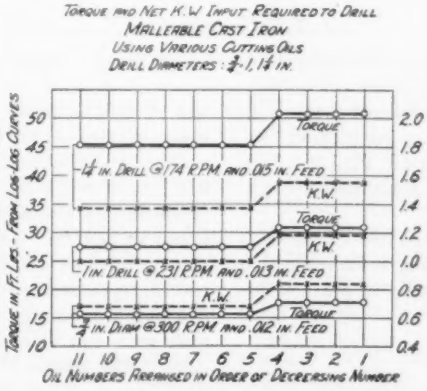

Fig. 27

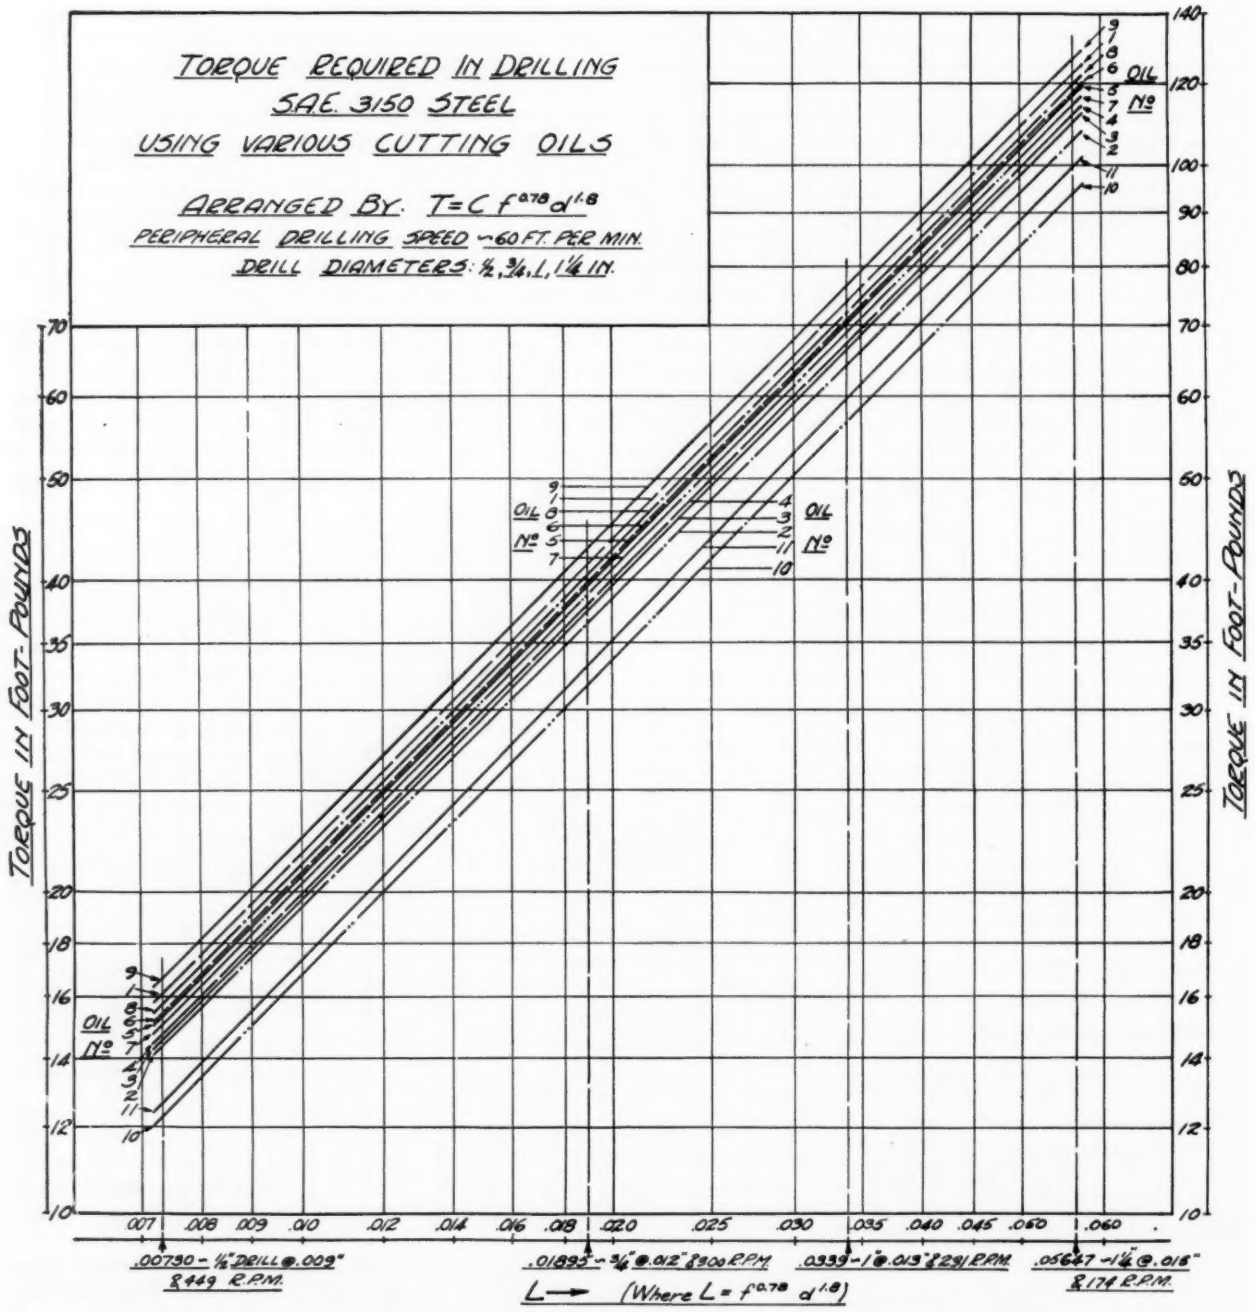

FIG. 30 TORQUE REQUIRED IN DRILLING S.A.E. 3150 STEEL, USING VARIOUS CUTTING OILS

thrust values for drilling the cast iron similarly are shown in Fig. 23. These thrust values are plotted over the oil numbers arranged in the order of increasing torque as used in Fig. 22. It is shown that the thrust for the different cutting fluids does not vary in the same proportion as the torque.

When drilling cast iron, the net power input in kilowatts is shown plotted for each drill diameter, operating at its respective speed and feed, over the oil numbers, arranged in order of increasing torque, in Fig. 24.

TESTS ON MALLEABLE IRON

A special series of drilling tests were run on the malleable-iron castings to determine formulas for torque and thrust as a function of the drill diameter and feed. The results of these tests are shown plotted on log-log paper in Fig. 25. In the variable-feed tests, a $1^1/_4$-in.-diam drill was used with feeds of 0.006, 0.009, 0.015, and 0.024 in. per revolution. The torque values are connected by a straight line, and the exponent of the feed was found to be 0.66. The thrust values for the $1^1/_4$-in.-diam drill at various feeds also indicate a straight line, the slope of which is 0.75, representing the exponent of the feed.

Using a constant feed of 0.015 in. per revolution, a series of tests were run with the $^1/_2$-in., $^3/_4$-in., 1-in., and $1^1/_2$-in.-diam drills. The results of the torque and thrust are shown in Fig. 25. The exponent of the drill diameter as a function of the torque is found to be 1.8. The values of thrust, plotted over

the drill diameter as a variable, do not give a straight line. By trial and error, the web thickness of the drill was introduced, so that a straight line is obtained using the thrust as a function of $(d/5 + w/d)$, the exponent of which is 1.75. The resulting formulas for torque and thrust when drilling malleable cast iron are therefore

$$T = C f^{0.66} d^{1.8}$$
$$B = K f^{0.75} (d/5 + w/d)^{1.75}$$

The results of the tests to determine the torque and thrust of the different drill diameters operating at their respective feeds and speeds, as influenced by the eleven cutting fluids, are plotted in Figs. 26 and 27. The torque values were plotted on log-log paper in Fig. 26 over the variable L, in which L equals $f^{0.66}\ d^{1.8}$, as taken from the torque formula. Only two straight lines, representing torque over the variable L, were obtained. The upper curve represents the torque values for all cutting fluids Nos. 1 to 4, inclusive, while the lower curve represents the torque values of the balance of the cutting fluids, consisting of the oils. It is interesting that malleable iron, whether drilled dry, with borax water, or with a soluble oil, produces the same torque, other conditions being equal. It also is interesting that if any oil, at least any of those from 5 to 11, inclusive, representing a wide range of types, is used, equal torque values are obtained. From these two curves, the constants in the torque formulas have been obtained and are shown listed in Table 4.

The values of thrust for this series of experiments also are shown plotted in Fig. 26 over the variable L, in which L equals $f^{0.75}\ (d/5 + w/d)^{1.75}$, as taken from the thrust formula. Again, two straight lines are obtained, the higher one of which represents the thrust for the various drills for cutting fluids Nos. 1 to 4, inclusive. The lower line represents the values of thrust for the balance of the cutting fluids—namely, the oils Nos. 5 to 11, inclusive.

From Fig. 26 there appears to be an increase in torque of about 13 per cent if the malleable cast iron is drilled dry or with water compounds instead of with any of the oils. An additional 17 or 18 per cent thrust is set up by cutting dry or using the water compound instead of the oils. Thrust coefficients also have been determined for each of the cutting fluids as listed in Table 4.

The values of torque and net power input in kilowatts are plotted for each drill diameter over the cutting oils arranged in numerical order in Fig. 27. The values of thrust for the various drill diameters are shown plotted over the cutting fluids arranged in numerical order in Fig. 28.

Tests on S.A.E. 3150 Steel

The results confirming the equation for torque and thrust in drilling the annealed S.A.E. 3150 steel are shown in Fig. 29. In these tests an emulsion consisting of 1 part of soluble oil to 50 parts water (No. 3) was used. The variable-feed tests were run with a 1-in.-diam "R" drill, whereas the variable-diameter tests were run with a constant feed of 0.009 in. per revolution.

The torque values at the 0.009-in. feed for various drill diameters are shown to be practically a straight line, the slope of which is 1.8. The torque values for various feeds for the 1-in.-diam drill also indicate a rather satisfactory straight line, the slope of which is 0.78. These values indicate the equation for torque

$$T = C f^{0.78} d^{1.8}$$

This equation confirms the equation for steel determined on a wide variety of types of steel and at different times, as reported on in the paper, "Power Required to Drill Cast Iron and Steel,"[4] and reported on further in a paper before the Society of Automotive Engineers, *Journal S.A.E.*, vol. 23, No. 3, p. 78.

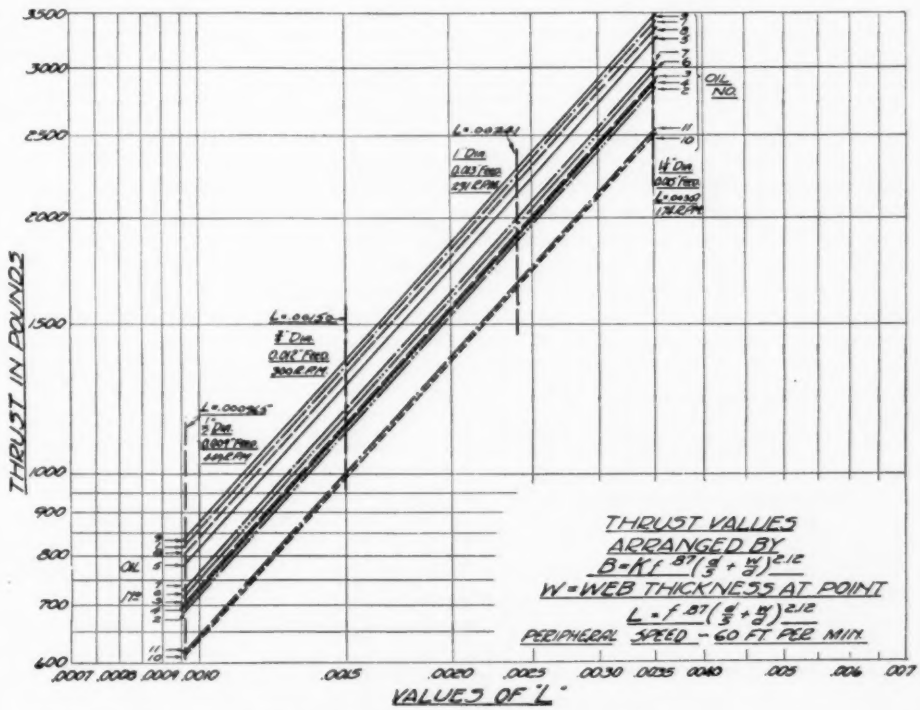

Fig. 31 Thrust for Various Values of L

The values of thrust for the 1-in.-diam drill operating at various feeds are shown as a straight line in Fig. 29, the slope of which is 0.87. The thrust, plotted for a constant feed of 0.009 but for variable drill diameters, appears to be a slightly curved line. A straight line is obtained when the thrust is plotted over the value $(d/5 + w/d)$. The slope of this line is 2.12. This indicates then that an equation for thrust is a function of the feed, $f^{0.87}$, and the value of $(d/5 + w/d)^{2.12}$, resulting in the equation for thrust

$$B = K f^{0.87} (d/5 + w/d)^{2.12}$$

These equations are confirmed when oils Nos. 6, 8, and 10 are used, as reported below Fig. 8 in the Progress Report No. 3.

The results of the tests for torque for the different drills, each drilled with all of the cutting fluids, are shown plotted on log-log paper in Fig. 30. The torque values were plotted over the variable L, where L equals $f^{0.78} d^{1.8}$. Straight lines are obtained. It is of interest to note that the mineral oil containing 5 per cent oleic acid produces a greater torque than when cutting dry (No. 1). The sulphurized oils (Nos. 10 and 11) produce

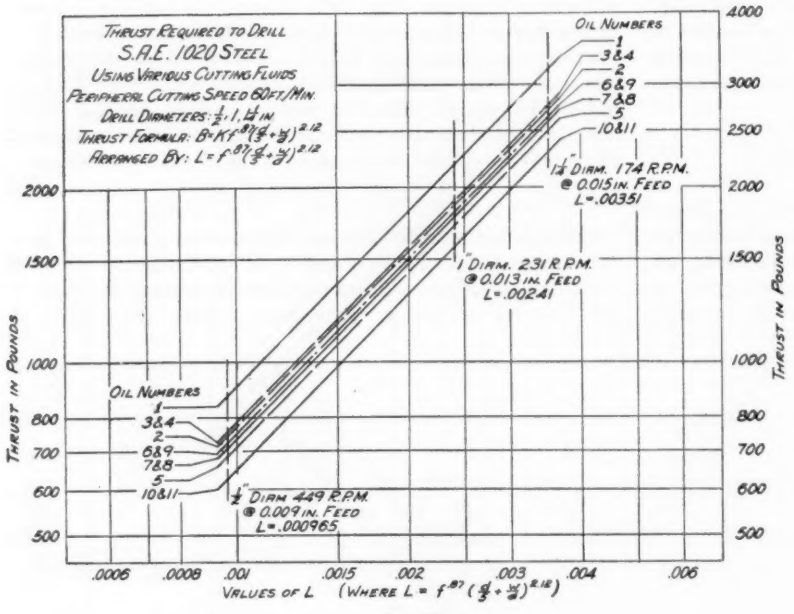

Fig. 36

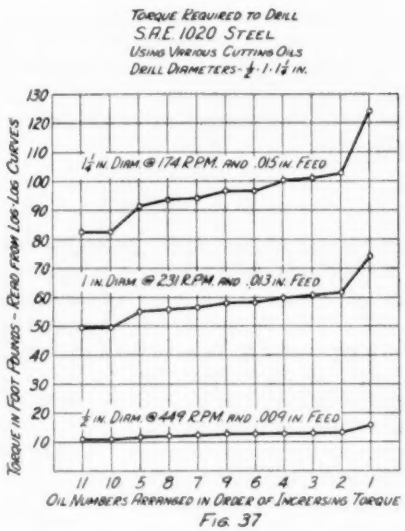

Fig. 37

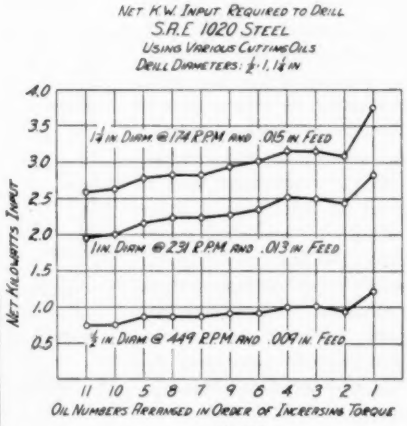

Fig. 39

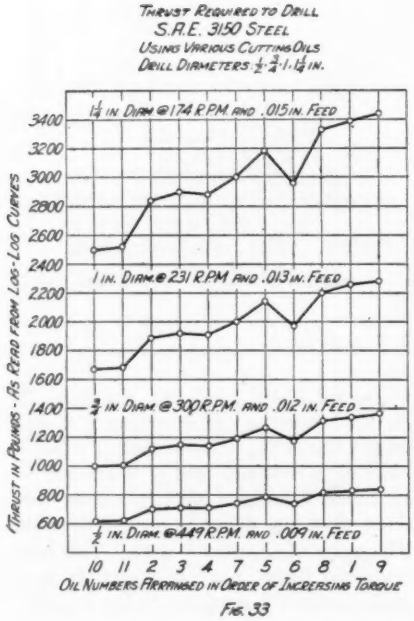

Fig. 33

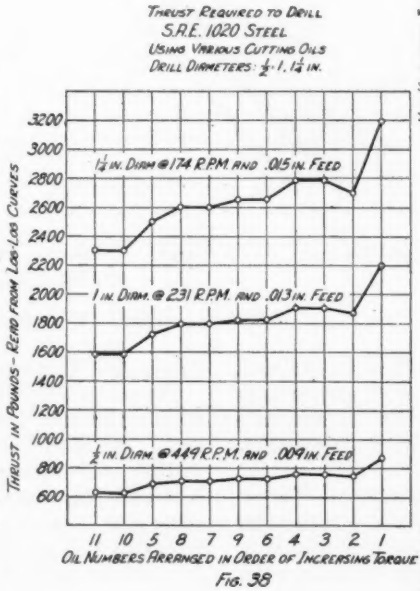

Fig. 38

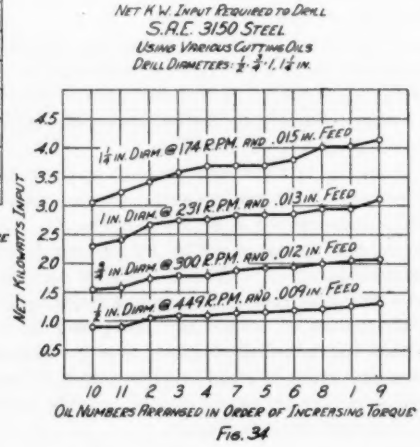

Fig. 34

the lowest values. These curves were discussed in detail in Progress Report No. 3.

The average experimental values of thrust are plotted on log-log paper in Fig. 31, over the variable L. Again, straight lines are obtained, and an order of oils quite similar to that for torque is found when arranged by magnitude.

Constants for both torque and thrust determined from the curves in Figs. 30 and 31 are listed in Table 4.

Values of torque for each drill size are shown plotted over the oil numbers, arranged in order of increasing torque, when cutting the S.A.E. 3150 steel, in Fig. 32. This shows an appreciable influence of the cutting fluid on the torque values. The values of thrust are shown in Fig. 33 plotted over the oil numbers arranged in order of increasing torque. Also, the net power input in kilowatts required to drill the S.A.E. 3150 steel is shown plotted for all four drill diameters, namely, $^1/_2$ in., $^3/_4$ in., 1 in., and $1^1/_4$ in., in Fig. 34. These results, relating to the S.A.E. 3150 steel, were previously reported on in detail in Progress Report No. 3.

Tests on S.A.E. 1020 Steel

Inasmuch as the special series of tests conducted to determine the torque and thrust formulas for the S.A.E. 1020 steel yielded the same formulas as determined for the S.A.E. 3150 steel, these data are not presented. Rather, the formulas for the torque and thrust, as developed for the S.A.E. 3150 steel, will be considered to apply to this steel. In fact, it has been found by many repeated tests that most steels, unless highly alloyed, follow these equations for torque and thrust. The constants, however, are dependent upon the particular steel as described below.

Comparative values of torque were determined for all of the eleven cutting fluids when drilling the S.A.E. 1020 steel, with the $^1/_2$-in., 1-in., and $1^1/_4$-in.-diam drills operating at their respective feeds and speeds. The torque values are shown plotted over the values of L, in which L is equal to $f^{0.78}\,d^{1.8}$ taken from the torque formula in Fig. 35. The values as plotted are the averages of experimental values. The torque values read from the straight lines of Fig. 35 were used in computing the constant C in the torque formula for the various cutting fluids. These are shown in Table 4.

A series of straight lines representing torque are obtained for each of the cutting fluids. The results as shown in Fig. 35 are of interest, inasmuch as dry cutting (No. 1) produces torque values much higher than any of the other cutting fluids. As with the S.A.E. 3150 steel, the sulphurized oils (Nos. 10 and 11) produce unusually low values of torque. It is also interesting to note that lard oil (No. 5) produces a torque lowest of all cutting fluids with the exception of Nos. 10 and 11, while the aqueous solutions (Nos. 2, 3, and 4) produce the highest torque values, except for dry cutting (No. 1).

The averages of experimental values of torque are plotted in Fig. 36 over a variable L, in which L equals $f^{0.87}\,(d/5 + w/d)^{2.12}$. Again, straight lines are obtained in almost identically the same order of magnitude as shown for torque in Fig. 35. Constants K for the thrust formula were computed from thrust values taken from these straight lines in Fig. 36, and are shown for each cutting fluid in Table 4.

The values of torque are shown plotted for each drill diameter over the cutting-fluid numbers arranged in order of increasing values of torque for the S.A.E. 1020 steel in Fig. 37. The increase in torque for dry cutting (No. 1) over sulphurized mineral-lard oil (No. 11) does not appear to be appreciative for the $^1/_2$-in.-diam drill operating at 449 rpm and 0.009-in. feed per revolution. The torque value is 15.96 ft-lb for cutting fluid No. 1 and only 10.62 ft-lb for cutting fluid No. 11. This represents 50 per cent increase in torque when cutting dry as compared to the torque when cutting with cutting fluid No. 11. This increase is more noticeable in connection with the torque values for the $1^1/_4$-in.-diam drill operating at 174 rpm and 0.015-in. feed per revolution.

The values of thrust are shown over the cutting-fluid numbers arranged in order of increasing torque in Fig. 38. It is seen that the thrust for borax water (No. 2) falls below the thrust for the soluble oils (Nos. 3 and 4), but otherwise the thrust values follow closely the order of torque. The increase of thrust for dry cutting (No. 1) over the sulphurized oil (No. 11) is 39 per cent. The net power input expressed in kilowatts required to drill the S.A.E. 1020 steel is shown for each drill diameter plotted over the oil number, arranged in order of increasing torque, in Fig. 39. Except for a slightly reduced value for borax water (No. 2), these curves correspond favorably with the torque curve, as might be expected.

Tests on S.A.E. 1035 Steel

The formulas representing torque and thrust when drilling the S.A.E. 1035 steel have been found to be identical with those formulas developed for the S.A.E. 3150 steel. They are therefore not repeated here.

The average values of experimental data for the torque and thrust are plotted over the variable L, computed from the torque formula in Fig. 40. The cutting fluids are arranged according to the magnitude of torque in practically the same order as when drilling S.A.E. 1020 steel, reported on. Values of the constant in the torque formula have been computed from torque values taken from the curves of Fig. 40 and are shown in Table 4.

The averages of the experimental values of thrust when drilling the S.A.E. 3150 steel with the various oils and drills are shown plotted on log-log paper over the value of L taken from the thrust formula in Fig. 41. The order of the oils, arranged according to magnitude of thrust, does not compare favorably with that when drilling the S.A.E. 1020 steel. Dry cutting (No. 1) gives the highest values. The aqueous solution, consisting of borax water (No. 2), and the soluble oils (Nos. 3 and 4), give next highest values. All of the oils are grouped together, giving the lowest values of thrust. Lard oil gives the lowest value of thrust, while the sulphurized lard-mineral oil (No. 11) and the mineral-lard oil (No. 8) give next lowest values of thrust. Constants K for the thrust formula are shown as computed in Table 4.

The values of torque as developed by each of the drill sizes are shown plotted in Fig. 42 over the cutting-fluid numbers, arranged in order of increasing torque. Again, the sulphurized oil produces the lowest torque, while dry cutting produces the highest torque value. The values of thrust for these drills are plotted over the cutting-fluid numbers arranged in order of increasing torque in Fig. 43. This shows some irregularities between the values of thrust and values of torque. The 1-to-10 soluble oil (No. 4), for instance, produces a thrust value slightly greater than the value for the 1-to-50 soluble oil (No. 3). The thrust values of the plain mineral oils (Nos. 6 and 7) are slightly lower than that for the mineral oil containing oleic acid (No. 9). The thrust value for lard oil is lowest of all. The net power input in kilowatts, as determined from the wattmeter readings, is shown plotted in Fig. 44 over the cutting fluid numbers arranged in order of increasing torque. Again, as might be expected, these lines correspond favorably to the torque lines in Fig. 42.

Tests on Carbon Tool Steel

The formulas for torque and thrust for the annealed carbon tool steel are identical with those developed for the S.A.E. 3150 steel, so that the results of the formula tests are not repeated.

The averages of experimental values of torque are shown plotted in Fig. 45 for each drill diameter when cutting with the various cutting fluids over the value of L determined from the torque formula. The line representing the values of torque when

cutting dry (No. 1) and that when cutting with a sulphurized mineral oil (No. 10) is lowest. The water compounds (Nos. 2, 3, and 4) are placed together about midway between the highest and lowest values, whereas the oils Nos. 6, 7, 8, and 9 are slightly above the water compounds, and lard oil (No. 5) is immediately below.

Constants for the torque formula have been computed from values taken from the curves of Fig. 45, as shown for each cutting fluid in Table 4. The averages of the experimental values of thrust have been plotted in Fig. 46 over the value of L taken from the thrust formula. The results obtained are quite different from any already presented for alloy or carbon steels. The thrust values obtained with the sulphurized oils (Nos. 10 and 11) are extremely low and in a class almost by themselves. The rest of the cutting fluids are grouped, the maximum differences of thrust for the various oils being relatively small. The thrust values when cutting dry (No. 1) appear centrally located in the group. The thrust values produced by the water compounds are shown below those for dry cutting (No. 1), as are the thrust values for the heavy mineral oil (No. 7) and the mineral oil containing oleic acid (No. 9). Strangely, thrust values produced by the light mineral oil (No. 6), lard oil (No. 5), and mineral lard oil (No. 8) lie slightly above those for dry cutting (No. 1). The constants K for the thrust formula have been computed from values taken from these curves in Fig. 46 and are shown for each of the cutting fluids in Table 4.

The values of torque for the different drill diameters are plotted over the cutting-fluid numbers, arranged in order of increasing torque, when drilling the carbon tool steel, Fig. 47. There is an appreciable saving in torque in drilling with the sulphurized oil over drilling dry (No. 1). The values of thrust are shown plotted over the cutting-fluid numbers, arranged in order of increasing thrust, when drilling the carbon tool steel, in Fig. 48. The favorable influence of the sulphurized oils in reducing the thrust is apparent. The highest thrust values are obtained with lard oil (No. 5) and the mineral-lard oil (No. 8), whereas the rest of the cutting fluids produce thrust values of approximately equal values. In Fig. 49 the net input power in kilowatts, as determined by the wattmeter, is shown plotted over the cutting fluids arranged in order of increasing torque. These curves again follow quite favorably the torque curves of Fig. 47.

Tests on S.A.E. 1112 Steel

It has been found by tests that the formulas developed for the S.A.E. 3150 steel also hold for the free-cutting steel corresponding to the analysis of S.A.E. 1112.

The averages of experimental values of torque are shown plotted on log-log paper over the value of L in Fig. 50. The results indicate that the torque when drilling a free-cutting steel is affected but little by changes in the characteristics of the cutting fluids. The two sulphurized oils (Nos. 10 and 11) give the lowest torque values. The borax water (No. 2) gives the highest torque values. Equal torque values are obtained for the rest of the cutting fluids, consisting of Nos. 1, 3, 4, 5, 6, 7, 8, and 9. The differences in torque values for this last-mentioned group were so small that they are considered equal. This shows that the torque value for cutting dry (No. 1) is not changed if cutting fluids of lard oil, straight mineral oil, or soluble oil are introduced. These results are due probably to the cutting characteristics of the high-sulphur steel. Constants C for the torque formula have been computed for each of the cutting fluids as shown in Table 4.

The averages of experimental values of thrust were plotted on log-log paper in Fig. 51 over the value of L as computed from the thrust formula. The differences in thrust values for the various cutting fluids are very small. It is of interest to note that the thrust values are lowest when the 1-to-50 soluble oil (No. 3) is used and the next lowest when the 1-to-10 soluble oil (No. 4) is used. The highest values of thrust are obtained when cutting dry (No. 1) and with the heavy mineral oil (No. 7), which gave equal values. The balance of the cutting fluids give intermediate and equal values. It is of interest to note that the borax water (No. 2) gives the same values of thrust when cutting this free-cutting steel as lard oil (No. 5), the sulphurized oils (Nos. 10 and 11), the mineral and mineral-lard oils (Nos. 7 and 8). This order of thrust does not compare favorably with the order of torque shown in Fig. 50. The values of the constants in the thrust formula have been determined for the various cutting fluids and are listed in Table 4.

The values of torque required to drill the free-cutting steel, S.A.E. 1112, for various drill diameters are plotted over the various cutting-fluid numbers, arranged in order of increasing torque in Fig. 52. The lowest torque values are obtained with the sulphurized oils (Nos. 10 and 11) and the highest with the borax water (No. 2). The values for the intermediate oils are practically identical. The values of thrust required to drill the free-cutting steel also are shown plotted over the oil numbers arranged in order of increasing torque in Fig. 53. This brings out the low values of thrust produced when the 1-to-50 soluble oil (No. 3) is used, and the high values when cutting dry (No. 1) and with the heavy mineral oil (No. 7).

The net power input in kilowatts, as determined by the recording wattmeter, required to drill the S.A.E. 1112 steel is also

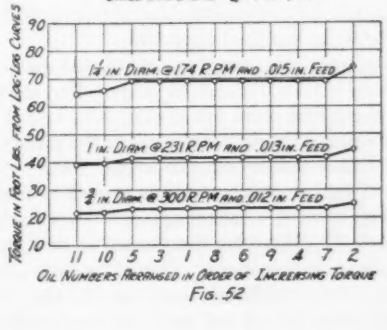

FIG. 52

plotted over the cutting-fluid numbers arranged in order of increasing torque in Fig. 54. These curves show the same general tendency as the torque curves in Fig. 52.

DISCUSSION OF DRILLING TESTS

In Table 4 are summarized the torque and thrust formulas for each of the nine metals tested. Values of the constants C and K in the torque and thrust formulas, respectively, are listed. Computed values of torque and thrust for the $^1/_2$-in.-diam drill operating at 0.009-in. feed per revolution and 449 rpm and for the $1^1/_4$-in.-diam drill operating at 0.015-in. feed per revolution and 174 rpm are given in Table 5. These torque and thrust values are given for the oil numbers appearing in the column to the left, the first of which gives the highest torque values and the second of which gives the lowest torque values. In general, the values of the thrust for the different cutting fluids follow the magnitude of the torque, although there are a few exceptions to this rule.

In every case, except for the free-cutting steel, bar MF, and the S.A.E. 3150 steel, bar KF, dry cutting (cutting fluid No. 1) gives the highest torque value. In the case of these two steels, the torque values for dry cutting have been included along with the maximum and minimum values to make the table more complete. The horsepower output as computed from the torque and thrust formulas, or that power actually delivered at the point of the drill, is shown for both the $^1/_2$-in.-diam and the $1^1/_4$-in.-diam drill. Also, values of horsepower output per cubic inch of metal cut per minute are tabulated for the various materials when drilled by the several cutting fluids. The cutting speed in rpm does not appear in the torque and thrust values as presented, although the speeds at which these values were obtained are recorded. These speeds, however, are used in determining the horsepower output as well as the horsepower output per cubic inch per minute. The power output per cubic inch of metal cut per minute computed for each drill size at its respective speed and feed furnish, therefore, a basis for comparing the drilling qualities of the various metals when cut with the different coolants.

Development of Drilling Formulas for Torque and Thrust

A routine adopted after developing a large number of drilling torque and thrust formulas when cutting a variety of materials with many standard and special types of drills is as follows: The drills were selected alike in respect to angles. They ranged in size from $^1/_2$ in. in diameter to $1^1/_2$ in. in diameter. In some instances the specimen of metal tested was not large enough to permit the use of the $1^1/_2$-in.-diam drill. The drills were very carefully sharpened on a Blau drill grinder and were checked to see that both lips or cutting edges were alike. One lip did not protrude beyond the other more than 0.0005 in. for the small drills or 0.001 in. for the larger drills.

Several holes were then drilled with each drill to take the initial keenness from the cutting edge. The torque and thrust values of these first holes are usually low, and it has been found that the smaller the drill, the greater the number of inches that must be drilled before uniform values result. The $^1/_2$-in.-diam drill was then run at a feed heavy enough to insure torque and thrust values of such a magnitude that they could be read accurately. All of the drills were then tested at that feed and the same peripheral cutting speed. One of the larger drills, depending on the size of the metal being tested, usually the 1-in. or the $1^1/_4$-in.-diam drill, was selected and tests run employing a number of different feeds. Three holes were drilled with each drill diameter and feed combination. If for any reason the results when tabulated did not check, a fourth or fifth hole was drilled. Average values were then plotted on log-log paper, as has been described, to determine the formulas.

For most metals and especially the free-cutting varieties, very favorable experimental results were obtained. For some metals, such as those of a sticky or non-uniform character, additional tests were often necessary, inasmuch as average results from the first test did not seem to fall on straight lines when plotted on log-log paper. It has been found by repeated tests that the same values of the exponent for the feed and depth are obtained with any combination of drill diameter and feed range; that is, the slope of a variable-feed line on log-log paper run with a $^1/_2$-in.-diam drill is the same as that for a line run with a 1-in.-diam drill with variable feed. The two lines are merely displaced vertically, one being above or below the other. This same condition maintains when the various drill diameters are used with a light feed or a heavy feed as a constant, or with any cutting fluid except for aluminum, as has been noted.

However, if the angles of the drills used in these formula tests are changed, different formulas result. One metal will respond more favorably to an increased helix (or rake) angle of the drill than another. The drills used to develop the formulas presented in this report were what are believed to be a representative standard type. It has been found in some instances that two drills, apparently identical, will give values consistently different by several per cent. This difference obviously is due to some other feature of the drill.

The formulas presented in this report will agree very closely with those obtained by standard drills of other manufacturers. The formulas presented were all determined using the same set of drills, so that they are directly comparative for the different materials.

The Formulas

In reviewing the formulas for torque and thrust presented in Table 4, several interesting facts are immediately apparent. The same torque and thrust formulas are obtained for all of the steels. The constants, however, vary between the different steels, as well as for the different cutting fluids. For aluminum, free-cutting brass, cast iron, and malleable iron the formulas show considerable variation. The web thickness seems to have about the same effect on thrust values for cast iron and malleable iron as for steel. It does not have nearly as much effect, however, when cutting aluminum and brass, and for this reason the simpler thrust formulas, omitting the factor of web thickness, are presented as giving satisfactory accuracy. When comparing the steels cutting dry or with any of the cutting fluids, a direct comparison may be made between the constants, as the formulas and exponents are alike. Such comparisons, however, cannot be made between the non-steels by comparing constants, due to the fact that the exponents of feed and drill diameter vary.

Influence of Cutting Fluids

It is interesting to note the type of cutting fluid which gives the lowest torque and power values for the different metals cut. For the steels it is always a sulphurized oil, either the sulphurized mineral oil (No. 10) or the sulphurized lard-mineral oil (No. 11). For malleable cast iron it does not seem to make any difference whether the material is cut with any one of a variety of oils or any one of a variety of water compounds. The oils give the lower values, however, and the water compounds the higher values. That is, all cutting fluids for malleable iron fall into one of two groups. When cutting cast iron and the non-ferrous metals, a compounded oil, such as mineral-lard oil (No. 8) or the mineral-oleic acid (No. 9), seems to give the lowest values. Better to indicate the possible power saving over dry cutting by

using the best oil for each metal, a column has been added to Table 5 showing the percentage saved, based on the values for dry cutting. The greatest saving of 33$^1/_3$ per cent results when drilling the S.A.E. 1020 steel, bar EF, with a sulphurized oil, either Nos. 10 or 11. The sulphurized oils produce a saving of 26 per cent, 21 per cent, and 23 per cent over dry cutting when cutting the S.A.E. 1035, carbon tool steel, and S.A.E. 3150 steel, respectively. It is interesting, however, that when cutting the free-cutting steel, S.A.E. 1112, only 6.8 per cent is saved through the use of the sulphurized lard-mineral oil (No. 11). The influence of the cutting fluids on free-cutting brass is seen to be negligible. The torque values are the same for all drill sizes, and there is only a slight reduction in thrust for the mineral oil containing 5 per cent oleic acid (No. 9).

It appears that as long as an oil is used, a saving of about 10 per cent in power results when drilling malleable cast iron. Except for a possible increase in tool life, there is no advantage in using a water compound as against dry cutting. A somewhat greater saving of 17.2 per cent is made over dry cutting when cast iron is drilled with the mineral oil containing 5 per cent oleic acid (No. 9). A saving of 31.7 per cent is made when cutting the cast aluminum over dry cutting by using the mineral-lard oil (No. 8). The straight or compounded oils as a group produce the lowest torque values when drilling aluminum. The water compounds, in the form of straight soluble oils or soluble oils containing kerosene, as well as pure kerosene, give torque values considerably above those of the oil group. Kerosene, therefore, does not appear to advantage when cutting this type of aluminum, particularly when power is the chief consideration.

The values of torque for the 1$^1/_4$-in.-diam drill operating at a feed of 0.015 in. per revolution and at a speed of 174 rpm (equivalent to 60 fpm) are shown plotted in Fig. 56 over the cutting-fluid numbers, arranged in numerical order, for all nine materials tested. A direct comparison is possible between the drilling properties of these metals with one another and shows the influence of the cutting fluids on each metal. The vertical scale is logarithmic, so that equal percentages are represented by equal spaces. The four uppermost curves, giving the torque for S.A.E. 3150 steel, carbon tool steel, S.A.E. 1020, and S.A.E. 1035 steel, are shown to be quite similar. The curve fifth from the top for S.A.E. 1112 steel seems to be in a class by itself, different somewhat from the other four steels. The torque as a function of the cutting fluids for each of the other metals—namely, malleable cast iron, gray cast iron, leaded brass, and cast aluminum alloy—is quite independent, and no satisfactory correlation seems possible. The results of torque as presented for these various metals seem to justify the many existing conflicting opinions as to the advantages or disadvantages of various cutting fluids. It appears that definitely to specify any cutting fluid for a given material complete information must be had as to the influence of all cutting fluids on that metal. Obviously it would be only by chance that a satisfactory solution of a cutting-fluid problem could be made when the selection of a cutting fluid is based upon so-called general practical results.

In Fig. 57 are shown plotted the corresponding thrust values for the 1$^1/_4$-in.-diam drill operating at a feed of 0.015 in. per revolution and a speed of 174 rpm (equivalent to 60 fpm). These thrust values are plotted for all nine materials over the cutting-fluid numbers, arranged in numerical order as in the case of the torque values given in Fig. 56. Again, lack of complete coordination between the performances of the cutting fluids as affecting thrust is seen for the different metals. In general, each curve corresponds in nature of slope to its respective torque curve of Fig. 56. The thrust values for the S.A.E. 1112 steel of Fig. 57 appear to be in closer agreement with the other steels above than is the case of the torque values for the S.A.E. 1112 steel in Fig. 56. Furthermore, the thrust values of malleable cast iron appear to be lower in the general scale than are the torque values in Fig. 56. In Fig. 56 all torque values for malleable iron are consistently (approximately 15 per cent) higher than the torque values for gray cast iron. In Fig. 57 the thrust values for malleable cast iron for oils Nos. 5 to 11, inclusive, are below the corresponding values for cast iron by about 9 per cent. It is also seen that the thrust values for the leaded brass are slightly lower than the torque values of Fig. 56, while the thrust values for aluminum, Fig. 57, are slightly higher than the torque values for aluminum in Fig. 56. Inasmuch as the torque values of Fig. 56 for each metal and the thrust values of Fig. 57 for each metal were computed from the formulas developed for identical cutting conditions—that is, with the same feed per revolution and speed in rpm—the torque values of Fig. 56 for any condition are directly comparable with any other torque value shown. This holds true also for thrust values given in Fig. 57.

In order to show clearly the influence of what might be considered the maximum torque values for each metal as produced by dry cutting (No. 1), the minimum torque values for each metal as produced by the sulphurized lard oil (No. 10), as well as the torque values for each metal determined when the mineral oil containing 5 per cent oleic acid (No. 9) was used, the torque values produced by each of the three oils are shown plotted over each material in Fig. 58. The materials are arranged from left to right in order of increasing torque. These three cutting fluids were selected inasmuch as they represent extreme cutting conditions for the different metals. Fig. 58 is prepared to show at a glance the influence of the cutting fluids on each metal. It is seen, for instance, that when cutting aluminum, dry cutting (No. 1) gives the greatest torque value, 30.2 ft-lb, and the mineral oil containing 5 per cent oleic acid (No. 9) gives the least torque value, 21 ft-lb. The difference is about 9.2 ft-lb. This 9.2 ft-lb represents a saving of 31.7 per cent due to oil No. 9 over dry cutting, as shown in Table 4, or it shows an increase in torque when cutting dry of 44.3 per cent over the torque value for oil No. 9. Also, it is seen from Fig. 58 that, when drilling the free-cutting brass screw stock, the torque values for the three oils, Nos. 1, 9, and 10, are identical. Perhaps the greatest range of torque for the different oils is for the S.A.E. 1020 steel. A torque of 123.5 ft-lb is produced cutting the S.A.E. 1020 steel dry (cutting fluid No. 1), while a torque of only 82.4 ft-lb is produced with oil No. 10. This represents a saving for oil No. 10 of 41.4 ft-lb. In other words, cutting dry requires 50 per cent more torque than when cutting with oil No. 10. It is of interest to note the relative position of the torque values for each metal produced when oil No. 9 is used. When cutting aluminum with oil No. 9, the lowest torque value is obtained, but when cutting the S.A.E. 3150 steel, the highest value of torque is obtained.

In Fig. 59 are shown the values of thrust plotted to logarithmic ordinate scale over the various metals for the 1$^1/_4$-in.-diam drill operating at a feed of 0.015 in. and 174 rpm. Again, the thrust values for cutting fluids Nos. 1, 9, and 10 are plotted. These curves indicate the diversity in thrust values produced for each metal between different cutting fluids. The diversity produced by the oils when cutting free-cutting brass is very small. When cutting S.A.E. 1112 steel, it is quite negligible. It appears to be greatest when cutting aluminum, and is very appreciable when cutting the S.A.E. 1020 steel and the S.A.E. 3150 steel. Again, the thrust values produced by oil No. 9 are lowest when cutting aluminum, free-cutting brass, and cast iron, but maximum when cutting the S.A.E. 3150 steel.

CONCLUSIONS

Conclusions as to the influence of cutting fluids when cutting the nine materials listed in the paper are first presented for each

of the several materials separately. After this more general conclusions are added.

Drilling Aluminum

1 The torque and thrust values resulting from the drilling of aluminum vary a great deal, depending on the type of cutting fluid used. The torque and thrust values are greatest when drilling the cast aluminum alloy dry (cutting fluid No. 1).

2 The water compounds consisting of cutting fluids Nos. 2, 3, and 4, as well as pure kerosene and 1 part kerosene in 4 parts cutting fluid No. 3, produce much the same results of torque and thrust when drilling the cast aluminum alloy. The torque values produced by these water compounds and kerosene are appreciably higher than the values produced by any of the oils.

3 There appears to be little difference in torque or thrust values when drilling with any oil, whether straight mineral oils, lard oil, compounded oils, or sulphurized oils.

4 Sulphur does not appear to be desirable in a cutting fluid for this cast aluminum alloy. Compounded oils, such as Nos. 8, 9, and 11, seem to produce the lowest values of torque and thrust in cutting this aluminum. The compounded oils are better than the straight mineral oils or the straight lard oils.

5 It appears that the formula for thrust as developed when cutting dry (No. 1) holds for all of the oils plus the kerosene and kerosene emulsion, but does not hold for the water compounds Nos. 2, 3, and 4. This is the first time that a cutting fluid has been noticed to exert such an influence on the drilling formula developed for any material.

6 A saving of 31.7 per cent power at the drill point is made if a mineral oil containing 10 per cent lard is used when drilling this aluminum instead of dry cutting.

7 The formulas for torque and thrust when drilling cast aluminum alloy, together with constants for various cutting fluids, are summarized in Table 4.

Drilling Free-Cutting Brass

1 All of the cutting fluids tested give almost identical torque values when drilling the free-cutting brass.

2 But little difference in values of thrust was found for the various cutting fluids used.

3 A light mineral oil gave the lowest thrust value and a heavy mineral oil gave the highest thrust value, except for dry cutting, indicating that when drilling free-cutting brass with mineral oil, thrust increases with viscosity.

4 There is no saving in power output at the drill point through the use of cutting fluids.

5 The drilling torque and thrust formulas, together with constants for free-cutting brass, are summarized in Table 4.

Drilling Cast Iron

1 It was found that cutting fluids have considerable influence on the torque when drilling cast iron, but less influence on the thrust. Almost identical values of torque and thrust were obtained for a number of the cutting fluids.

2 The lowest torque when drilling cast iron was obtained with the mineral oil containing 5 per cent oleic acid (No. 9); the next lowest torque was obtained with the sulphurized mineral oil (No. 10).

3 The highest torque when drilling cast iron was obtained when drilling dry.

4 A saving of 17.2 per cent of the power output at the drill point is made if the oil No. 9 is used instead of dry cutting.

5 The sulphurized oils (Nos. 10 and 11) give values of thrust among the highest, while the water compounds give values slightly below the average.

6 The formulas for torque and thrust, together with the constants for various cutting fluids when drilling cast iron, are summarized in Table 4.

Drilling Malleable Cast Iron

1 Cutting fluids exert a marked influence on both torque and thrust when drilling malleable cast iron. The cutting fluids fall into two groups: The first group, consisting of dry cutting and the water compounds (cutting fluids Nos. 1 to 4, inclusive), gives high and equal torque and thrust values, while the second group, consisting of all of the oils, gives low and equal torque and thrust values.

2 There is a distinct saving in power for thrust in drilling malleable cast iron with an oil. The saving in power amounts to 10.5 per cent as compared to the power required to drill dry.

3 The torque and thrust formulas for malleable cast iron, together with constants for various cutting fluids, are summarized in Table 4.

Drilling S.A.E. 3150 Steel

1 Cutting fluids exert a considerable influence on the torque and thrust values when drilling the chrome-nickel steel, S.A.E. 3150. The highest torque value is obtained when the mineral oil containing 5 per cent oleic acid is used, with dry cutting (No. 1) a close second.

2 The sulphurized oils (Nos. 10 and 11) give by far the lowest values of torque and thrust.

3 The water compounds (Nos. 2, 3, and 4) give torque and thrust values below those for all of the oils, Nos. 10 and 11 excepted.

4 A saving in power at the drill point of 23 per cent may be made by drilling the S.A.E. 3150 steel with sulphurized mineral oil (No. 10) over dry cutting.

5 The formulas for torque and thrust for the S.A.E. 3150 steel, together with the constants for each cutting fluid, are summarized in Table 4.

Drilling S.A.E. 1020 Steel

1 The various cutting fluids materially influence the torque and thrust values when drilling the S.A.E. 1020 steel. All cutting fluids give torque and thrust values considerably below those for dry cutting.

2 As was the case with the S.A.E. 3150 steel, the sulphurized oils (Nos. 10 and 11) produce unusually low values of torque and thrust.

3 The aqueous solutions (Nos. 2, 3, and 4) give the highest values of torque and thrust of all of the liquids.

4 The cutting fluids for reducing torque and thrust are arranged in almost identical order.

5 Approximately 33 per cent saving in power output at the drill point is effected by drilling the S.A.E. 1020 steel with the sulphurized oils (Nos. 10 and 11) rather than with dry cutting.

6 The formulas for torque and thrust, together with the constants for each of the cutting fluids when drilling the S.A.E. 1020 steel, are summarized in Table 4.

Drilling S.A.E. 1035 Steel

1 The various cutting fluids exert a marked influence on the torque and thrust values when drilling the S.A.E. 1035 steel.

2 The torque curves, plotted over the cutting-fluid numbers arranged in numerical order, of the S.A.E. 1020 and 1035 steels are practically identical, the torque line for the S.A.E. 1020 steel being approximately 10 per cent higher. The thrust lines for the S.A.E. 1035 and S.A.E. 1020 steels are in close agreement, except for the values of thrust produced by the sulphurized oils (Nos. 10 and 11). The sulphurized oils do not seem to produce such low values of thrust when drilling the S.A.E. 1035 steel as

might be expected from the corresponding curve for the S.A.E. 1020 steel.

3 For the S.A.E. 1035 steel the lowest value of thrust is obtained when lard oil (No. 5) is used. The next lowest values of thrust are obtained with the sulphurized oils (Nos. 10 and 11), with the thrust for mineral lard oil (No. 8) almost equal in value.

4 Power savings at the drill point of 26 per cent can be effected by the introduction of the sulphurized mineral oil (No. 11) as compared with dry cutting.

5 Torque and thrust formulas when drilling the S.A.E. 1035 steel, together with constants, are shown in Table 4.

Drilling Carbon Tool Steel

1 The torque and thrust values vary considerably as different cutting fluids are introduced when drilling this carbon tool steel.

2 The sulphurized oils (Nos. 10 and 11) produce the lowest values of torque and thrust.

3 The highest torque values in drilling the carbon tool steel are obtained when cutting dry (cutting fluid No. 1).

4 The water compounds (Nos. 2, 3, and 4) and lard oil (No. 5) give torque values averaging 6 per cent below the torque values for the straight mineral oils and compounded oils.

5 The torque values for the carbon tool steel are about 5 to 10 per cent below those for the S.A.E. 3150 steel, whereas the thrust values for the carbon tool steel are, with the exception of the value for oil No. 9, 8 to 10 per cent above those for S.A.E. 3150 steel.

6 About 21 per cent saving in net power output at the drill point can be made by drilling the high-carbon tool steel with the sulphurized mineral oil as compared with dry cutting.

7 Torque and thrust formulas when drilling carbon tool steel, together with constants for the various cutting fluids, are summarized in Table 4.

Drilling S.A.E. 1112 Steel

1 Cutting fluids seem to have little effect on torque and thrust values when drilling this free-cutting steel.

2 The lowest torque values are obtained with the sulphurized oils (Nos. 10 and 11), whereas the highest torque value is obtained with the use of the borax water (No. 2).

3 The torque for dry cutting seems to be about equal to that when cutting fluids Nos. 3 to 9, inclusive, are used.

4 The lowest value of thrust when drilling the S.A.E. 1112 steel is obtained for the 1-to-50 soluble oil (No. 3). The values of thrust for all other cutting fluids are practically identical.

5 The maximum saving in net power output at the drill point by using sulphurized mineral oil (No. 11) is 6.8 per cent as compared with that for dry cutting.

6 Torque and thrust formulas when drilling S.A.E. 1112 steel, together with constants for the various cutting fluids, are summarized in Table 4.

General Conclusions

1 In the derivation of torque and thrust formulas for drilling various metals, the values of the exponents of the variables are not changed by using different values of the constant. That is, if the exponent of feed as the variable is determined for the constant drill diameter of $^1/_2$ in., the same feed exponent would be obtained if a 1-in.-diam drill were used. Similarly, in determining the exponent of drill diameter as the variable for a constant feed, if a light feed is used, the same exponent would be obtained as with a heavy feed. The lines drawn through the torque values as a function of variable feed or diameter on log-log paper are always straight. Thrust lines are straight only for aluminum and brass. For the other metals the web thickness must be considered to get satisfactory straight lines.

2 The values of the exponents of feed and diameter in the torque and thrust formulas do not change for different cutting fluids. Aluminum S.A.E. 33 is the only exception as far as the data presented in this paper show. The constant of the equation alone is affected in most cases by the different cutting fluids.

3 One torque and thrust formula has been found to hold for all steels tested in this paper. Each of the other metals, however, such as aluminum, free-cutting brass, cast iron, and malleable cast iron, has its own formula.

4 There appears to be no general single conclusion that can indicate the best cutting fluid for any given material. The torque lines for the various carbon steels, when plotted over the oil numbers, appear in general to be similar in shape but above or below one another. The torque line, Fig. 56, for the S.A.E. 3150 steel agrees, in a general way, with the tendency of the lines for the straight carbon steels. The compounded oils (Nos. 8 and 9), however, give torque values disproportionately high for the S.A.E. 3150 steel.

5 There is little similarity between the torque curves when plotted over cutting-fluid numbers for malleable iron, gray cast iron, leaded brass, cast aluminum alloy, and the steels. This indicates that the results of a series of cutting-fluid tests on one material would be of little value in predetermining good practice in the use of cutting fluids on another material.

6 The torque and thrust values for free-cutting steel and brass are affected but little by the various cutting fluids.

7 Theoretically the value of thrust contributes less than 1 per cent to the power developed at the drill point. It adds more to the input power due to the added friction for higher thrust values.

8 The sulphurized oils give torque values lower than any other cutting fluid on all of the steels tested. The sulphurized oils do not appear to show an advantage over the other oils, such as the lard, mineral, and compounded, when cutting malleable cast iron, gray cast iron, and free-cutting brass. When cutting aluminum, the sulphurized mineral oil appears to disadvantage when compared with the other oils. (See Fig. 56.) The various water compounds and oils do not appear to reduce the power when drilling the free-cutting steel and the free-cutting brass.

Acknowledgments

This paper represents a progress report of the Sub-committee on Cutting Fluids of the Special Research Committee on the Cutting of Metals of The American Society of Mechanical Engineers. Funds for carrying on the work were provided by the Engineering Foundation. The work was done at the University of Michigan in the Department of Engineering Shop as a project of the Department of Engineering Research.

The authors wish to express their appreciation to Mr. Charles E. Kraus, who conducted the tests and worked up the data, and to Mr. Theodore R. Thoren, who prepared the drawings and assisted in the experimental work.

The National Twist Drill and Tool Company, of Detroit, furnished the drills gratis. The various cutting oils were furnished gratis by the Standard Oil Company of Indiana, Chicago; the Sun Oil Company, Philadelphia; the Atlantic Refining Company, Philadelphia; Swift & Co., Chicago; and D. A. Stuart & Co., Chicago. The malleable cast iron was furnished gratis by the Cadillac Malleable Foundry.

Grateful acknowledgment is made to Prof. Clair Upthegrove, of the Department of Chemical Engineering, and Mr. Stephen Urban, of the Department of Engineering Research, for their assistance in connection with the metallurgical work.

Discussion

ROBERT COREY DEALE.[5] The writer was impressed by the amount of experimental work necessary to secure the data here recorded, but cannot feel that these results are of any great value to the industry as a whole, because of the manner in which the experiments have been carried out. No information is given as to the tool life of a given drill point, cutting a given grade of material at a given speed and feed, and with a specific type of cutting fluid. Furthermore, no data are given to show any relationship between torque and tool life.

F. W. Taylor, in "The Art of Cutting Metals," gives considerable attention to the method of conducting cutting tests and emphasizes that the important fact in the testing of cutting tools is the tool life secured when cutting under specific conditions of speed, feed, etc. His statements, while based primarily upon his very extensive experiments with roughing tools in lathes and boring mills, were made after he had retired from the installation of scientific methods in industrial plants, and it is believed that he intended them to apply to all types of metal cutting. If no relationship could be discovered between cutting speed and tool pressure in the case of a simple turning tool, it is still more difficult to discover such a relation in the case of more specialized forms of tools, such as drills and milling cutters.

The production man must know the speeds and feeds to be used under a given set of conditions under which he will get the lowest cost of removing metal, after taking into consideration all factors, including tool cost and grinding time. For him to make direct use of cutting data, they must be in the form of curves or a table giving cutting speeds for given conditions of feed, depth of cut, metal being cut, shape of tool, size of tool, material of tool, cutting fluid used, quantity of cutting fluid, under known conditions of tool life. Preferably he should be provided with data showing the variation of tool life with cutting speed.

The manufacturer of machine tools must know the feed pressure and power required for the cut for which he expects to design the machine, but these values are generally secured by a single set of tests on a late type of his own machines, although formulas giving this information with the necessary degree of accuracy have been available for at least 20 years. When the writer was assistant chief engineer of the Pond plant of the Niles-Bement-Pond Company, he always found it desirable to make such a test before the final design of a new machine in order to check any figures previously available. The manufacturer of cutting tools must have the same information as that required by the production man, although he must investigate the effect of changes in design and material, while the shop is ordinarily limited to the tools commercially available.

[5] Consulting Management Engineer, Babylon, N. Y. Mem. A.S.M.E.

For these reasons, it is believed that tests such as are described in this paper are of little practical value. While it is realized that tests based on tool life are considerably more expensive to make than tests based on torque or tool pressure, in the present state of knowledge it is believed that it is necessary to conduct such tests in such a way that cutting speeds and tool life will be secured directly, rather than to depend on unproved inferences, as is necessary when conclusions are reached from tool pressure data. Furthermore, it is highly desirable to secure data which may be used directly by industry.

The writer believes that the standardization of tests for metal-cutting tools which he proposed in the October, 1932, issue of *Mechanical Engineering*, might well be extended to include other types of tools than the turning tools described. He has never seen data on the life of drills under varying conditions, but sees no reason why all drilling tests, whether intended to show possible speeds and feeds, the comparative value of various designs of drills, or the comparative value of various cutting fluids should be based on a definite tool life, either expressed in minutes of cutting time or inches of hole drilled. It would probably be necessary to further standardize the depth of test hole and determine whether the hole was to be allowed to break through or not. Probably this depth of hole should vary with the size of drill, because of the different lengths of the drills.

It would be further desirable to determine the equation expressing the variation of drill life with the variation of peripheral speed, so that accelerated tests might be made, and then reduced to some standard tool life.

Determination of an equation accurately expressing the variation of drill life with drill diameter, peripheral speed, and feed would be very valuable so that the speeds and feeds giving most economical operation might be readily determined for any machine.

When making drilling tests, it would be desirable to calibrate the machine used in the tests, so that both power input and power at the tool might be recorded. Such data would give all necessary information for the design of the driving mechanism of drilling machines, and in addition would allow production men to readily determine whether definite speeds and feeds were within the capacity of a given machine.

No data have been given showing any relation between tool pressures and cutting speeds for a definite life of the tool between grinds. Until such a relation has been well authenticated, it would seem that any experiments based on tool pressures are of doubtful value, particularly as they give no information as to proper speeds and feeds. Such experiments as those reported in this paper should be so conducted as to show the relation between cutting speed and tool life for a given set of conditions.

ALVAN DAVIS.[6] The following remarks refer to only two metals: leaded free-cutting brass and S.A.E. 1112 free-cutting steel. In the case of free-cutting brass, it is the opinion of some of our machine-shop foremen that there is but little gain in using a cutting fluid so long as the cutting speeds are of the general order of those used in the interesting tests covered by Progress Report No. 4. Thus there is some practical opinion in support of the findings reported. However, in commercial production, our speeds for automatic machines running on free-cutting brass are about five times as fast as in the tests (1430 rpm for a $^{3}/_{8}$-in. drill with a feed of 0.01 in.). At this speed, we use a copious stream of light paraffin oil as a coolant. Otherwise, the tools will burn up.

[6] Research Engineer, Scovill Manufacturing Company, Waterbury, Conn. Mem. A.S.M.E.

In the case of free-cutting steel, we do not use S.A.E. 1112, because the modern super-free-cutting steel is so much better,[7] permitting nearly 50 per cent higher speed. With such steel, our cutting speeds are about two-thirds those for brass, and the energy consumed is about the same. Were we to use S.A.E. 1112, our speeds would be reduced to about 46 per cent of those for brass. This, again, gives about equal rate of energy delivery through the nose of the tool. This is a check on the relative horsepower per cubic inch per minute given in column 10 of Table 5 of the report. That is, 0.301 hp for brass and 0.670 hp for 1112 steel show a ratio of 45$^1/_2$ per cent.

HANS ERNST[8] AND MARIO MARTELLOTTI.[9] The selection of the proper kind of cutting fluid in relation to the cutting tool and the material being cut has always been a matter of conjecture, owing to a lack of information on the performance of cutting fluids. In presenting this report the authors have greatly extended the field covered by their earlier paper, Trans. A.S.M.E., MSP-54-2. It is to be hoped that they will extend this work to cover other types of cutting tools.

The most significant feature developed is the consistent superiority shown by the sulphurized oils Nos. 10 and 11 when drilling steel. This fully corroborates the results of the tests previously reported on S.A.E. 3150 steel. Of the two sulphurized oils, the lower cost oil No. 10 is actually better than the higher cost oil No. 11 for all the steels except the free-cutting steel S.A.E. 1112; yet in the latter case the benefit obtained by the use of any cutting fluid is relatively small owing to the free-cutting nature of this material.

The superiority shown by the sulphurized oils in this test is in agreement with our own experience, where such oils have given remarkably good results in certain difficult machining operations. In one case involving a threading operation on a low-carbon-steel pipe, the cutting fluid which had been used was a straight lard oil, and difficulty was encountered in obtaining a smooth thread due to the tearing of the material. After several unsuccessful attempts to improve the conditions by changing the angles of the chasing tools, it was decided to try various cutting fluids. The best results, with a complete elimination of tearing, was obtained with a sulphurized paraffin-base oil of the composition of 1 part of 9 per cent sulphurized mineral oil to 5 parts of paraffin oil.

In another case a heavy face-milling operation on S.A.E. 1050 steel was materially improved by the use of the same sulphurized oil. In this instance the sulphurized oil gave a much better and smoother finish, and in addition caused an appreciable reduction in power consumption.

The superiority of sulphurized oil in the cutting of steel is so marked as to warrant a thorough investigation as to its cause; thus any information which the authors may have obtained or theories which they have developed on this subject would be of universal interest. Our own observations lead us to believe that the effectiveness of a given cutting fluid is a function both of its lubricating qualities and of its surface tension with respect to the material being cut, at the temperatures reached when the fluid is interposed between tool and chip. The lower the surface tension, the more rapidly a drop of the fluid will spread over the surface of the work and the more readily the surface will be wetted.

In the case of sulphurized oils it is probable that the finely divided particles of sulphur, which are carried in suspension in the oil, will be trapped between the face of the tool and the under surface of the chip. Under the high temperature existing at this point it is possible that the sulphur will actually become fluid, and thus act directly as a lubricant between the flowing chip and the tool. The existence of a high temperature at the nose of a cutting tool is clearly indicated by the smoke evolved when using any type of oil as the cutting fluid. With sulphurized oil, in fact, the quantity of smoke evolved is a fair indication of the degree of dullness of the tool.

It is probable that the addition of sulphur to a mineral oil (which already possesses good lubricating characteristics and low surface tension as compared with water) will provide a further reduction of surface tension, particularly at the temperature of operation. The reduction in surface tension by increase of temperature in oils of this type is very great indeed, and in view of the apparent importance of this property we would like to see it included in the list of the properties of the cutting fluids given in Table 1. For proper comparison, of course, it is necessary to determine the surface tension with respect to the work material, at the temperature encountered in normal operation.

It is noteworthy that the torque formulas show that the exponent affecting the drill diameter is practically independent of the material being cut, while this is not the case with respect to the exponent of the feed. On the other hand, for the various steels tested the exponents of both the feed and the diameter remain constant. This further emphasizes the importance of the subject of chip flow and indicates the need for further investigation of the mechanism of chip removal. In materials where the mechanism is similar, such as the various steels, the exponents are constant, while for dissimilar materials, where the mechanism of chip flow is radically different, the exponents (particularly for the feed) vary with each material.

In the thrust formula for all materials except the aluminum alloy and the leaded brass, the thickness of the web is introduced. The ratio of web thickness to drill diameter is not the same for the different drills used, but varies as follows:

$^1/_2$-in.-diam drill $W/d = 0.162$
$^3/_4$-in.-diam drill $W/d = 0.138$
1 in.-diam drill $W/d = 0.141$
1$^1/_4$-in.-diam drill $W/d = 0.144$
1$^1/_2$-in.-diam drill $W/d = 0.141$

It would be of interest to determine whether the thrust formula could be expressed in the simple form $B = Kf^a d^b$ if the ratio of web thickness to diameter of drill could be maintained constant. Values of w/d for $^3/_4$, 1, and 1$^1/_4$ in. drills are not far different, and in Fig. 29 it will be seen that the thrust values for these three drills may be very nearly represented by the equation $B = K f^{0.87} d^{1.11}$. Thus it would seem probable that a similar relation would hold true for any diameter of drill if the ratio w/d were kept constant.

Further progress reports of the Sub-committee on Cutting Fluids will be awaited with interest.

W. H. OLDACRE.[10] It is almost impossible to consider the machinability of metal without considering lubricants, as certain metals which it is difficult if not impossible to machine with improper lubricants become easily machinable when properly lubricated. The report of the committee clearly demonstrates this fact and should result in an aroused interest and further investigation of the effect of lubricant on machinability.

In the November issue of *Machinery*, C. W. Bettcher, secretary of the Eastern Machine Screw Corporation, of New Haven, gives an interesting report of an investigation of the power con-

[7] Super-free-cutting steel contains 0.20 to 0.30 per cent S, average 0.25 per cent, as against 0.075 to 0.150 per cent S in S.A.E. 1112, average 0.115 per cent.

[10] Director of Engineering and Research, D. A. Stuart & Co., Chicago, Ill.

sumed by self-opening die heads. An interesting check on the report of the committee might be secured in a test on the machine described.

Further, some interesting work has been done by various research organizations, and several machines have been developed for testing the load-carrying or anti-scuffing values of lubricants. Among these are the Mougey and Almen machines, developed in the General Motors Research Laboratories, and the Timken lubricant tester, developed by the Timken Roller Bearing Company. Unquestionably, the resistance to metal scuffing, which is one of the characteristics measured by these machines, plays an important part in the lubrication of cutting tools, and an investigation of various cutting lubricants with these machines and an attempt to coordinate the results with practical experience in the machining of metals should prove of definite interest.

GEORGE M. CUNNINGHAM.[11] Much present-day discussion revolves around various sulphurized animal and vegetable oils and their blends with mineral oils for use in the metal-working industry. Yet the several methods of sulphur determination in organic combinations are at variance, and the results of analysis are often misleading. This paper is presented in the belief that the Carius method gives the most consistent results in sulphur analysis with the least necessary equipment and with the hope that an attempt will be made by the industry to standardize on its method of sulphur analysis, so that producer and consumer of sulphurized oils may speak the same language when talking sulphur content. This standardization of sulphur analysis will become increasingly more important if it is later proved that increased efficiency of a sulphurized cutting fluid is directly proportional to its sulphur content.

The Nopco Laboratories had occasion to analyze samples of sulphurized oils, to determine the percentage of sulphur in each sample. Two methods of analysis were used in these determinations:

1 The Eschka method, described in "Standard Methods of Chemical Analysis," by W. W. Scott, 4th edition, Vol. 1, p. 495. This method is also described in A.S.T.M. Standards, 1930, part 2, p. 701.

2 A modification of the Carius method, described in "Standard Methods of Chemical Analysis," p. 145, under the title "Determination of Halogens in Organic Compounds."

In the Carius method we used a 0.1–0.2 gram sample of sulphurized oil held in a small-bore, thin-walled glass tube closed at one end and 4–5 cm long. The sample was then placed in a heavy-walled bomb-glass tube 50 cm long, 2 cm in diameter, having a 2 mm wall thickness and sealed at one end. About 10 cc of fuming nitric acid was introduced by means of a long-stemmed funnel, to avoid wetting the upper portion of the tubing. The bomb-glass tube was then sealed at its open end by fusion, placed in an iron tube in a bomb furnace, and heated 8 hr at 200 C. The tube was then cooled, opened by cutting its end off, and the contents thoroughly washed out with hot water. Sulphur content was then determined by precipitation with barium chloride, as barium sulphate, which was then filtered, washed, dried, ignited, and weighed to constant weight.

We found a difference of nearly 10 per cent sulphur content in the samples analyzed by the Eschka and Carius methods, the lower value being obtained by the Eschka method. From our raw-material balance of the amount of elemental sulphur going into the manufacture of our sulphurized oils, we found that the Carius method gave us a very close check as to the true amount of sulphur in the material analyzed.

[11] Technical Department, National Oil Products Company, Harrison, N. J.

We are therefore of the opinion that the Carius method gives an exact analysis in the determination of sulphur in sulphurized oils and that the Eschka method tends to give low values. A third method, consisting of repeatedly digesting the sample with hot concentrated nitric acid, with subsequent oxidation by means of bromine and more nitric acid, with final precipitation as barium sulphate, gave results which checked the Eschka method, but which were low.

The oxygen-bomb method for sulphur determination, as described in A.S.T.M. Standards, 1930, p. 542, was not used, inasmuch as a less complicated procedure was required.

J. F. BEKOLA.[12] Certain cutting fluids, especially the sulphurized oils, have recently acquired considerable importance due to the increase in research on the part of the users. This work has brought out much new information and many new ideas. The writer wishes to congratulate the authors on their contribution. In this and preceding papers by Mr. Boston there has been a striving toward methods for testing cutting fluids under actual working conditions.

The conclusions arrived at by the authors agree fairly with the writer's observations. However, in the cutting or drilling of the softer metals and alloys, the writer has found that a light mineral oil of a paraffin base, with a little addition of fatty acid, gave as a general rule the best results.

In agreement with the author, the sulphurized oils appear to be the most desirable in the cutting and drilling of the harder alloys. These sulphurized oils may contain anywhere from $^1/_2$ to 4 per cent added sulphur. The general tendency seems to be toward highly sulphurized oils, though the writer cannot see any appreciable advantage in cutting oils of over 2 per cent added sulphur. It is interesting to note that the No. 10 fluid used by the authors contained 4.38 per cent sulphur "compounding by analysis." The writer is inclined to believe that this was the per cent sulphur by analysis and not by compounding. If this is so, the oil probably contained about 2 per cent inherent natural sulphur and the remainder as added sulphur. It is quite commonly accepted that a straight mineral oil, of a base and viscosity similar to that of No. 10 fluid, will hold only $1^1/_2$ to 2 per cent added sulphur at saturation. This may be increased to as high as $3^1/_2$ per cent by keeping the oil in constant agitation, but this excess will immediately begin to precipitate as soon as the agitation has ceased. The heavy mineral oils will hold as high as 8 or $8^1/_2$ per cent added sulphur. Fixed or stable sulphur, of which state natural inherent sulphur is, is of little or no benefit in cutting oils. The sulphur must be in the unstable or semi-unstable form, and therefore added sulphur. If all this is true, the No. 10 fluid gave the results of a mineral oil containing $^1/_2$ to 2 per cent added sulphur.

To increase the ability of an oil to hold added sulphur requires compounding with other fats or oils. Lard oil is most commonly used for that purpose, though it is also added for its lubricating quality. A 10 per cent lard oil addition to a mineral oil of a paraffin base with a viscosity of about 150 at 100 deg will bring the added sulphur content at saturation up to about 3 or $3^1/_2$ per cent. Soy-bean oil, linseed oil, and other oils of the semi-drying and drying type will increase the amount of added sulphur retained in mineral oil much more than will the addition of lard oil. However, they have a tendency to oxidize in use, and therefore are likely to become thickened or sluggish. Pine oil has recently come to the attention of oil users mainly due to its claimed high added sulphur content at saturation, approximately 23 per cent. Whether this high percentage of sulphur will remain in suspension during use has not as yet been definitely agreed upon.

[12] Detroit, Mich.

The main function of sulphur in oils is, to all appearance, to act as a coolant. Sulphur is said to combine with oil in three states—unstable, fixed, and semi-fixed. The semi-fixed sulphur is of the form that, though nearly fixed, will become unstable after a period of time or under heat or pressure.

Many users specify that their cutting fluids be free from acids or alkalis mainly because of their corrosive effect on tools, machines, and work, and also being detrimental to the workman. Some of the other properties considered are viscosity, heat conductivity, specific heat, and at times, depending on the particular type of cutting, the film strength and adhesiveness.

The first sentence in point 4 of the general conclusions, "There appears to be no general single conclusion that can indicate the best cutting fluid for any given material," seems to be inconsistent with the data of the paper. The superiority of sulphurized oils in the drilling of the harder alloys appears to be quite clearly shown.

In conclusion, the writer would suggest that in an investigation of cutting fluids, more attention should be given to the fluids and less to the derivation of torque and thrust formulas.

Authors' Closure

Apparently Mr. Deale expects complete information as to speeds and feeds when drilling various metals with the 11 cutting fluids in which drill wear or tool life is included. General cutting speeds under various conditions are recommended for commercial purposes in much of the technical literature of drill manufacturers. It was not the purpose of this paper to give commercial data, but rather to throw light on performance under definite cutting conditions. Before tool life is studied, it was felt desirable to select, from the numerous cutting fluids used in these tests, those which were outstanding from a point of view of performance or economy, inasmuch as drill-life tests require more time and a great quantity of material to be cut. It was not the object of the paper to give a relationship between torque and tool life. In Progress Report No. 3, some information as to wear on a drill and its relation to the value of the resultant torque is shown for dry cutting in Figs. 4 and 5 and for drilling with cutting fluid No. 4 in Fig. 6. These curves show the rather gradual increase in torque and thrust as a function of the number of inches of S.A.E. 3150 steel drilled until the point of failure is reached.

The authors doubt the reliability of drilling data which have been available for the last 20 years, inasmuch as the materials being drilled today are quite different from those of 20 years ago and the drills themselves differ materially in shape and steel. The formulas presented in this paper were developed in order that a complete background of the performance of these drills when operating in the various materials with the selected cutting fluids could be known definitely. It is believed that, until these Reports Nos. 3 and 4 were issued, there was no reliable information to show that the exponents of feed and drill diameter remained constant whether cutting dry or with any type of liquid. Many comparative tests have been run from which the wrong conclusions have been reached, inasmuch as the tests covered too limited a range. It has been proved that, for a given tool shape and material, the curve expressing torque and thrust for various feeds and drill diameters for drilling and the tool-life cutting-speed curve for turning are displaced only vertically when the cutting fluid is changed. If, however, in turning, the profile of the tool is changed, the slope of the cutting-speed tool-life curve also may be changed. Various experimenters have found that the exponent of the tool life in the cutting-speed equation, when other factors are constant, is $1/7$ or $1/8$. It is known that, by changing the profile of the tool, the exponent of T can be changed to $1/5$ or $1/20$ or any other exponent desired. Unless this is definitely understood or unless the tools are identical, conclusions may be, and often are, misleading.

French and Digges found in their paper, "Rough Turning With Particular Reference to the Steel Cut" (Trans. A.S.M.E., Vol. 48, 1926, p. 533), that for their tool shape, size, and general cutting conditions, the exponent of tool life was $1/7$ (see p. 543). On the other hand, in their paper, "Turning With Shallow Cuts at High Speeds" (Trans. A.S.M.E., Vol. 52, 1930, p. 55), they found that, for light cuts, the value of the exponent of T was $1/10$ or $1/12$. A different tool shape was used, along with lighter cuts, than was used in the first paper, so it is difficult to tell whether these different exponents are due to the tool shape or to the size of cut, and yet no change from the straight line on log-log paper is obtained in the range of cuts used in the first paper, particularly as the light cuts are approached. In some of the authors' work, as yet unpublished, it is definitely proved that the change in exponents is due to the change in tool profile.

Again, in Fig. 14 of the French and Digges paper, "Turning With Shallow Cuts at High Speeds," it is shown that the exponent of tool life in the cutting-speed tool-life formula is 0.10 for dry cutting, 0.115 for lard oil, and 0.131 when water was used as a cutting fluid. Obviously, if one were to obtain comparisons at a point to the left of the intersection of any two of these three lines, one conclusion would be reached, whereas the opposite conclusion would be reached if the tests were run under conditions on the right side of the intersection. It was to make sure that no such conditions occurred in these drilling tests that the numerous combinations of feed and drill diameter were used and that the complete formula determinations were made.

It also is obvious, from the fact that various formulas are obtained for different metals, that erroneous conclusions would be reached if the performance of a cutting fluid when drilling one metal were compared with that when drilling another.

Mr. Davis brings out very clearly the usefulness of the cutting fluid as far as tool life is concerned when machining free-cutting materials. Higher speeds may be used due to the cooling action of the cutting fluid, as might be expected.

The confirming results from Mr. Ernst's discussion are indeed encouraging. His inquiry as to why sulphurized oils are superior to those of other types is appropriate. The whole investigation of cutting fluids, as conducted by the authors, has been one to find facts upon which further work can be based, with hopes that eventually enough scientific information may be obtained which will explain the phenomena of metal cutting and the use of cutting fluids. A program already has been laid out for a continuation of this study when confined particularly to sulphurized oils of different types and with different amounts of sulphur. This project, however, at present lacks sufficient support to carry it forward. Obviously, the condition of the sulphur in the oils, whether it is in a chemically active or chemically inactive state, has a great deal to do with its resultant performance. This point, however, has not been proved. It is not yet definitely known what the complete purpose is of the cutting fluid with or without sulphur, so it appears that much work is to be done before a complete understanding of metal cutting can be had and the application of cutting fluids put on a scientific basis.

Numerous experiments have been conducted by the authors with drills of the same diameter but having different thicknesses of web, but no experiments have been conducted with drills of different diameters having web thicknesses of a constant ratio to the diameter, as suggested by Mr. Ernst. The torque in drilling is affected but little by a wide range in thickness of web as a variable. The thrust, however, is affected as indicated by the formulas. The results with the 1-in.-diam drills with various thicknesses of web agree with the formulas as determined with the commercial drills used in the work of the paper.

Mr. Bekola raises a number of questions of interest. The influence of the quantity of sulphur as the only variable in a sulphurized oil has been a project for future experiments by the authors. Nothing comprehensive has been done as yet, however.

Some tests have been run with sulphurized oils in which three oils containing, respectively, 5, 10, and 25 per cent of flowers of sulphur were held in suspension. No particular difference in performance was found in several types of tests. There must be some limiting quantity of sulphur beyond which further material gain in performance, either as indicated by reduction in power, increase in tool life, or better finish, is obtained, but the authors are not in a position to state what this limit is, because of lack of information.

The authors are gratified to observe the interest in the work of this sub-committee. It is hoped that efforts may be correlated so that step by step positive information can be obtained which will lead to a final and complete solution of the problem.

RP-55-2

Grinding Cemented Tungsten- and Tantalum-Carbide-Tipped Tools Economically

By J. M. HIGHDUCHECK,[1] EAST PITTSBURGH, PA.

Present-day speeds and efficiency in handling enormous production have been made possible only by the development of modern tool equipment and set-ups which hasten service and assure quality. In this paper the author outlines a tungsten-carbide-grinding set-up which is efficient and profitable.

PERHAPS one does not exaggerate in saying that cemented tungsten-carbide cutting materials have received more publicity over a period of four years than any other product of the present machining age. In spite of all this, there are many who still consider cemented tungsten carbide as impractical for their use. The manufacturers of carbide cutting materials have been generous in presenting research information to the public, so that today the fundamentals of this cutting material are no longer a secret. The trade papers have outlined practical applications and the proper grades of carbide to use. Rules and helpful suggestions in the selection of proper speeds and feeds in the machining of certain materials are available. The materials that can and that cannot be machined by turning, milling, or drilling have been presented to the machining public, until all that is left to develop is perhaps the maintenance of carbide cutting tools.

Before describing the grinding set-up at the Westinghouse company's East Pittsburgh Works, it might be of interest to outline the system of tool control and how carbide applications are selected. Every tungsten- and tantalum-carbide application in production is demonstrated by a demonstrator who understands the full merits of this material and who can operate any machine as well as the operator on the job. Each application is watched until the operator agrees with the demonstrator that he can maintain the speed. For every application two sets of tools are provided. These tools are charged to the operator by a check system at the department toolroom. Every tungsten-tantalum-carbide application is recorded on a standard form in triplicate—one copy for the time-study department, one for the tungsten-carbide division, and the third copy for the demonstrator who made the application. Every carbide tool, large or small, is numbered. No two tools carry the same number, regardless of size, shape, or type. These tools are recorded at the tungsten-carbide division office. At this office there is kept a record of the purchase order number, cost, size and type of tool, grade of carbide material, and the division to which the tool was assigned.

When an operator is assigned to operate a machine that is equipped with carbide tools, he is charged by the toolroom with every carbide tool on that application. When the tools become dull, the operator on presenting the dull tools at the toolroom receives new or resharpened tools. The toolroom cancels all checks bearing the dull tool numbers and charges the operator with the sharp tools. In a large plant it is always difficult to keep the different sub-toolrooms from losing tools, especially when all carbide cutting tools are resharpened by the main toolroom. To overcome this condition, the sub-toolroom requisitions its tools by type and serial number. Each sub-toolroom is provided with a board upon which are five tools, representing different steps in the manufacture and maintenance of cemented tungsten- or tantalum-carbide-tipped tools. The sub-toolroom tender is responsible for noting on the requisition the classification of the reconditioning of the tool. These tools are sent to the main toolroom and resharpened by an experienced tool grinder. At the main toolroom, where the carbide tools are resharpened, there is a similar board. On this board class A represents a new tool (generally known as a new tipped tool); class B is one with the tips broken off, not more than 20 per cent of the original size; class C, a dull tool; class D, a tool requiring hand honing; class E, a tool generally used for fine finishing, which is always highly diamond lapped. These classifications have time studies in respect to type and size of tool, and the man reconditioning these tools is paid accordingly. On this board is displayed a sketch showing the correct and incorrect method of grinding (see Fig. 1). The main toolroom records the classification and the tool serial number on a form (see Fig. 2) provided by the tungsten-carbide division. The operator turns in his time as approved by the time-study department and inspector for the grinding and resharpening of carbide tools.

There are many factors to be considered in determining the proper and economical use of tungsten carbide. Most of these various factors, however, have been overestimated. In general, in preparing and maintaining carbide tools so that they may perform efficiently, grinding plays a most important part. A material so entirely foreign to steel in composition and physical properties naturally requires different grinding methods and wheels, and the principles to be observed in grinding must be given special consideration. There is no question that tungsten and tantalum carbide has been widely adopted as a "super" cutting tool, in much the same manner that its predecessor, high-speed steel, was received in the beginning of the century.

Cutting carbides should be ground with appropriate care because of their unusual properties. Localized heating of any one part of a tool bit must be avoided in order to prevent cracking

---

[1] Supervisor of cutting tools and applications, Westinghouse Elec. & Mfg. Co. The author was born in Hoboken, N. J., in 1887. After graduating from high school, he attended the Gressley's Academy of West Newton, Pa., also enrolled with the International Correspondence School, of Scranton, Pa., and completed the study of electrical and mechanical engineering. He received his industrial training in pattern making and tool making while engaged with the United States Radiator Company, of West Newton, Pa. Later he was engaged by the Kelly & Jones Company, of Greensburg, Pa., as a mechanical engineer. During the World War he was employed by the Railway Industrial Engineering Company in the capacity of tool supervisor and assistant superintendent of production. After the war he was employed by the Westinghouse Elec. & Mfg. Co. as a mechanical and electrical engineer in the circuit breaker department. Later he became chief inspector of manufacturing in that division, and then was moved into his present position.

Contributed by the Special Research Committee on Cutting of Metals and presented at the Machine Shop Practice session at the Annual Meeting, New York, N. Y., December 5 to 9, 1932, of The American Society of Mechanical Engineers.

Note: Statements and opinions advanced in papers are to be understood as individual expressions of their authors, and not those of the Society.

and checking. Soft grinding wheels should be used, and the wheel must have sufficient strength to prevent its breaking down too rapidly. Again, wheels that are too soft will make the grinding operation unprofitable. After several years of experimenting with different grinding wheels and machines, we learned that to efficiently rough-grind clearance angles on tungsten-carbide-

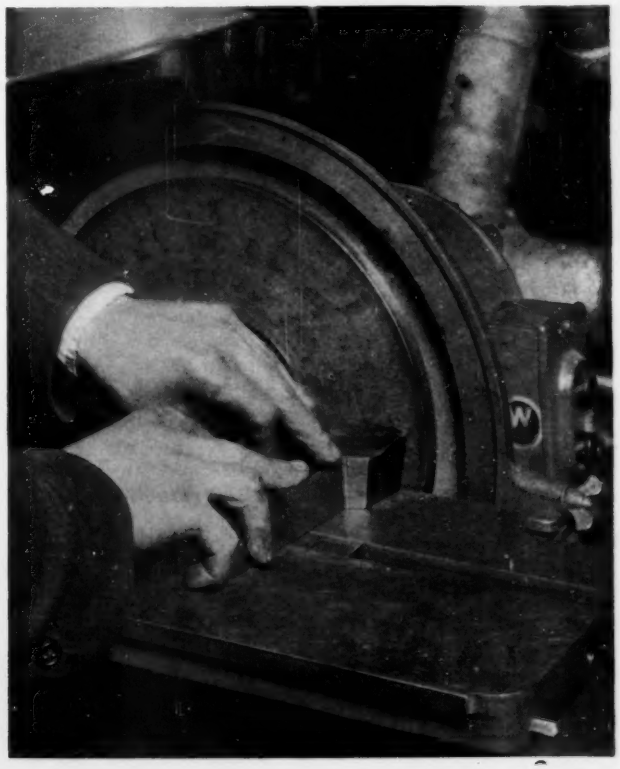

FIG. 6 DIAMOND-LAPPING TUNGSTEN-CARBIDE-TIPPED TOOLS

tipped tools, it is necessary that the contact between the tool and the grinding wheel be a line and not a surface, using plenty of water when grinding (see Fig. 3). Our experimenter demonstrated repeatedly that a plane surface of a grinding wheel cannot be used for rough-grinding carbide tools, wet or dry, successfully and profitably because the wheel surface and the surface being ground soon coincide, with the results of no cutting and

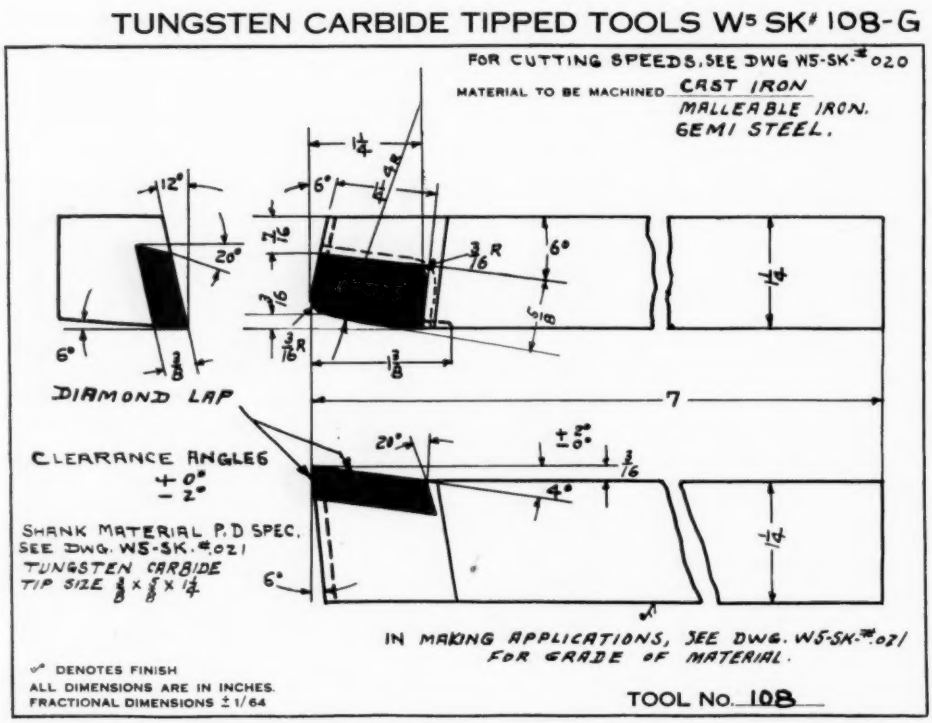

FIG. 7 DIMENSION DRAWING OF A POPULAR PRODUCTION TUNGSTEN-CARBIDE-TIPPED TOOL

much heating, generally ending in checking or cracking the carbide tip. It must be remembered that the carbides are not steel or alloys, but are bonded materials composed of almost microscopic particles approaching the diamond in hardness.

In a plant where thousands of carbide tools are used, the system of maintenance becomes important. To allow operators to grind their own tools when in production is out of question, both from the grinding-equipment and skill standpoints. We have found that the central grinding department system is the most economical system. In Fig. 4 is shown a carbide grinding department which permits the grinding of tipped tools from $1/4 \times 1/4$ to 3×3 in. square. As already stated, all tools that are new tipped are rough-ground by line contact. There are two sizes of machines to cover the field of shank sizes. The machine used for roughing tools from $1/4$ in. square to $1\frac{1}{2}$ in. square is shown in Fig. 3. After the tool is roughed down, it is transferred to the machine shown in Fig. 5, where it is finish-ground dry, semi-offhand. If the tool is assigned to machining resinous products, it receives a diamond lapping operation on a machine as shown in Fig. 6. The tools are carefully inspected and returned to the department to which they are assigned.

Generally, the most interesting point to the user of carbide tools is the cost of the maintenance. Before we inaugurated the set-up, as shown in Fig. 4, to grind a tool, as shown in Fig. 7, it required $1\frac{1}{2}$ hr. At the present time, by means of the new set-up, the same tool is ground to finish size at an average time of 21 min, or a saving of 1hr 9 min on each tool. The tool shown in Fig. 7 is generally recognized by the trade as Carboloy type 14. We have purchased these tools in semi-finished form, in which the supplier of carbide furnishes the tip and brazes it to the shank, all grinding being done by us. In brazing the carbide tip to the shank the supplier generally allows the carbide to project from the shank, which leaves from 10 to 20 grams of cemented carbide to be ground off on the type of tool shown in Fig. 7. An experienced tool grinder can remove this carbide at the rate of 1 gram per minute. Of course, this record is based on equipment such as shown in Fig. 3. To remove carbide by the dry-grinding process, as shown in Fig. 5, the best results obtained were 1 gram removed in 7.1 min, but with considerable danger of heating the tool. The grinding wheels play a very important part in the success of good carbide tools. The proper selection of grinding wheels can be made only by experience and trial. The manufacturers of grinding wheels can furnish the user general information, but special cases require special attention. At the Westinghouse plant, in the set-up shown in Fig. 4, the following grinding wheels are used. For rough grinding (see Fig. 3), Carborundum 80 grit, grade R, bond W.G.G., or Norton No. 3760/1-19. For finishing (see Fig. 5) on one end of the machine, all tools are semi-finished on a Norton or Carborundum wheel, the same as the one used on the machine in Fig. 3, except on a cup wheel design. After this operation the tools are finally finished on the opposite end of the machine on a similar cup wheel, Carborundum or Norton No. 37100/2-H6. The cup wheels are of the same diameter and bore as those used on the machine shown in Fig. 3. The idea is to use the grinding wheel after it is worn down on the machine for which it was intended. In this way maximum wheel life can be obtained. The wheel cost in grinding new tipped tools averages 35 cents per tool, plus the operator's time and the department overhead. The best wheel performance is obtained between 4500 to 5000 sfpm.

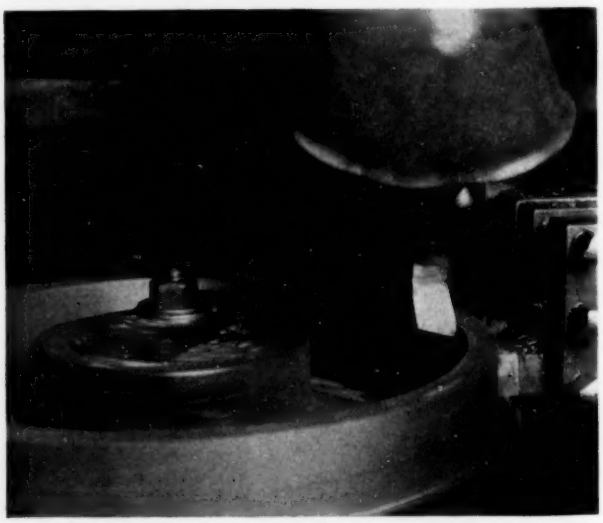

FIG. 8 PRODUCTION JOB ON A BORING MILL
(Two carbide tools turning semi-steel at 280 sfpm, using 1/16 in. feed per revolution.)

Discussion

MALCOLM F. JUDKINS.[2] Because the difficulties and expense of grinding cemented carbide tools have been asserted by adherents to older cutting materials, it is gratifying to have a large user affirm that grinding is no obstacle to use.

We have found that, if plenty of coolant is thrown directly on the tool being ground, wet grinding is cheaper, faster, and safer than dry grinding. The coolant keeps the carbide cool and flushes away the abrasive particles resulting from wheel wear and maintains a clean, free-cutting wheel surface.

One type of tool bit, $^3/_8$ in. thick and 1 in. wide, with a $^1/_8$ in. thick tip across the 1 in. blade width, gave trouble until we used a hydraulic-feed surface grinder. Carbide can be ground very rapidly and with rather hard bond wheels, with no danger of cracking, checking, or chipping, if the time the wheel is in contact with the work is held to a minimum. We use a table traverse of 540 in. per minute and a wheel speed of 5500 sfpm, with a down feed of 0.001 in. and a cross feed of 0.042 in. per pass. This operation is done under a copious supply of 1-to-50 soluble oil coolant thrown directly on the work. The output per 9-hr day is about 200 blades of the inserted-blade milling-cutter type. The blades must be held to 0.375 in. plus or minus 0.001 in. all over. The magnetic chuck load is six pieces. About 0.015 in. stock is removed—0.003 in. from the carbide face and 0.012 in. from the reverse side.

Recent grinding tests on the milling-cutter blades referred to, using a much heavier hydraulic surface grinder than the one installed in our plant, with a 3-in.-width wheel and a table feed of 1200 fpm, showed that the chuck load could be increased from 6 to 12 and that 0.0058 in. and 0.0065 in. were removed in 4 and 4.6 min, respectively, for total vertical feeds of 0.025 in. and 0.030 in. Blades were ground under these conditions until the carbide was only $^5/_{64}$ in. thick. These blades are tipped with a hard grade of Firthite.

Because we have little use for the part remaining after a cup wheel has been used to the scrapping point, we use ring wheels cemented with sulphur in steel adapter plates. Our grinding-wheel scrap is very low.

The author reports a much higher rate of stock removal when grinding wet than when grinding dry. We do almost all of our finishing wet. The writer would like to know the author's objections to wet finishing.

Almost all of our tools are subjected to a lapping operation, but we no longer use diamond. We have found that on a Belgian cast-iron lapping disk with Carborundum finishing compound No. RS-9 or RI medium, the lapping action is very rapid and effective and is of course much cheaper than using diamond dust suspended in olive oil or some other carrier.

The author recommends roughing tools on the Sellers type of wet-tool grinder which provides for line contact, because the tool is moved in the vertical plane tangentially past the periphery of a grinding wheel. For those shops which do not have this type of grinder we have recommended that the steel shank beneath the tip be ground on an aluminum-oxide wheel at from 2 to 5 deg. more clearance than the desired clearance on the carbide tip itself. The carbide is then ground on a silicon-carbide wheel. This method is desirable because if the carbide and steel are ground together on a wheel suitable for cemented carbide the steel loads the wheel and glazes the surface, tending to overheat the carbide, with possible danger of cracking or checking it.

COLEMAN SELLERS, 3D.[3] The author states that for efficient rough grinding of tungsten-carbide tools it is necessary that the contact between the tool and the grinding wheel be a line and not a surface. This is understandable, as when the surface of the tool is in contact with the surface of the cup wheel, heat is generated quickly, and no amount of water will cool this surface. Water cannot reach any further than the edge of the tool, so that the edge will be cool and the center of the surface hot. For this reason, with surface contact, wet grinding is worse than dry.

Those who have ground a large number of carbide tools in the last few years have usually come to the same conclusion—that wet grinding is safer and quicker. With a line contact the water can at all times reach the part of the tool being ground and prevent overheating.

Grinding with a line contact will not do by hand. If a tool is pressed against the periphery of the wheel, we soon have surface contact. The tool must be passed back and forth in a plane while in contact with the wheel or the wheel must be moved in a plane and the tool held stationary.

The tool-crib system is certainly the most economical in any shop unless very small. The old custom of having every man grind his own tools can no longer be tolerated. When most of the tools used were made of high-speed steel, it was possible to have individual grinding only because the tool steel was capable of considerable abuse and the tools would cut even though the angles, rakes, etc., were not the best or most efficient. With the carbide-tipped tools, improper grinding is fatal, and shop executives are realizing that they must have central grinding. They are also finding that their tools made of high-speed steel or other materials are giving much more efficient performance when they are handled by a tool crib and centralized grinding.

We have found that the time required to grind depends on the hardness of the material as well as on the amount to be ground off. The time of 21 min. for the tool shown in Fig. 7 seems about right for the harder grade of Carboloy, grade 44. From our experience, a similar tool of grade 55 with $^3/_{16}$ in. projection of the tungsten carbide would take about 16 min.

The figure of 1 gram per min is interesting. This is probably a very hard grade of the material. Our rate of grinding on grade such as 44 is from 2 to $2^1/_2$ grams per min and on grade 55 or equivalent 4 to 5 grams per min. In fact, we have rough ground the softer grade as fast as 13 grams per min.

Wheel wear will vary from 0.15 to 0.35 cu in. per gram of carbide, depending on the hardness, provided the proper wheels are used. With wheels too soft, this figure would be much higher. Lower figures indicate too hard a wheel, which tends to glaze and burn the tool rather than to grind it.

The cost of wheel is about $8^1/_2$ cents per cu in. of wheel. Our grinding rate averages 0.2 cu in. of wheel per gram of tungsten carbide on a grade such as 55 Carboloy. With 20 grams to be ground off, our wheel cost would be $0.085 \times 0.2 \times 20 = 0.34$, which agrees with the author's figure within 1 cent.

ROGER D. PROSSER.[4] From this paper it would appear that all of the finish grinding is done dry. It is the writer's opinion that wet grinding, with an ample flow of water, is far superior to the dry process, for both roughing and finishing. There is much less danger of cracking the hard metal tip, because it is kept cool by the water. The grinding can also be done much faster as the wheel does not glaze, a much heavier feed can be used, and it is not necessary to change tools or stop and wait for the tool to cool off because it can no longer be held in the hand. Furthermore, with wet grinding, there is no danger that the operator will suddenly place the hot tool in water, with consequent cracking of the tip.

[4] Thomas Prosser & Son, New York, N. Y. Assoc-Mem. A.S.M.E.

Another point is that the rest should have an indexing device, so that the clearance and other angles can be maintained accurately. An important factor in the operation of tungsten-carbide tools is to keep the clearance angle as small as possible consistent with free cutting, and a few degrees' excessive clearance angle makes considerable difference in tool life.

The author's estimates of the amount of cemented carbide which it is possible for an experienced tool grinder to remove in a given time seem excessively small. In finishing, of course, much depends on the class of finish desired and the type of tool being ground, but the figure of 1 gram per min given for wet grinding seems very low. In the Widia tool manufacturing department at Krupp's, the average time required to rough grind away the excess metal on a simple tool, making it ready for finish grinding, is less than 1 min, with from 3 to 10 grams to be removed. The finish grinding is also done very rapidly, by the wet process. It is not often necessary in this country to remove large amounts of cemented carbide, nor is it desirable, on account of the expense, but the foregoing will indicate how much a proper wet grinder with plenty of power and a large wheel will facilitate and speed up the grinding processes where there is considerable of this work to be done.

Author's Closure

The author appreciates the frank discussion, which has brought out many interesting points regarding economical grinding of cemented tungsten- and tantalum-carbide cutting tools.

It is particularly evident that all discussing this subject think alike with regard to the importance of fast and accurate rough grinding of carbides, especially by the wet process, and on the periphery of the grinding wheel (see Fig. 3). The question asked by Mr. Judkins and Mr. Prosser regarding the author's objections to wet finishing brings up the point that the author has none. This operation, perhaps, is a matter of opinion and the kind of set-up one has for grinding carbide tools. The rough-grinding operation as explained in the paper is so accurate and fast that very little material is removed when finish grinding the tools. Therefore a simple dry-grinding operation (first a semi-finish and then a final finish operation) brings the cutting edge to a very fine degree of finish. The author has found that very little heat is generated in the method of finish grinding. Therefore it would be useless to use water. On the other hand, on this type of a machine the water would splash around and would cause the workman to become more or less inaccurate in his work.

RP-55-3

A Test Method for Determining the Quantitative Effect of Tube Fouling on Condenser Performance

By P. H. HARDIE[1] and W. S. COOPER,[2] BROOKLYN, N. Y.

P. H. Hardie

The purpose of this paper is to show the importance and practicability of adding another vital measurement to condenser tests which will give a specific value for the degree of tube fouling existing at the time of the test. Since the majority of condenser installations are subjected to some type of fouling, and since conventional means of cleaning seldom if ever restore the tubes to their original state, it is evident that the performance of many condensers cannot be correctly appraised without a knowledge of their cleanliness factors. Cleanliness factor is the term used to express the degree of tube fouling, and is defined as the ratio of the heat transmittances[3] of fouled and new tubes subjected to the same operating conditions. Several methods of measuring the cleanliness factor are described, and data from six tests are included. The importance of avoiding inconsistent procedures in making the measurements and computing the data is stressed.

W. S. Cooper

CONDENSER performance, like that of other power-plant equipment, has shown marked improvement in the last ten years. During this period there has been a growing tendency toward more specific and stricter guarantees. This was possible only for plants that were fortunate enough to be free from condenser-tube fouling. For the others, which represent by far the majority, equitable bases for making guarantees were impossible because of the lack of a reliable method for determining the condenser cleanliness factor. If condenser performance is to be correctly appraised, it is just as important to know the cleanliness factor as to know the circulating-water temperature and velocity. The quantity of scale or slime on the tube surfaces is not in itself a direct measure of the reduction in performance. Therefore attempts to estimate the cleanliness factor by visual inspection of the tubes cannot be considered as being any better than rough estimates.

Although under certain conditions fouled tubes can be cleaned thoroughly enough to restore their performance to that of new tubes, their cleanliness factor after a thorough cleaning is generally sufficiently below unity to warrant measurement. Some contracts specify the manner of cleaning to be used just prior to the acceptance test, with the expectation that such cleaning will produce either new-tube condition or some known cleanliness factor less than unity. This procedure is only approximate, because the same manner of cleaning will not produce at all times the same cleanliness factor at a given station, and the variation will probably be greater at different stations.

The authors will describe the development over a period of five years of a test method that is designed to eliminate the uncertainty of fouling, and when applied to acceptance tests, manufacturers have a rational basis on which to make performance guarantees and purchasers have a reliable means of checking them. Since the A.S.M.E. Power Test Code Committee has recently decided to incorporate in the condenser code a method for measuring cleanliness factor, it is believed that a description of this test method, which has been successfully applied in the acceptance tests of five large condensers, will be of interest and value to others.

Cleanliness Factor Defined

For a given water velocity, cleanliness factor is the ratio of the heat transmittance of a fouled tube to that of a new tube through which water has been passing only the short time necessary to get the test started. The two tubes must be supplied with circulating water at the same inlet temperature, and the velocities through the tubes must be equal. Similarly, the tubes must be subjected to the same conditions on the steam side.

---

[1] Test Engineer, Brooklyn Edison Company, Inc. Assoc-Mem. A.S.M.E. Mr. Hardie was graduated from the Alabama Polytechnic Institute with the degree of B.S. in Mechanical Engineering in 1921 and later received the degree of M.E. The following year was spent at the Massachusetts Institute of Technology, specializing in design and testing. He received early practical training with the Hardie-Tynes Manufacturing Company, of Birmingham, Ala., and was associated with the Westinghouse Elec. & Mfg. Co. until 1926, doing steam-turbine design work. Since 1926, he has been engaged in power-station testing for the Research Bureau of the Brooklyn Edison Company, Inc.

[2] Assistant Engineer, Brooklyn Edison Company, Inc. Assoc-Mem. A.S.M.E. In 1917–1918, Mr. Cooper was a member of the Instrument Test Department, Taylor Instrument Companies; in 1924, was graduated from Cornell University with the M.E. degree; in 1932, received the M.M.E. degree; was appointed to the engineering teaching staff, Cornell University, in 1924, and was connected with the Turbine Engineering Division of the Westinghouse Elec. & Mfg. Co. during the following three summers; has been associated with the Research Bureau of the Brooklyn Edison Company, Inc., since 1926.

[3] Variously termed thermal transmittance, heat-transfer, and heat-transfer coefficient, all expressed in Btu per hr per sq ft per deg F log m.t.d. (or mean temperature difference).

Presented at the meeting, New York, N. Y., November 28, 1932, of the Metropolitan Section of The American Society of Mechanical Engineers.

Note: Statements and opinions advanced in papers are to be understood as individual expressions of their authors, and not those of the Society.

By "new tube" is meant a tube in the same condition as when received from the manufacturer, and of course it must be of the same size and material as the fouled tube.

Having defined the cleanliness factor of a single tube, it is merely a matter of selecting and testing a sufficient number of representative tubes from different parts of the tube bank and averaging their cleanliness factors in order to obtain the cleanliness factor for the entire condenser. This is similar to well-known sampling processes, which while not 100 per cent accurate, are sufficiently so to justify their use. Certainly it is a far more reliable procedure than resorting to guesswork, which has been the general practise in the past.

Two Means of Measurement

The measurement of tube-cleanliness factor can be done in two ways: first, by isolating the test tubes and testing them in place in the condenser; second, by removing the selected tubes and testing them in a calorimeter. Both methods have their good points, but the authors consider the test in place preferable for the following reasons:

Fig. 1 Typical Installation of Test-Tube Thermometers in Outlet Connections

(1) The removal of tubes and subsequent shipping, which is required if a tube calorimeter is not available at the plant, may result in an improvement in the cleanliness of the tubes, thereby giving an erroneous value for the cleanliness factor of the condenser.

(2) The apparent increase in accuracy of a laboratory calorimeter test is offset by possible inaccuracies inherent with this method. For instance, the measurements must be made on short sections of the condenser tubes, and therefore greater accuracy is required in measuring the temperature rise. Actual condenser tubes are seldom an exact multiple of the length required for a calorimeter, which means that a small section of each tube would have to be discarded. If the cleanliness factors of the sections of a test tube differed greatly, their average might not give the same value as that obtained if the full-length tube had been tested.

(3) Should the cleanliness factors of the full-length tubes differ considerably, there would be no means of computing the weighted average. With the test in place, this can be done easily, since the new tube in each group is a measure of the relative effectiveness of its respective part of the condenser. The cleanliness factors of the tubes near the top, for example, have a greater effect on the performance than ones near the air offtake, because they transfer more heat.

(4) Where tubes foul rapidly, it is important that the cleanliness factor be measured for each run. If the calorimeter method is employed, it would be impracticable to test any more than one group of tubes removed before the first run and one group removed after the last run.

Some of the advantages of both methods may be obtained by moving all the selected old tubes to the top of the condenser and testing them simultaneously with the overall test. Objections (1) and (3) given for the calorimeter method would still apply, however.

Test Procedure

For the cleanliness-factor determinations discussed in this paper the usual process of measuring individual tube heat transmittance was employed. The data required for its evaluation are of course the tube's cylindrical area, the enveloping vapor temperature, the inlet and the outlet temperature of the cooling water, and the rate of flow of the water. As implied in the foregoing section, the cleanliness factor data are observed simultaneously with the overall condenser data. This procedure provides a continuous record of variations in cleanliness factor throughout the test.

For the tests on the single-pass units reported, the selected test tubes were isolated in place by means of rubber-hose jumpers which carried their cooling-water supply across both water boxes. Rubber hose has the advantage of insulating the test-tube water from temperature effects of the water in the boxes. On the inlet end the test tubes were connected through the water-box cover to a distributing manifold receiving water from the same source as for the entire condenser. With this arrangement water of the same quality and very nearly the same temperature as at the inlet to the condenser was available. A "master valve" installed in the supply line to the manifold served to regulate the supply pressure to the values required by the test. The outlet end of each test tube was connected with rubber hose to a control valve, and a nozzle for measuring the water flow through it. This arrangement afforded a simple method for maintaining individual tube velocities equal to the estimated average water velocity through the entire tube bank.

Mercury thermometers inserted directly into the water stream through rubber stoppers were used to indicate the inlet and outlet temperatures of each tube. Fig. 1 shows an installation of thermometers in the outlet of the test tubes for condenser *A*. Where several tubes are tested in a group, only one inlet thermometer per group need be used, but a thermometer is required in the outlet of all tubes. The type of thermometer used by the authors was 10 in. long and had a scale graduated from 30 F to 100 F by 0.5-deg divisions. The 0.5-deg divisions were large enough to permit a fairly accurate estimation of 0.1 deg.

Where two-pass units are involved, modifications in procedure are needed as follows: Fundamentally, the same number of test tubes may be used as in the single pass, but each tube in the first pass is combined with a corresponding one in the second pass. The test tubes are projected across the reversing box just as with the single-pass unit, but the corresponding tubes of any two groups are connected together outside the reversing box. The inlet-water temperature of a given group is read as before, and the outlet temperatures of all tubes are read at the outlet of both passes.

For measuring the head on the nozzles, mercury manometers were used for some of the tests and water-column sight glasses for the others. With a mercury manometer and closed nozzle chamber, the range of measurement is greater, but this means is not as accurate as measuring the head on the nozzle directly in feet of water. The construction of the equipment for the latter method, only, will be described. Fig. 2 shows the arrange-

ment of the standpipes used on one of the tests described. The standpipes shown are 5-ft lengths of standard 3-in. iron pipe open at the top and threaded at the base. The nozzles were made from 3-in. brass pipe plugs and attached to the standpipes by means of couplings. The plugs were bored and reamed to 0.5 in. in diameter, rounded and polished on the inside to a $1^3/_8$-in. radius, and given a $^1/_{16}$-in., 45-deg chamfer on the discharge side. Each nozzle was given a weighed flow calibration over the range of flows expected. Fig. 3 shows diagrammatically the flow circuit for test tubes installed in a single-pass condenser.

The question of selecting test-tube locations that will represent the condition of an entire condenser in regard to fouling is one of importance. The number of old tubes required to determine with engineering accuracy the cleanliness factor for any given condenser depends on the size of the condenser, the layout of the tube bank, and the uniformity of fouling. The more uniform the distribution of fouling, the more nearly will a limited number of sample tubes represent the condition of the entire tube bank. As an expedient in producing uniformity of fouling, the condenser tubes should be cleaned just prior to the test by the customary method in use in the plant. No rational formula may be stated that will give the correct number or location of test tubes which will adequately represent the average condition of the entire condenser. The exercise of experience and judgment must therefore be relied upon. Eighteen old tubes and six new tubes have been found by the authors to be adequate for large condensers.

Two general schemes of test-tube arrangement have been used. With the first arrangement, a "single group" located near the top of the tube bank is used. The group contains one or more

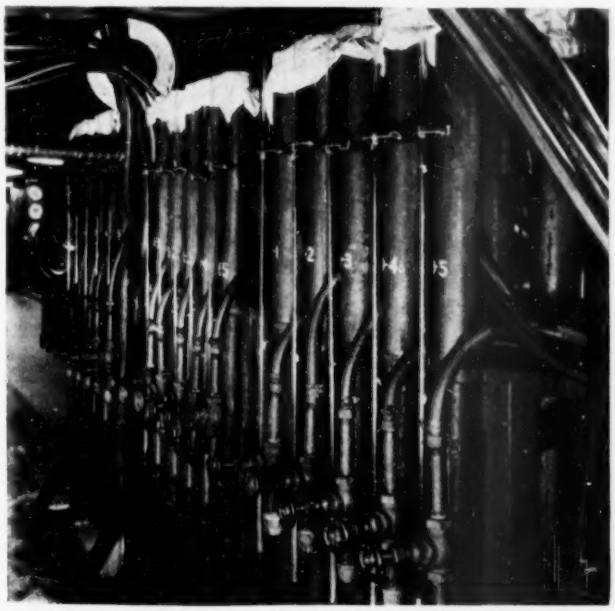

FIG. 2 NOZZLE STANDPIPES USED FOR REGULATING TEST-TUBE WATER FLOW

new tubes installed just prior to the test and several old tubes that have been removed from various representative parts of the tube bank and inserted in this group. The group may also contain an old tube that has not been moved. The location of the test group for this method is shown in Fig. 4 for condenser *A*. The second scheme, known as the "multiple group" method, consists in selecting several groups of tubes at various representative positions in the condenser's tube bank and testing them in place. Each group contains one new tube installed just before the test and one or more old tubes that have been in continuous service up to the time of the test. This method was used for the other five tests reported. The test on condenser *C* was made with two test tubes per group consisting of one new tube and one old tube. For the tests on condensers *A* (multiple group) and *B*, one new tube and three old tubes per group were used, and for *D* and *E* one additional new tube was included which was supplied with non-fouling fresh water (city water). The purpose of the fresh-water new tubes was merely to indicate any tendency of the standard new tube to foul during the period of test.

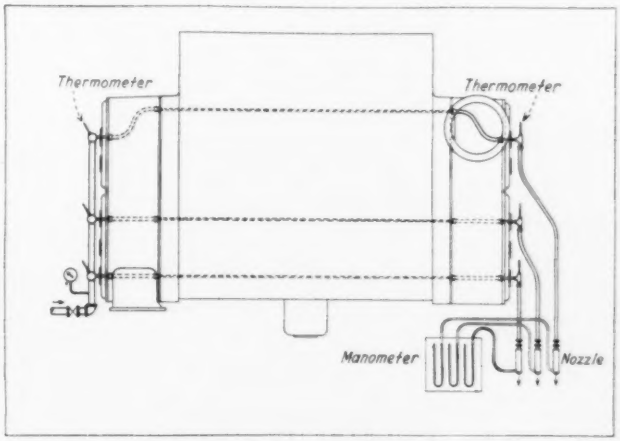

FIG. 3 ARRANGEMENT OF APPARATUS FOR TESTING TUBES IN CONDENSER

In tests *A* and *B*, the test groups were located symmetrically with respect to the vertical center line. Two of the groups were in the top peripheral row of tubes, while the others were taken fairly near the periphery. The thought at the time these two tests were run was that groups located too far into the tube bank would not yield reliable results because of the reduced tube loading and increased air richness in these parts. Nevertheless, it is probably a tenable assumption that these factors would affect both old and new tubes alike and so would not affect the reliability of the cleanliness factor as measured. In tests *C*, *D*, and *E*, the group locations were taken in more diverse positions without regard to symmetry of locations. For these three tests the average performance of the old test tubes naturally agreed more closely with the overall performance. No doubt certain other combinations would have proved equally adequate.

Test runs of 1 hr duration should be made at several condenser loads (Btu per hr) with each velocity at which it is possible to operate the circulating pumps. The test-tube temperatures should be read every $2^1/_2$ min in order to produce reliable averages. If test runs are longer than 1 hr, the frequency of reading these temperatures may be safely reduced. Test runs should be made in rapid succession with as little time allowed between them as possible in order to minimize the tendency of the new tubes to foul. If there is considerable time in between runs, as when tests must be discontinued overnight, the water supply to the new tubes should be shut off on the inlet end and allowed to drain in order to preserve their cleanliness as well as possible. The water flowing through the old tubes must, however, continue flowing at a velocity corresponding to the normal operating velocity in order that they remain representative of the entire condenser.

METHOD OF COMPUTATION

The heat transmittance of the old and new tubes is readily computed from the following equation:

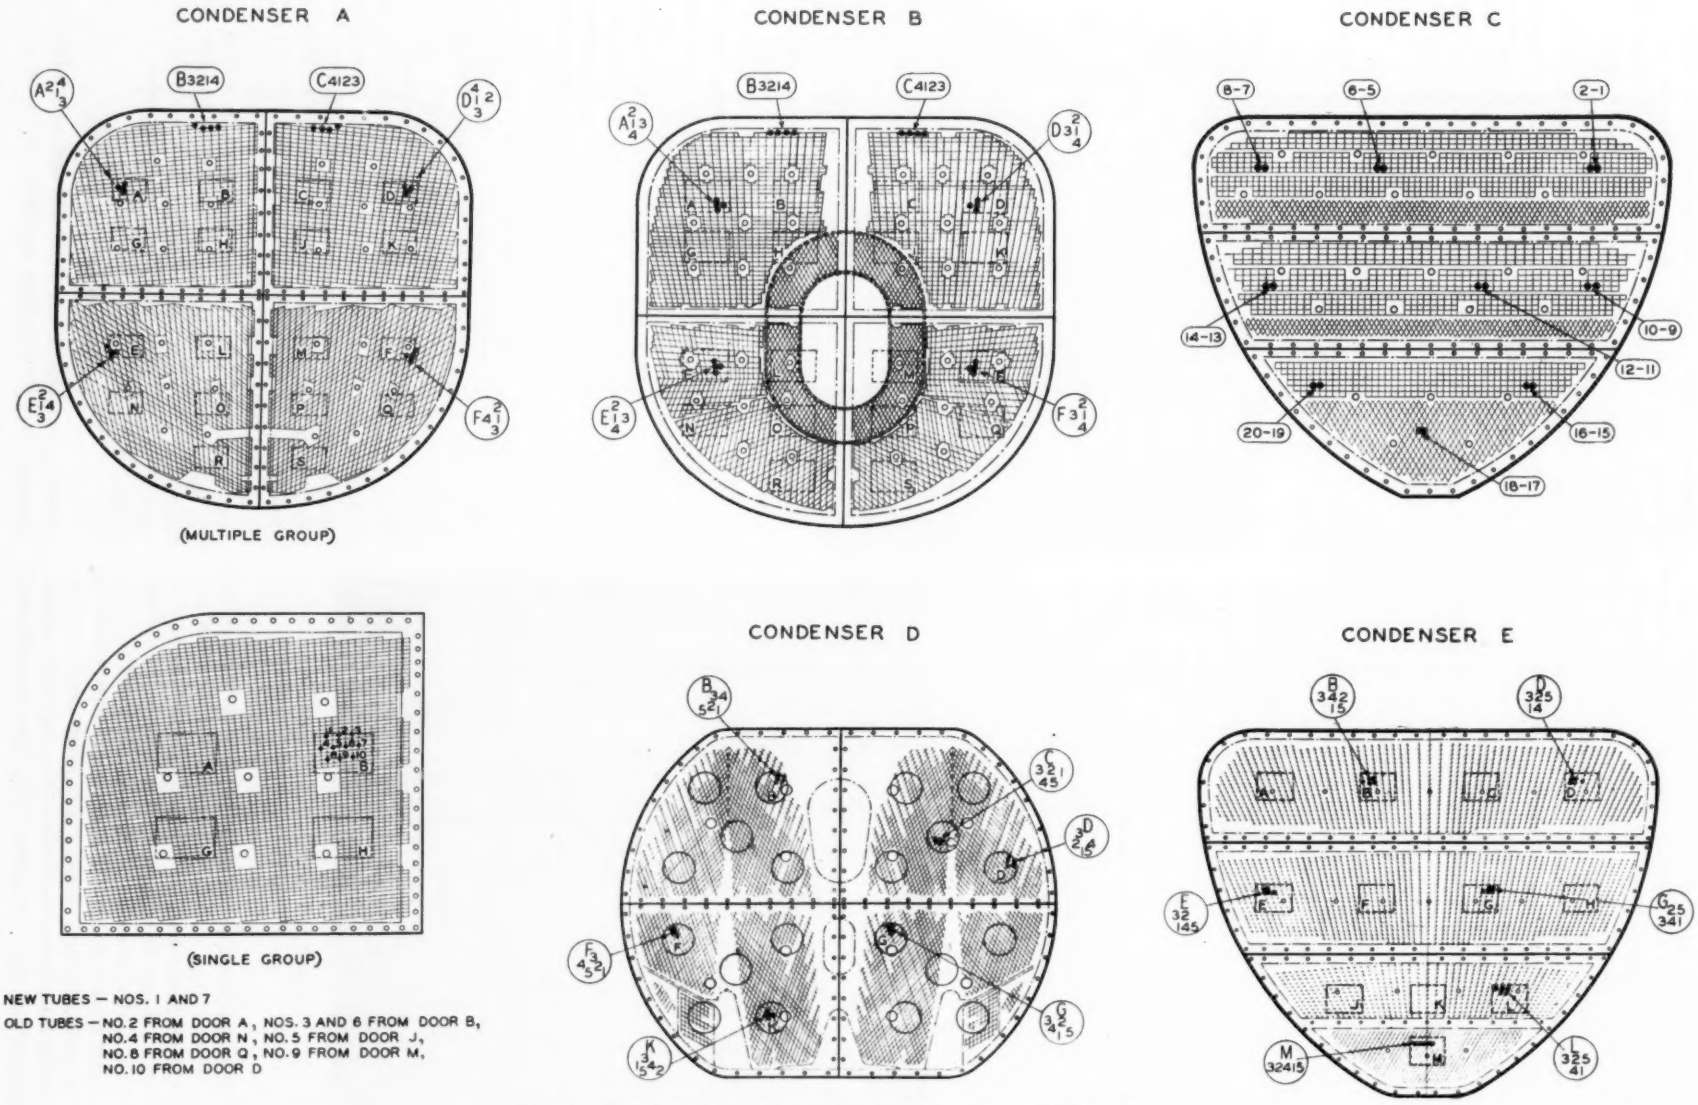

FIG. 4 TUBE-SHEET DIAGRAMS, SHOWING LOCATIONS OF TEST TUBES

$$U = \frac{WC}{S} \log_e \frac{T_a}{T_b} \quad \ldots\ldots\ldots\ldots\ldots\ldots [1]$$

where

U = heat transmittance, Btu per hr per sq ft per deg F log m.t.d.
W = water flow, lb per hr
C = specific heat of water
S = surface area per tube, sq ft
T_a = initial temperature difference, deg F
T_b = terminal difference, deg F

The equation given is based on the true, or logarithmic, mean temperature difference. For any water velocity, WC/S is a constant and may be used as such for all runs at a given velocity. For the group method, the cleanliness factor of each old tube is determined, as implied in the definition, by dividing the transmittance of each old tube in the group by that of the new. The average cleanliness factor for the entire condenser, at any water velocity, is properly found by first averaging the transmittances of all the old tubes and of all the new tubes, followed by computing the ratio of these two averages.

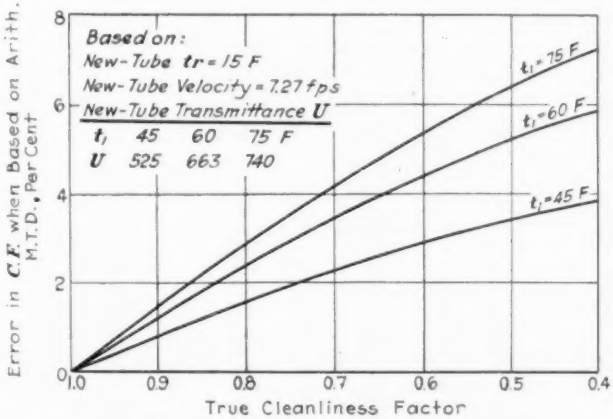

FIG. 5 EFFECT OF ARITHMETICAL MEAN TEMPERATURE DIFFERENCE ON ACCURACY OF CLEANLINESS FACTOR

In computing the transmittance either for the entire condenser or for individual tubes, the true, or logarithmic, mean temperature difference must be used if serious error is to be avoided. The effect of using the arithmetic mean temperature difference is to indicate a higher cleanliness factor than actually exists. The magnitude of this error is shown graphically in Fig. 5.

The performance of the test tubes should, in strict analysis, be referred to the saturated-vapor temperature corresponding to the absolute pressure adjacent to them. For those test tubes located well down into the tube bank, there is an appreciably lower vapor temperature due to the vapor pressure drop across the tube bank. Referring the performance of these test tubes to the vapor temperature at the condenser neck, results in giving a value of cleanliness factor which is higher than the true value, as can be seen from Fig. 6. For tests on condensers which have a low pressure drop, the error is small, and this simplification in the computation is therefore justifiable. For the test on condensers *A*, *B*, and *D*, the test-tube performance was computed using the vapor temperature at the top for all tubes, while for the test on condensers *C* and *E* the more accurate method was used. The vapor temperature for each group in the latter case was obtained by assuming a linear relation to exist between the number of tubes and the temperature drop from the top of the condenser to the air offtake.

The condenser circulating-water flows are generally known only approximately until after the test runs are concluded, unless preliminary checks have been made. Consequently it may be found after test that the estimated velocity at which the test tubes were operated did not exactly equal the average for the entire condenser. As explained in a later section, the cleanliness factor varies inversely as some power of the velocity. Using this relation, the actual cleanliness-factor measurement may be corrected, within limits, to the average velocity in the condenser which existed during the test.

The determination of the velocity exponent referred to in the foregoing may be accomplished as follows: Since,

$$CF = f(1/v^n) \quad \ldots\ldots\ldots\ldots\ldots\ldots [2]$$

where

CF = cleanliness factor
v = velocity in any units
n = velocity exponent for cleanliness factor,

it is found that

$$\frac{CF_1}{CF_2} = \left(\frac{v_2}{v_1}\right)^n \quad \ldots\ldots\ldots\ldots\ldots\ldots [3]$$

Hence

$$n = \log \frac{CF_1}{CF_2} / \log \frac{v_2}{v_1} \quad \ldots\ldots\ldots\ldots\ldots\ldots [4]$$

Since test runs are usually performed at two or more water velocities, it is a simple matter to solve for the exponent. As an alternative method, CF may be plotted versus velocity on log-log cross-section paper. The slope of the resulting straight line is the value of the exponent.

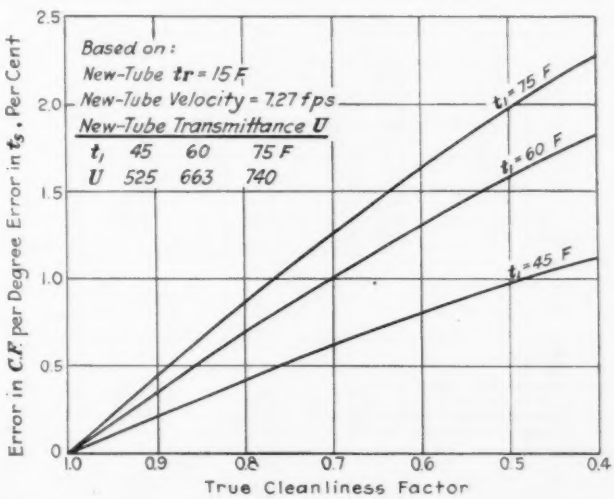

FIG. 6 EFFECT OF STEAM TEMPERATURE ON VALUE OF CLEANLINESS FACTOR

TEST DATA

Tables 1 to 6, inclusive, are introduced to show the results of typical cleanliness-factor tests. The size of the condensers in which these tests were made ranged from 85,000 sq ft to 101,000 sq ft of condensing surface. With the exception of condenser *C*, the test tubes were designated by letters and numbers, the letters referring to the groups and the numbers to the tubes in the group. In condenser *C*, using one new and one old tube per group, the test tubes were numbered consecutively. Fig. 4 may be used

conveniently in connection with the tables when studying the performance of the test tubes with reference to their location.

Application

The cleanliness-factor measurement probably will have its greatest field of application in connection with acceptance tests. In fact, the method described in this paper was developed with that particular purpose in mind, although it is equally applicable to other condenser tests.

The best method of illustrating the application of the cleanliness factor is to show how it is taken into account in the performance curves guaranteed by different condenser manufacturing companies during the last five years. These differ somewhat as to the expected reduction in the overall heat transmittance for cleanliness factors less than unity. Three typical sets of performance curves or cleanliness factors from 1.0 to 0.5 are shown, in Fig. 7. These curves are plotted for the variation in heat transmittance with load. A per cent scale is used for the ordinate because other conditions, such as water velocity and temperature, tube diameter, etc., influence the absolute value of the heat transmittance.

Fig. 7 (*a*) shows the simplest method of guaranteeing for cleanliness factors less than unity. As can be seen, the product of the cleanliness factor and the new-tube heat transmittance is the expected heat transmittance for the fouled conditions irrespective of the load.

Fig. 7 (*b*) shows another way of guaranteeing for cleanliness factors less than unity. Here the heat transmittance for a fouled condenser operating at high loads is the product of the cleanliness factor and the new-tube overall heat transmittance. These lines which are horizontal extend to the left until they intersect the unity cleanliness-factor curve. For lower loads the unity cleanliness-factor curve is followed. This method is similar to the first at high loads, but not at low loads.

The third method of guaranteeing is shown in Fig. 7 (*c*). These graphs show the shape of the performance curves affected by both cleanliness factor and temperature. Only at 75 deg circulating-water temperature is the performance for fouled conditions equal to the product of the new-tube overall heat transmittance and the cleanliness factor. For lower temperatures the overall performance is assumed to be reduced less than 1 minus the cleanliness factor; e.g., the performance at 55 deg

circulating water and a cleanliness factor of 0.5 is shown to be 60 per cent of the maximum value instead of 50 per cent. At light loads the relation of the curves for different cleanliness factors is a sort of mean of those in Figs. 7 (*a*) and 7 (*b*). The lower the water temperature, the higher the load at which the curves begin to drop off.

The loading undoubtedly has an effect upon the amount of reduction in overall heat transmittance due to a given degree of fouling, and possibly temperature has some effect also, but how much effect either will have for a particular condenser is difficult to predict. Six of the leading condenser manufacturers have adopted standard commercial factors,[4] and these include a "loading curve," which is the same as the unity cleanliness-factor curve in Fig. 7 (*a*). This curve is assumed by the condenser manufacturers to be applicable for all makes and to be independent of circulating-water temperature. With this assumption there is probably little justification for a different shaped loading curve for each cleanliness factor. Then, only the unity cleanliness-factor curve is necessary, and the new-tube overall heat transmittance multiplied by the cleanliness factor will give the value for the fouled-tube condition, or, vice versa,

[4] See article in *Power*, September, 1932, p. 133.

the fouled-tube overall heat transmittance divided by the cleanliness factor will give the value for the new tube condition.

Two convenient equations for computing the absolute pressure when guarantees are given on the heat-transmittance basis are as follows:

$$t_s = t_1 + \frac{Q}{WC\,(1 - e^{-x})} \quad \ldots\ldots\ldots\ldots\ldots [5]$$

$$t_s = t_1 + \frac{tr}{1 - e^{-x}} \quad \ldots\ldots\ldots\ldots\ldots [6]$$

$$x = \frac{US}{WC}$$

where

U = heat transmittance, Btu per hr per sq ft per deg F log m.t.d.
Q = heat transferred, Btu per hr
S = area of condensing surface, sq ft
W = quantity of circulating water, lb per hr
C = specific heat of the circulating water
e = Napierian base (2.718)
t_1 = inlet temperature of circulating water, deg F
tr = temperature rise of circulating water, deg F (this will be the same for the guarantee as for the test)
t_s = saturation temperature in deg F, from which the corresponding absolute pressure at the top of the condenser can be obtained from the steam tables.

New Tubes

New tubes received from the mills are not absolutely uniform as regards their performance, and this fact accounts for some of the apparent inconsistencies in the data obtained. Where several new tubes (one for each group) are used, however, their average has been found to be a reliable measure of new-tube performance for the conditions under which they were operating. Since the overall cleanliness factor is based on the average performance of the old and new test tubes, the accuracy of the measurement is not impaired by inequalities in the new tubes so long as a sufficient number is used to give a reliable average.

Tubes left over when a condenser is tubed are preferable ones to use for new tubes during the acceptance test. If these tubes are carefully stored, there will be little or no depreciation in their performance. The data reported in Table 7 give the results of tests made on condenser *E* to determine the comparison of newly drawn tubes with tubes that had been stored from the time the condenser was installed. The No. 2 tubes in all groups were the stock tubes used during the test reported in Table 6. The No. 3 tubes were from stock also, but appeared to be not as well taken care of as the No. 2 tubes. The No. 4 tubes were drawn less than a week prior to the test. As can be seen, the difference between the average for the newly drawn and the stock tubes is so small as to be negligible.

Tubes in the same condition as when received from the manufacturer are commercially new, and no attempt should be made to improve their performance prior to using them on a test. Some methods of cleaning are as likely to reduce the performance of a new tube as to increase it.

TABLE 8 VARIATION OF HEAT TRANSMITTANCE AND CLEANLINESS FACTOR WITH WATER VELOCITY

Cleanliness factor		0.68	0.68	0.69	0.70	0.72	—0.11[a]

[a] Since the cleanliness factor varies inversely as some power of the velocity, the exponent is negative.

Effect of Water Velocity

It will be noticed from the data reported that the cleanliness factor is different for different water velocities through the tubes. This is as it should be according to theory, and is explained by the fact that the heat transmittance varies with some power of the velocity and that the exponents for new tubes are higher than for old tubes. Since the cleanliness factor is the ratio of the heat transmittance of old to new tubes, it is readily seen that the cleanliness factor will vary with a power of the velocity equal to the exponent for the old tubes minus the exponent for the new tubes. This will give a negative exponent, which means that the cleanliness factor decreases with increasing velocity. Table 8 shows test-tube data obtained on condenser B for a wide range of water velocities, and the variation in cleanliness factor is shown graphically by the solid curve in Fig. 8. The dotted curves were plotted from calorimeter measurements on individual tubes from other condensers. The slopes of the cleanli-

ness-factor curves are not great, and therefore the velocity through the test tubes can differ slightly from the velocity for the entire condenser without seriously affecting the accuracy of the measurement. If tests are made at two or more velocities, the cleanliness factor can be corrected for velocity, as explained under "Methods of Computation."

Progressive Fouling

Some condensers maintain an approximately constant cleanliness factor for a day or two after cleaning, while others foul rapidly. If there is no apparent decrease in the cleanliness factor during the period of test, the cleanliness factors for all runs at the same speed can be averaged, thereby increasing the accuracy of this measurement. Where the cleanliness factor decreases rapidly, it is necessary to apply the measured value for each run. Fig. 9 shows the variation in the cleanliness factor with time for the test on condenser *E*. There was a sufficient number of runs in this particular case to draw a curve which fairs the points. Values taken from this curve were considered to be more nearly correct than the individual points.

When the runs are made in the descending order of loads, a slight decrease in the cleanliness factor may be due to reduced pressure drop, where the pressure at the top has been used for the

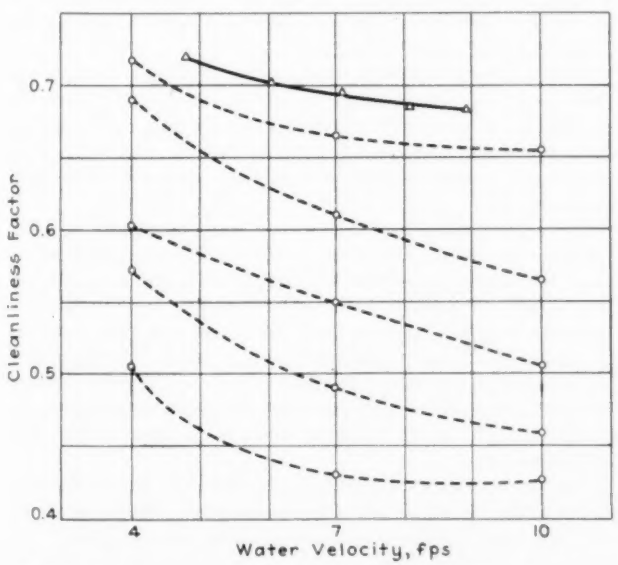

Fig. 8 Variation of the Cleanliness Factor With Velocity of Water Through the Tubes

test-tube computations, or it might be due to the inaccuracies inherent with light-load measurements. In this case those responsible for the test must decide whether an average value or the individual values are to be used.

With the method of operating test tubes described under "Test Procedure," it is assumed that the old tubes will foul at the same rate as the remainder of the condenser. The shorter the period over which it is necessary to apply this assumption, the more reliable the results will be. Every effort should be made, therefore, to start testing as soon as possible after the unit is returned to service, following the installation of test equipment, and to complete all runs as quickly as possible.

If the new tubes are operated only during the periods when tests are in progress, they are not likely to foul perceptibly before all runs are completed. Repeating the first run at the end will provide a definite check upon this condition.

Chlorination

The sterilization of circulating water with chlorine is often assumed to be so effective in eliminating fouling that the condenser maintains its new-tube performance. If this were true, it would be unnecessary to include the cleanliness-factor measurement in tests on chlorinated condensers. Experiments with chlorine on isolated test tubes in condensers *D* and *E*, however, indicate that the cleanliness factor of a chlorinated condenser is

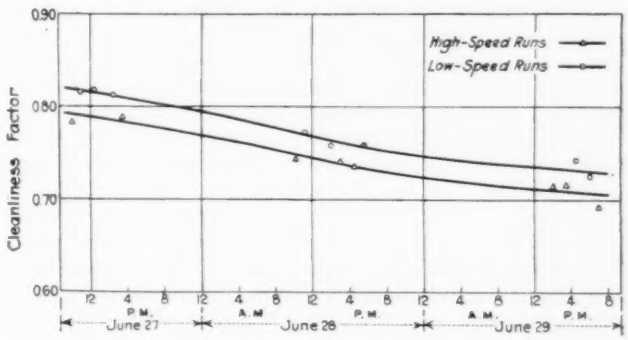

Fig. 9 Progressive Fouling During Test on Condenser *E*

probably between 0.90 and 0.95. Even these values may be optimistic, because the rate of chlorine injection during the experiments was higher than would be economically justifiable. Both old and new tubes were tested for a sufficient period for the performance of each to become constant. The tubes gave different cleanliness factors with the same dosage and frequency of application. Few of the old tubes attained as high cleanliness factors as those to which the new tubes decreased.

Conclusions

The cleanliness-factor measurement has proved its practicability and has eliminated the uncertainty of fouling in appraising the performance of the condensers on which it was applied. By eliminating the necessity for unusual methods of cleaning prior to the acceptance tests, the overall test performance was indicative of normal operation.

Those who have been dubious of, or hostile to, the test-in-place method have objected on the ground that tubes tested in the center and bottom of a condenser will give erroneous values for their cleanliness factor. In practise this has not been found to be the case. The fact that there is a greater percentage of air in the steam that flows over these tubes apparently does not affect the ratio of the heat transmittance of a fouled tube and its adjacent new tube, even though the heat transmittance of both tubes is greatly reduced. It is preferable, therefore, to test the tubes in place rather than moving them to the top of the condenser or to a calorimeter.

Acknowledgments

Mr. J. N. Landis, mechanical engineer of the Brooklyn Edison Company, Inc., was responsible for obtaining the condenser guarantee based on a cleanliness factor to be determined from isolated tube measurements made at the time of the acceptance test. This purchasing procedure led to the development of the method of test described.

The authors also wish to acknowledge the cooperation of the following manufacturers and their staffs in the tests described in this paper: Westinghouse Elec. & Mfg. Co.; Worthington Pump and Machinery Corporation; Ingersoll-Rand Company.

Discussion

D. W. R. Morgan.[5] This collection of data points the way to a measurement of condenser performance and is valuable in that it may be used as an instrument by the designer to further improvements in condenser design.

The authors state that it is just as important to determine the cleanliness factor as it is to determine circulating-water temperature and water velocity through the tube. The writer thoroughly agrees with the conclusion, but in his opinion the thermometers generally used and the means for determining the temperature rise are inadequate, particularly for determining the performance of single-pass condensers where large quantities of water are circulated and where the temperature rise is relatively small.

One may infer that it is the intention of the Power Test Code Committee to incorporate in the condenser test code the means of testing described by the authors. The writer agrees that similar data should be included in the test code; he does not think the method proposed is sufficiently accurate for the purpose. For example, certain tubes have been selected as representing the performance throughout the condenser. This assumption may or may not hold for all installations, and as a matter of fact, serious consideration should be given to the use of weighted averages of performance throughout the condenser rather than the designation of a relatively few tubes from which the performance is determined.

The selection of the tubes for test introduces a real problem, as the performance of the condenser is not only dependent upon the design of the condenser itself, but may be adversely affected by the distribution of steam issuing from the turbine exhaust. There are records of condenser performance from one station in the New York territory indicating that the performance of the condenser installed in 1914 was superior to that of the condenser installed in 1925. An examination of the data clearly indicates that the good performance of the earlier designed condenser can be attributed entirely to the uniform distribution of steam from the turbine exhaust throughout the tube length of the condenser, whereas in the more recent design the tube length was greatly in excess of the turbine exhaust opening, resulting in a non-uniform distribution of steam, carrying with it a relatively poor condenser performance. Progress in condenser design will result only through thorough study and investigation and the introduction of such elements as are necessary to secure uniform distribution of steam to the tube nest of the condenser.

The writer agrees with the authors that it is absurd to consider the removal of tubes from the condenser for test purposes for the reasons set forth by the authors. On the other hand, the choice of tubes for test must be such that the steam distribution be uniform to insure loading of the tube for its entire length. The authors state that tubes located near the top of the condenser have a greater effect on performance than those near the air offtake. There are many tests on record which prove conclusively that the tubes in the top row are not necessarily the most effective. This depends largely on the distribution of steam from the turbine exhaust, and on the other hand, by the design of the condenser itself. Further, tubes near the offtake perform just as important a function as the tubes near the outer periphery, and this should be recognized in determining the performance of the entire tube nest.

The authors describe a distributing manifold arrangement at the inlet end of the condenser. It would be well for the authors to keep in mind the possibility of error due to an accumulation of air in the manifold. It is stated that the water for the test tubes is taken from the same source as the main condenser. The authors show that the water is taken from the inlet-water box. While it may be taken from the same source, if it passes through the house service pump, there is every possibility that it will contain less debris than if introduced through the main circulating pump.

The authors suggest that in order to produce uniformity of fouling, the condenser tubes should be cleaned prior to the test. We have several instances in the testing of large condensers where the heat-transfer rates were reduced following cleaning such as proposed by the authors. In other words, the deposit on the tubes originally was non-uniform, and when followed by cleaning the tubes, it resulted in a more uniform distribution of the deposit on the tube, which actually reduced the effectiveness of the tube. Therefore this suggestion depends largely upon the nature of the debris and upon the nature of the deposit upon the tube plate itself.

The single-group arrangement would lead to an erroneous idea of the overall results, as readings would not represent the general averages.

The authors describe a method for determining the fouling of tubes through which city water is circulated. They, however, fail to include the amount of fouling that occurred in the tubes through which city water was circulated. No doubt a certain amount of fouling occurred, which demonstrates that it is impractical to use this method for comparison and determining the rapidity and amount of fouling.

What one really desires to obtain on condenser tests is the actual result, and the writer does not regard the data presented as sufficient to permit of such definite conclusions, as reached by the authors, and neither does he agree that the effect of fouling is the same on tubes that are required for cooling non-condensible vapors.

The authors suggest that the tests be made rapidly so as to minimize the effect of the fouling of the new tubes. This statement in itself suggests that the method proposed is unsatisfactory. It is also suggested that on tests of long duration the new tubes be plugged to preserve their cleanliness. This arrangement is unsatisfactory, as it produces the equivalent of a baking and cracking process used so successfully in removing scale and debris from evaporator tubes, and therefore, depending upon the nature of the deposit, would in some instances seriously affect the overall results.

The assumption as to pressure drop from the top of the condenser to the air offtake would depend largely on the design of the condenser and whether or not external air coolers were used.

Authors' Closure

Mr. Morgan's contentions regarding the accuracy of this method seem to be based in general on the fact that little is known about what occurs inside the steam space of condensers. The authors do not consider that this knowledge is necessary. The test tubes are not selected for the purpose of determining the average heat transmittance of the condenser, but rather the degree of fouling, which varies much less than the heat transmittance and is affected very little, if any, by steam distribution. The overall heat transmittance must still be determined the same as usual. The true accuracy of any test measurement is very difficult of proof. However, the authors hope to present in the future the results of an investigation to be conducted for the specific purpose of definitely determining the accuracy of the cleanliness-factor measurement.

Mr. Morgan's statement that in several instances the heat transmittance of condensers was known to be reduced by cleaning prior to the test seems to illustrate quite forcefully the necessity for a cleanliness-factor measurement so that such unusual conditions can be evaluated. As stated in the paper, the only pur-

[5] Manager, Condenser and Pump Division, Westinghouse Elec. & Mfg. Co. South Philadelphia, Pa. Assoc-Mem. A.S.M.E.

pose in cleaning just prior to the test is to make the fouling of all tubes as uniform as possible, since a comparison of test and guarantee performances can be made as well at a cleanliness factor of 0.50 as 0.90. Other relevant points raised by Mr. Morgan are fully covered in the paper.

Mr. J. F. Grace[6] has asked the cost of making the cleanliness-factor measurement. This is hard to answer because of the difference in test facilities and method of computing the cost of tests at different plants. In general, however, the labor cost of the condenser test is doubled when the cleanliness-factor measurement is included, and $800 to $1000 is required for additional equipment when the test is performed for the first time.

If this method should come into more general use, the condenser manufacturers would probably maintain the special equipment in order to have it available for acceptance tests in those plants where the cost of the equipment would make the method prohibitive.

RP-55-4

The Pressure of Saturated Water Vapor in the Range 100 C to 374 C[1]

By N. S. OSBORNE,[2] H. F. STIMSON,[2] E. F. FIOCK,[2] and D. C. GINNINGS,[3] WASHINGTON, D. C.

The method and apparatus employed, and the measurements made in this determination of the vapor pressure of water are described, and the results obtained are given and formulated.

The method used was the "static method" in which the pressure is determined at the stationary boundary between the liquid and vapor phase in equilibrium at a constant temperature in a closed container.

The container for the water sample was a calorimeter specially built for high-pressure work. Pressures were measured by a precision piston gage which balances the pressure by the gravitational force on a piston loaded with weights. Temperatures were measured by platinum-resistance thermometers supplemented by thermoelements.

A total of 394 measurements were made at 38 temperatures so distributed as to facilitate formulation of the pressure-temperature relation.

The formulation was made by using an empirical equation which was fitted to the results in two temperature ranges. Values of pressure and its derivative with respect to temperature are tabulated from this formulation in standard atmospheres, centibars, and kilograms per square centimeter at each degree centigrade, and in pounds per square inch at each degree fahrenheit. This provides a mutually consistent group of vapor-pressure tables in convenient form for practical working tables of fundamental steam data.

It is estimated that the results are reliable to 3 parts in 10,000.

I—INTRODUCTION

THE relation between the temperature and the pressure of saturated water vapor is of prime importance in establishing the thermodynamic behavior of steam. This relation, commonly called the vapor-pressure relation, is a characteristic property which can be observed directly. Moreover, its derivative is an essential factor in correlating other important thermodynamic properties. It is evident that adequate knowledge of this property is indispensable to the success of any systematic effort to determine and formulate the thermal properties of steam.

The vapor-pressure measurements to be described here were made as a coordinate part of the larger and more formidable project of calorimetric measurement of the enthalpy (heat content) of saturated water and steam. Since pressure and temperature of saturated vapor are definitely related, measurements of other thermal properties may be referred to either temperature or pressure as an independent variable, depending on which is the more expedient. This characteristic was utilized in planning a new high-pressure calorimetric apparatus[4] for surveying the behavior of saturated steam. As a refinement in technique, provision was made for observing both the temperature and the pressure of a water sample in the calorimeter. The arrangements for control and measurement of temperature, and for transmission of pressure to the measuring gage, were perfected to a degree which permits the rapid and reliable measurement of saturation pressure in the range from 100 C to 374 C.

Measurements within this range have already been made in several laboratories in accordance with definitely specified, recognized standards, permitting reduction of the results to a common basis. The results of these independent determinations, differing considerably in method and technique, have been regarded as in virtual agreement for technical purposes. Nevertheless, close scrutiny disclosed discrepancies that seemed unnecessarily large, particularly in the derivative on which reliance must be placed for making thermodynamic correlations of other experimental data.

The equipment available in this laboratory provided a favorable opportunity for making vapor-pressure measurements. These were undertaken prior to the calorimetric measurements with the object of further verifying the numerical values for this property.

To provide for trustworthy correlation of thermodynamic properties, it is necessary not only that the observations of the corresponding pressures and temperatures be adequate in number, distribution, and precision, but also that a formulation be used which yields reliable values of the derivative. This latter requirement has been met by the successful application of a type of empirical equation that conforms with remarkable fidelity to the observed behavior of saturated steam.

II—METHOD AND APPARATUS

1—General Description

In the calorimetric equipment used in making the vapor-pressure measurements, provision is made for observing temperature, pressure, mass of water sample, and the energy added. The arrangements provided for controlling the state of the fluid in the calorimetric experiments are also especially appropriate for the determination of vapor pressure. In this report, which concerns only the latter, the description is intended to record those features which are essential to the vapor-pressure measurements.

A schematic diagram of the vapor-pressure measuring equipment is shown in Fig. 1. The metal calorimeter shell contains besides the water sample an electric heater and a system of radial silver plates for diffusing heat. This shell is suspended within a thermally controlled enclosure or envelope, which shields it against heat exchange with the surroundings.

The pressure in the calorimeter is transmitted directly through a tube from the bottom of the calorimeter shell to a cell with a thin, elastic metal diaphragm which readily transmits pressure, yet prevents escape of the water sample. The pressure in the calorimeter is thus transmitted through this sensitive diaphragm to a column of water, and through this column to a balancing artificial atmosphere of air. The meniscus between the water

and air is visible in a glass capillary, and serves to indicate balance between the air pressure and the pressure in the calorimeter. The pressure of the artificial atmosphere, which is subject to very delicate manual control, is transmitted to the measuring piston gage through an oil column. The air-oil meniscus is visible in another glass capillary, and is used as an indicator to show when the piston is properly loaded.

The temperature of the water sample, which is observed after the load on the piston has been properly adjusted, is obtained by the combined use of platinum-resistance thermometers and thermoelements. Resistance thermometers located in a reference block of thick silver, yield the temperature of the block according to the International Temperature Scale. The thermoelements

with principal junctions distributed on the shell and reference junctions located on the reference block, indicate the small differences which exist between the calorimeter and the reference temperature. The thermoelements can be used in series to indicate average temperatures, or individually to indicate local temperatures. A diagrammatic scale drawing of the assembled apparatus is shown in Fig. 2. The principal parts will be described in detail forthwith.

2—THE CALORIMETER SHELL

The calorimeter shell shown at *C* in Fig. 2 provides a receptacle for the sample of water so that its thermal behavior may be observed. It has the shape of a cylinder with hemispherical ends and, as assembled with the various accessory parts in place, will hold approximately 320 cu cm. The material is a special alloy steel containing about 19 per cent chromium, 7.5 per cent nickel, 4.5 per cent tungsten, 1.3 per cent silicon, 0.5 per cent manganese, and 0.46 per cent carbon. This material was chosen because of its resistance to creep and to attack by water at temperatures up to 400 C. The shell was machined from a solid bar and was made in two similar parts held together on a thin silver gasket by the tension developed in the right- and left-threaded band which is screwed on by powerful wrenches engaging the machined lugs. This annular joint was formed by machining one member to a plane surface and the other to a blunt-angled edge, giving a contact with the silver gasket of about a half-millimeter width All parts were accurately machined and the surfaces well polished.

The shell, having a thickness of 0.125 in. (3.2 mm), was designed to stand steam pressures up to the critical without permanent deformation. Actually in hydraulic proof tests, it showed no permanent stretch for an internal pressure of 4500 lb per sq in. After carrying a charge of water at 350 C, the inner surface showed on examination no sign of attack by the water other than the formation of a very thin film of light-straw color similar to that formed on the outside where in contact with air.

3—THE CALORIMETER HEATER

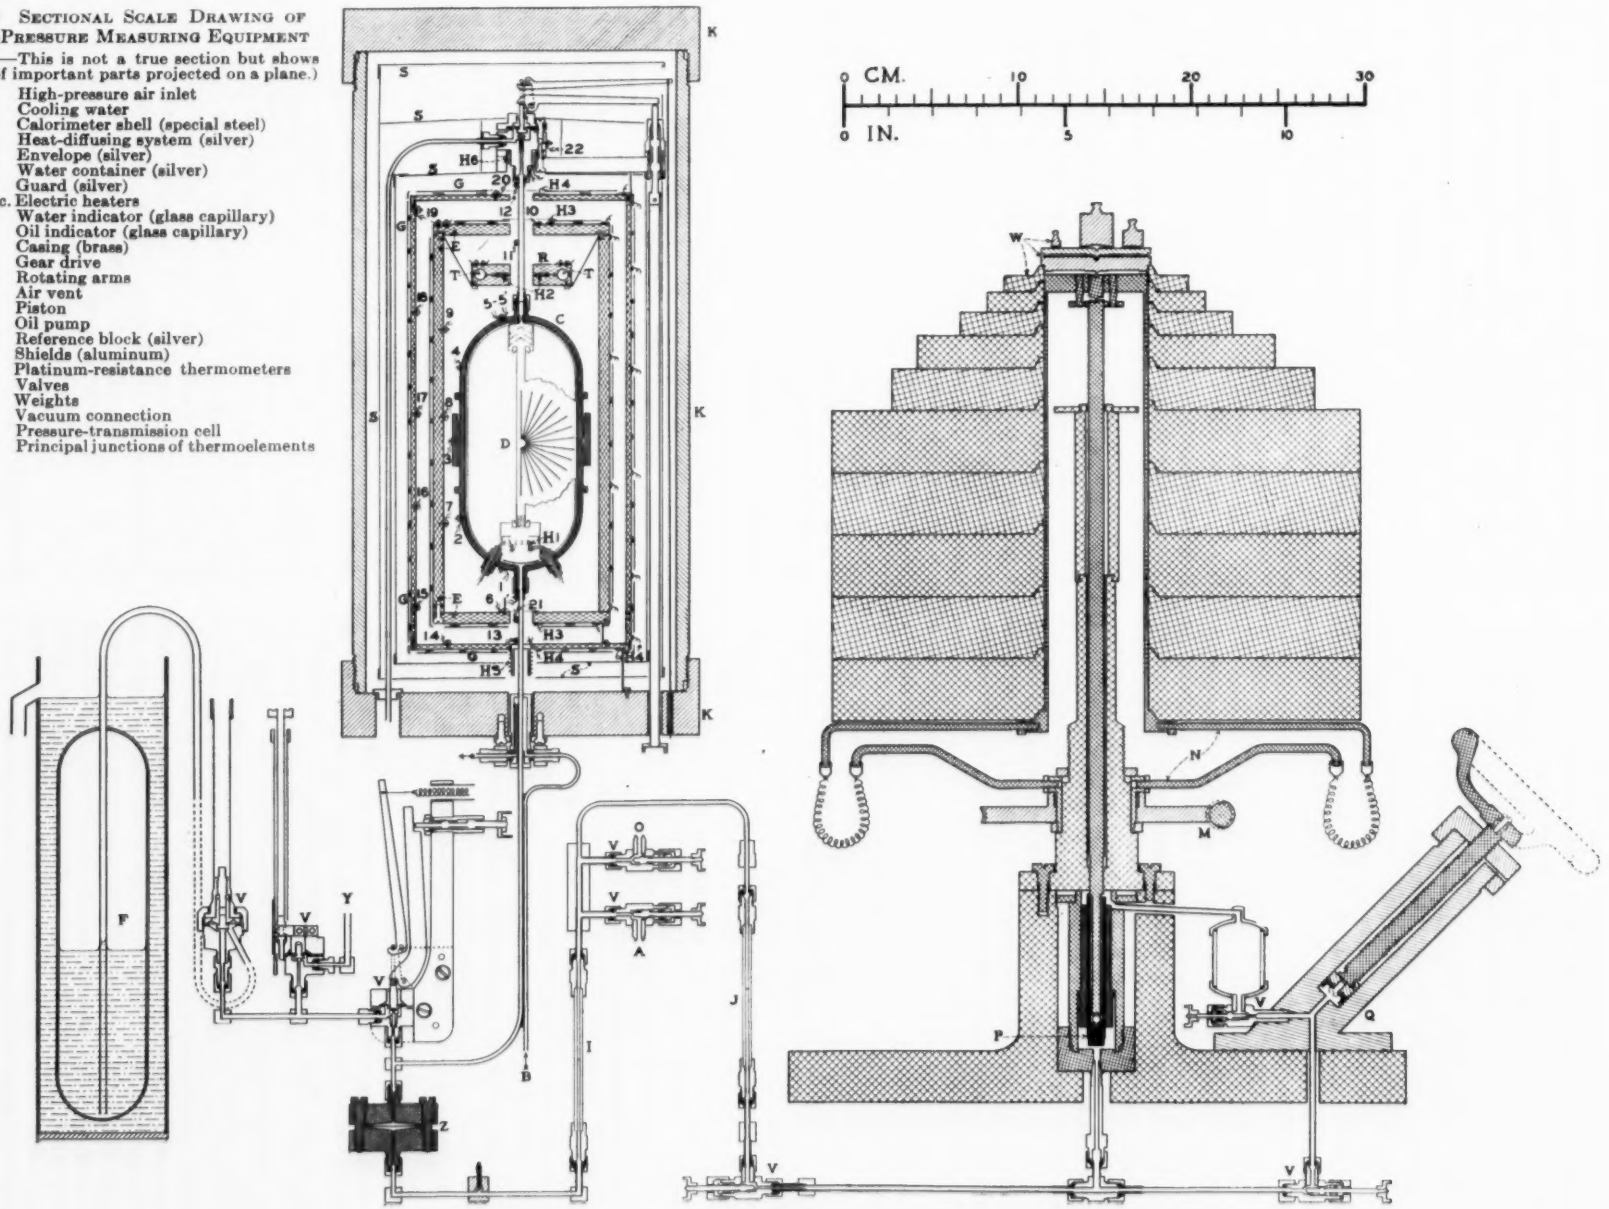
The electric heater in the calorimeter shell, shown at *H1*, Fig. 2, is an insulated resistor encased in a metal tubular coil sealed to the shell. It consists of about 10 ohms of calido wire, 0.2 mm in diameter, with gold leads. This resistor was wound in helical form, 0.6 mm outside diameter, and embedded in magnesia for insulation. It was sheathed in a platinum tube drawn down tightly on the magnesia to an outside diameter of about 2 mm. This sheathed resistor was then bent into the form of a helical coil 12 mm in outside diameter, the resistor occupying about two turns. Each projecting end of this heater was put through a threaded plug of silver-palladium alloy and sealed by soldering with gold. To complete the seal, the shoulders of these plugs were drawn down tightly on thin silver gaskets by threaded nuts outside the shell.

The design of this heater was chosen with regard to influence on the calorimetric performance of the instrument. The heater surface has been made small with three objects in view, namely, to avoid unnecessary heat capacity, to permit operation with small amounts of liquid, and to avoid excessive accumulation of energy as superheat in the liquid. The characteristics of the heater have relatively little to do with the technique of pressure measurements, since it is used only for bringing the water sample to a desired temperature.

4—THE HEAT DIFFUSER

For promoting temperature equalization in the calorimeter shell, a system of heat-conducting plates is provided. This heat-diffusing system consists of 30 flat plates of silver 0.5 mm thick, shaped to conform to the vertical profile of the shell and held radially in two slotted hubs so as to penetrate and interconnect the space within the shell with a good heat conductor. The chief function of this arrangement is to hasten the equalization of temperature after a period of change. This feature is important in both the calorimetric and the pressure measurements, and to some extent compensates for the lack of positive circulation by mechanical means.

5—THE ENVELOPE



The principal purpose of the envelope that surrounds the calorimeter shell is to provide protection from fortuitous exchanges of heat. This feature, which is vital to the energy accounting in calorimetry, contributes to the suitability of the instrument for pressure measurements by favoring the attainment of thermal equilibrium of the water sample and its container.

This protecting envelope is a double-walled enclosure formed of two coaxial cylindrical silver shells with flat ends, the inner one 6.3 mm thick and the outer one 3.2 mm thick, which will be designated as "envelope" and "guard," respectively. Electric heating elements are distributed over the outer surfaces of these shells. Subdivision of these heaters provides for meeting various local thermal requirements. The heater on the envelope is used only when its temperature is being raised. The guard may also be heated at a controlled rate, or its temperature may be main-

tained automatically at any desired value by a sensitive thermoregulator using a platinum-resistance thermometer.

At a steady temperature the guard heater supplies the heat loss to the outside while the envelope temperature remains fixed. Such conditions are favorable for the establishment and maintenance of temperature equality of the calorimeter and its contents. In the space outside the guard two thin aluminum shields are placed to impede the loss of heat by radiation and convection. These light shields, 0.05 mm thick, furnish effective thermal insulation and prevent excessive heat loss without introducing any considerable thermal lag. The whole is enclosed in a heavy brass casing which serves not only as a cover but also as protection in case of an explosive failure.

6—Connections to the Calorimeter Shell

The calorimeter shell is held in place by two tubes of silver-palladium alloy. The one at the top bears the weight of the shell and the one at the bottom centers it. Besides furnishing firm, thermally resistant support for the shell, these tubes serve also for the transfer of fluid to or from the calorimeter. The upper tube is intended for a vapor outlet to be used in calorimetric measurements of heat of vaporization, and was temporarily closed during the pressure measurements by a disk in the union at the top of the shell. This suspension tube reaches from the body of the vapor valve, which is carried on a light but firm support from the guard shell.

The lower tube is used as a connection to transfer liquid to or from the calorimeter, and also to transmit pressure from within to the auxiliary measuring equipment outside. A cylindrical brass cell for cooling water surrounds this tube where it passes through the outer brass casing. Where the tube passes through the outer silver guard shell it bears an electric heater mounted on a silver support attached to the tube. There is a free length of about 2.6 cm between this heater and the union at the shell. The purpose of the heater is to control the thermal gradient in this section of the tube, as indicated by thermoelements installed for that purpose. Similarly, the gradients on the upper tube are controlled by a heater on the vapor-valve body.

The lower tube is always filled with liquid while observing saturation behavior in the calorimeter. From the union just below the cooling cell at the bottom, connection is made through a copper-nickel tube to the liquid valve and the pressure-transmission cell. Beyond the liquid valve the line extends to a union by which the water receiver with its valve is connected. A side connection leads through a valve to a vacuum pump to permit evacuation of the calorimeter and its connecting lines.

7—Pressure Connections and Auxiliary Indicators

Pressure is transmitted from the free surface of the liquid in the calorimeter through a continuous column of liquid water to the elastic diaphragm of the pressure-transmission cell to be described forthwith. The purpose of this cell is to allow the pressure in the calorimeter system to be communicated to the pressure-measuring gage, while at the same time interposing a barrier to the escape of water from the system through the gage line. A limited amount of inward and outward movement is allowed the water column by the necessary flexibility of the transmitting device, but this movement is restricted to the small volume displacement of 0.04 cu cm required for observation. In this transmitting cell, a circular diaphragm of thin silver about 3 cm in diameter is held under slight tension between the two parts of the cell which clamp the diaphragm tightly near the edge. Small pressure changes suffice to move the diaphragm back and forth across the space between the two parts. The inner cell walls are shaped to conform approximately to the figure of the distended diaphragm. The delicate diaphragm must encounter support from the cell walls to avoid deformation beyond its elastic limit when the pressures are far out of balance.

The cell is made of two disks of stainless steel, each about 5 cm in diameter and about 1.4 cm thick, provided with 12 screws to draw them tightly together on the silver diaphragm. The two parts have nipples with unions for making connections with the lines as shown. The apertures to the inner cell are made only 0.035 cm in diameter to avoid too large an unsupported area of the thin silver diaphragm. This diaphragm is a vital part of the device, and its characteristics determine the limit of sensitivity of the transmitting cell. It is of rolled sheet silver about 0.06 mm thick. The diaphragm and cell were put together at a temperature of about 150 C in order to produce sufficient tension, when cooled, to flatten out the slight unevenness of the sheet which otherwise would interfere with the freedom of motion between the cell walls. This procedure left enough flexibility to give a satisfactory sensitivity to pressure change.

On the measuring or gage side of the diaphragm a continuous column of liquid water extends and transmits pressure to air at the meniscus boundary in a glass capillary indicator. The volume of this water column is small. The meniscus is a reliable indicator of the position of the diaphragm and is used as a null device to tell when the pressures on the two sides are balanced to bring the diaphragm to a chosen zero position, near the neutral. The air column extends to the end of an oil column in a second glass capillary indicator, whence the pressure is transmitted through the oil directly to the piston of the measuring gage. Sensitive needle valves permit fine adjustment of the pressure in the air line to balance the pressure in the calorimeter. When these pressures are balanced and the piston gage is also balanced by weights, the vapor pressure in the calorimeter may be found from the pressure measured at the piston by taking into account the fluid columns between the piston and the free surface in the calorimeter and whatever pressure differences the diaphragm may support.

The fluid columns to be accounted for are the oil, air, and water columns. The oil-column correction is constant and is easily measured. The air-column correction depends on the pressure and is almost negligible. The correction for the water column is somewhat more complicated owing to the variation of the position of each end. The position of the meniscus in the glass capillary is directly observed and easily corrected for in each measurement. From a reference point on this capillary to a point near the calorimeter there is a constant pressure correction which is computed from the difference in height. From this latter point to the free surface the pressure correction varies both with the filling in the calorimeter and with its temperature, and was computed for the conditions of each measurement.

The correction for pressure difference supported by the diaphragm is small, but arises because the chosen zero position is not necessarily the neutral or unstrained position. It was determined by making a vapor-pressure measurement near 100 C with the air column open to the atmosphere instead of being connected to the piston gage. Since the vapor pressure of water is one standard atmosphere at 100 C by definition of the International Temperature Scale, and its temperature variation there is well known, the difference between the computed pressure at the open end and the observed barometric pressure gives the desired diaphragm zero correction. This correction was determined occasionally during the progress of measurement. This method of calibration connects the scale of pressure with the standard unit at the 1-atm fixed point and in effect includes that point in the range of the observations.

A preliminary calibration of the assembled diaphragm with its capillary indicator was made at atmospheric pressure to determine its sensitivity to pressure differences. This showed the

diaphragm displacement to be nearly proportional to the pressure difference over a considerable portion of the middle range. Within this linear range a pressure difference of 0.001 atm was found to correspond to about 0.6 mm on the capillary indicator. This sensitivity calibration is merely an index of the limit of precision to be expected when the diaphragm is set to a chosen zero position and does not enter into the reduction of the observations.

8—The Pressure Gage

The pressure-measuring gage used in these determinations was one of a group of piston gages whose construction and calibration have been described previously.[5] These gages were designed and built at this Bureau to meet a need for precision pressure-measuring instruments in determining thermodynamic properties of fluids. They have been studied with great care to determine their reliability as standard instruments.

This type of gage employs a loaded rotating piston which is supported in a vertically mounted, closely fitting cylinder by oil under the pressure to be measured. A balancing load of weights on the piston is borne axially above it on a carrier which engages the piston. A horizontal couple applied to the carrier by motor-driven arms produces a slow rotation which is transmitted through it to the piston. Thus the entire load consisting of piston, carrier, and weights is rotated without introducing any appreciable vertical component of driving force. The rotation of the piston maintains a lubricating film of oil between it and the closely fitting cylinder. This provides greater freedom for vertical motion of the loaded piston in case of unbalance, by preventing direct contact between the piston and cylinder.

The gage chosen for the present work and shown in Fig. 2 has a piston area of about 1 sq cm. It was designed for the range from about 3 to 100 atm pressure. As it was desired to cover the range of steam pressures from 1 atm to 218 atm, it was necessary to make some modification to provide for this extension of the range. This was done by substituting for the original weight carrier two special ones, the first very light to permit a small load on the piston, and the second a larger carrier to accommodate the extra weights for the high pressures. This gage is provided with a set of weights in units ranging from 20 kg to 0.1 kg, specially built to stack on the carrier with proper stability. Standard laboratory weights were used for the range 100 grams to 1 gram. The weights were calibrated at the time of their use in these measurements, and corrections were applied where significant.

The effective piston area had been determined in 1928 by a series of calibrations using a multiple-column mercury manometer as the fundamental standard. Direct comparisons with this standard manometer were made at a pressure of 15 atm. In addition to these, comparisons were made at pressures up to 75 atm, using another gage to step up from the 15-atm limit of the manometer to the higher pressures. These calibrations all gave a value of 0.9961 sq cm at 20 C for the effective piston area at that time.

During the course of the present pressure measurements a comparison was made with two other similar standard piston gages, and with the vapor pressure of a standard sample of carbon dioxide as a precaution against any significant change in the effective piston area which might have occurred since its 1928 calibration. The results of these comparisons gave the same value of 0.9961 sq cm.

9—The Thermometric Installation

The thermometric installation used in the control and measurement of the temperature of the water sample includes platinum-resistance thermometers and thermoelements. Thermoelements alone suffice for the survey of temperature distribution. For determining the actual temperature of the water sample, certain of the thermoelements are used to supplement the indications of the platinum-resistance thermometers.

(*a*) *The Reference Block.* A silver reference block located in the space above the calorimeter shell serves as an isothermal union between the resistance thermometers and the reference junctions of the thermoelements. Thus the thermometers measure the temperature of the reference junctions, while the thermoelements indicate the small additional differences between this reference temperature and that of chosen points where the principal junctions are located.

The reference block is made of two similar rectangular pieces of pure silver, each 5.6 cm × 3.8 cm × 0.63 cm, held together flatwise by screws. It is suspended horizontally from the top of the envelope by four slender straps of stainless steel. A pair of electric heaters and two resistance thermometers fit in receptacles machined across the horizontal mid-section. A hole 12.7 mm in diameter in the vertical axis accommodates the small tube which suspends the calorimeter shell. This well-conducting block of silver is designed to keep the reference junctions at the same temperature as the resistance thermometers.

(*b*) *The Thermoelements.* The temperature-measuring system includes thermoelements with 38 principal junctions. These thermoelements are connected in groups to economize leads and

to permit combinations for surveying temperature distribution, for indicating average temperature differences of surfaces, and for determining the temperature of the water sample. These combinations are completed at the option of the observer by the use of specially built distributing switches with all-copper circuits.

The thermoelements which are used to indicate the temperature of the water are a group of five with principal junctions located on the calorimeter shell at points selected as representative. These chosen points lie in one vertical element of the shell. The five junctions, designated as 1, 2, 3, 4, and 5, are spaced as shown in Fig. 2. The indications of these five junctions may be observed individually, giving the temperature difference between any zone and the reference block, or all five may be observed in series to give a composite of the temperatures of the five zones. The single junctions may also be observed differentially against junction No. 5 at the top of the calorimeter to show directly the vertical distribution of temperature on the shell. The ability to make such a temperature survey enables the observer to follow the approach to equilibrium and make due allowance of time to assure a reliable temperature determination.

Each thermoelement is made of one wire of "Chromel P," 0.127 mm in diameter, and two wires of "Copel," 0.10 mm in diameter, the latter twisted together. For insulation and support, these wires are threaded through thin strips of mica which are assembled

[5] Meyers and Jessup, Research Paper No. 324, *Bureau of Standards Journal of Research*, vol. 6, June, 1931.

with mica separators and covers into sturdy but light and flexible bundles carrying groups of thermoelements.

Each principal junction of chromel to copel is made by silver soldering the wires to a tiny gold terminal which is used to attach the junction in the desired place. The reference junctions, two to each element, are made similarly by attaching gold terminals to the chromel and copel wires. These gold terminals make electrical connection to gold lead wires and provide for attachment of the reference junctions to the reference block.

Fig. 3 shows how the terminals are installed to secure good thermal union, electrical insulation, and electrical connection where desired. They are held firmly under nuts on threaded studs which are screwed into the metal at the desired places. The terminals are insulated electrically from above and below by mica washers, and from the stud by centering. Additional thermal attachments of the gold lead wires are made in a similar manner at the reference block and at the bottom of the envelope to prevent thermal lead conduction from directly affecting the

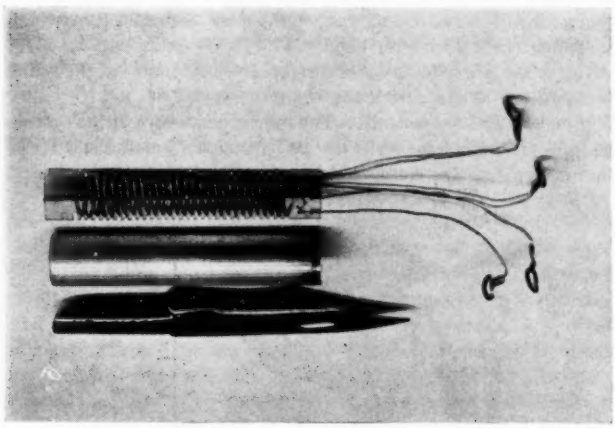

FIG. 4 PLATINUM-RESISTANCE THERMOMETER AND SHEATH, WITH PEN POINT FOR COMPARISON OF SIZE

reference junctions and thus causing erroneous temperature indications.

Gold wires, insulated with mica as described above, are brought out in a bundle from the reference junctions within the heated space to an accessible place at the temperature of the room. Here an isothermal attachment on copper blocks is provided for the junctions between these gold wires and the copper wires which lead across to the observing station.

The electromotive forces of the thermoelements, amounting in nearly all cases to less than 20 microvolts, are measured on a Wolff potentiometer designed by F. Wenner. Calibration of this instrument showed its corrections to be negligible. When the temperature of the calorimeter is being observed by means of the five thermoelements in series, a scale deflection of 1 mm corresponds to about 0.001 C.

The five thermoelements which are used in the measurement of water temperature were calibrated in place against a resistance thermometer in the reference block by the following procedure. With the block at nearly the same temperature as the calorimeter, a small emf is indicated on the thermoelements. When the block is heated the thermoelement reference junctions are heated by the same amount as the resistance thermometer. Therefore, the change in thermoelement emf is equivalent to the change in temperature as indicated by the thermometer. Calibrations were made at every temperature where pressure observations were made.

(*c*) *The Resistance Thermometers.* Two specially constructed platinum-resistance thermometers were used as working standards for the temperature measurements. These are of the four-lead potential-terminal type. They were made small and compact to fit into the receptacles in the reference block. The windings were made of highly refined platinum which showed at 100 C a resistance as high as 1.392 times that at 0 C. The platinum wire, 0.1 mm in diameter, was first wound in the form of a helix 0.45 mm in diameter, and this was then wound into a second helix 4.8 mm in diameter upon a mica cross with the edges notched to carry the winding, yet leave it free from mechanical constraint. Initial strains were relieved by annealing the completed thermometer at 660 C. Each thermometer is mounted in a cylindrical silver case which fits the receptacle in the reference block. Fig. 4 shows the construction of one of these thermometers.

This type of thermometer winding has been described by C. H. Meyers[6] and is particularly adapted to use where large size is objectionable. The question as to whether a platinum winding of this compact double-helical type will define the same temperature scale between the fixed points as a winding of the customary strain-free type, has been studied by making a direct comparison between one of the thermometers of this apparatus and one of the earlier standard thermometers of this laboratory. In the interval from 200 C to 320 C, the maximum observed difference in indication was at 270 C and amounted to 0.013 C, which is not more that attributable to the uncertainty of reproduction of the scale itself.

The two thermometers used (M-22 and M-26) were selected from a group of eight by consideration of their characteristics and behavior over a period of time. They were calibrated according to the specifications of the International Temperature Scale,[7] which uses the fixed points of ice, steam, and boiling sulphur as 0, 100, and 444.6 deg, respectively. The thermometers were calibrated before and during the progress of the pressure measurements and showed no significant changes. Thermometer No. M-22, which was used in all the experiments, had the constants $R_0 = 27.6637$, $R_{100} = 38.5158$, $\delta = 1.496$, which were used in the Callendar formula (given later) for the temperature computation. Thermometer No. M-26, which was used only occasionally to check the other thermometer, had the constants $R_0 = 27.7640$, $R_{100} = 38.6555$, $\delta = 1.496$.

The resistances of the thermometers are measured with a Mueller[8] bridge built by O. Wolff. The bridge coils are immersed in a thermostated oil bath. A separate commutator switch permits the observation of either thermometer. The bridge coils were recalibrated several times during this investigation. A bridge current of 4.5 milliamperes was used both in the calibration and in the measurements of temperature. A galvanometer-scale deflection of 1 mm corresponded approximately to 0.0001 ohm, or to about 0.001 C for the thermometers used.

III—EXPERIMENTAL PROCEDURE

The first step in a vapor-pressure determination is the introduction of a chosen amount of pure air-free water into the calorimeter. The water used in these measurements was prepared from distilled water by continuous low-pressure distillation in a special apparatus. The air was removed by pumping from the condenser a small fraction of the vapor which carried with it all but a trace of the air dissolved in the original water. This purification was found adequate to avoid any measurable partial pressure of air in the steam. A measured sample of the purified water is transferred without contact with air from the distilling apparatus to

[6] *Bureau of Standards Journal of Research*, vol. 9, Dec., 1932, R. P 508.

[8] Mueller, *Bulletin of the Bureau of Standards*, vol. 13 (1916), p. 547.

a special container. With this container attached to the evacuated calorimeter system, the water is driven into the calorimeter shell by heating the container. Weighing the container before and after this operation checks the amount transferred to the calorimeter. This must be known in order to compute the correction for the height of the liquid at any time.

The calorimeter with its charge of water is next brought to the desired temperature by adding heat electrically. At the same time the envelope, guard, reference block, and connecting tubes are all heated in a similar manner and at about the same rate. Their temperatures are finally adjusted by successive approximations while the calorimeter with its contents approaches the desired uniform stationary temperature. As this chosen temperature is approached, the automatic temperature control of the guard shell is put into operation.

The behavior of the fluid in the calorimeter varies appreciably in the temperature range covered by these experiments. At temperatures below 350 C, thermal gradients produced by heating the fluid, diminish quickly, leaving only small persistent gradients. As the critical region is approached, however, these persistent gradients become larger. The procedure used to hasten favorable conditions for observing pressure at these high temperatures is first to heat the water above the desired temperature and then to cool by lowering the envelope temperature. This produces condensation on the upper calorimeter walls, bathing them with liquid, which tends to bring them nearer the effective saturation temperature.

As equilibrium is approached, successive approximations are made to the adjustments necessary for a pressure measurement. The calorimeter pressure is balanced by the air pressure, which in turn is balanced by the load on the piston. If the temperature and pressure in the calorimeter were stationary and the measuring apparatus adjusted to proper balance, the diaphragm of the pressure cell would be at rest in its zero position, the two capillary indicators stationary, and the loaded rotating piston of the gage neither rising nor falling. This ideal condition of absolute constancy is not necessary to a satisfactory measurement. After close control and adjustment have been obtained, they are held over a period of about two minutes while a series of temperature readings is taken. The definitive value of the load is that at the mid-point of this period. The pressure observation includes the balancing load on the piston, temperature of the piston, barometric pressure, and height of fluid columns in the capillary indicators. The balancing load could always be determined to the nearest gram, and at low pressures it was possible to estimate fractions of a gram. At the higher pressures it is unnecessary to determine the load more closely than to 1 gram in order to have the precision of the pressure measurement correspond with that of the temperature.

For determining the effective saturation temperature, four successive temperature readings are made at equal time intervals. Each temperature reading consists of simultaneous observations of resistance thermometer and thermoelements. The above-described method of reading several successive temperatures is desirable for several reasons. First, the four-lead potential-terminal resistance thermometer requires at least two observations to eliminate the lead resistance from the measurement. Second, increasing the number of readings decreases the accidental error of observation. Third, a regular schedule of readings takes account of slight drift of temperatures. Fourth, the schedule permits the observation of local temperature irregularities during the measurement.

The best selection of thermoelements to determine the temperature of the free surface of the water depends on the temperature distribution and the location of the liquid level in the calorimeter. In the range of temperature below 350 C, the water and calorimeter reach a steady state promptly. Below 200 C this steady state was a uniform temperature, as indicated by surveys. All five thermoelements were therefore taken to indicate the saturation temperature up to 200 C.

Between 200 C and 350 C, after the steady state was reached, the bottom of the shell showed a small persistent depression of temperature and the top a small elevation due to inability to control the surroundings perfectly. In this range the three intermediate thermoelements, Nos. 2, 3, and 4, were used.

Above 350 C a difference in the behavior of the fluid was observed. The steady state was reached more slowly and thermal gradients were larger over the entire shell. The saturation temperature was estimated from the indication of a single thermoelement located in the vicinity of the liquid level in the calorimeter. If the quantity of water in the calorimeter is checked as previously described, the location of the liquid level is reliably known at temperatures below 370 C. Near the critical region, a comparatively small difference in the water sample determines whether saturated vapor, superheated vapor, or compressed liquid is present. Experiments were therefore made to indicate the state of the water in the calorimeter. These experiments started with a calorimeter supposed to be full of liquid water. After the pressure was observed, a chosen small amount of liquid was withdrawn and the pressure again observed. This procedure was repeated until the observed pressure, when reduced to a given temperature, showed a constant value, indicating existence of the saturation state.

During the progress of the vapor-pressure measurements, two types of experiments were made to prove the absence of an appreciable amount of permanent gas in the calorimeter. In the first type, pressures were measured before and after the withdrawal of liquid, which increased the vapor space in the calorimeter. In the second type, the presence of gas in the calorimeter after removal of the liquid was tested by a McLeod gage. These tests gave no indication of enough gas to affect the vapor pressure results.

IV—RESULTS OF MEASUREMENTS

The results of the entire series of measurements have been assembled in Table 1, which includes each measured temperature, reduced to degrees of the International Temperature Scale of 1927[9] and the corresponding measured pressure reduced to International standard atmospheres.[10] This table also contains the reduction of the observed pressures to values corresponding to even temperatures to permit comparison of the individual determinations and to facilitate the formulation of the entire group of results.

Each measured temperature is computed from the observed data consisting of four readings of the bridge when balanced with the platinum-resistance thermometer in circuit, and the four simultaneous readings of the potentiometer when balanced against the thermoelements, as described above in III—Experimental Procedure.

Each measured pressure is computed from the following observed quantities: the load on the piston gage, temperature of gage, position of water meniscus and oil meniscus, amount of water in the calorimeter, and barometer reading, including its temperature.

The auxiliary data used in these reductions include the density

[9] Burgess, Research Paper No. 22, *Bureau of Standards Journal of Research*, Oct., 1928, p. 635.

[10] "Standard atmospheric pressure is defined as the pressure due to a column of mercury 760 mm high, having a mass of 13,5951 g/cm³, subject to a gravitational acceleration of 980.665 cm/sec² and is equal to 1,013,250 dynes/cm²," *Bureau of Standards Journal of Research*, Oct., 1928, p. 637.

of water and of oil, value of gravity at the Bureau of Standards, the relative elevation of gage and barometer from the gravity bench mark, the results of calibrations of the bridge, resistance thermometers, thermoelements, and the piston gage with its connecting lines and weights.

The mean of the four bridge readings corrected for the bridge calibration gives the resistance of the platinum thermometer (R_θ) at the mean temperature of the series. The temperature θ is computed from this resistance by use of the Callendar formula

$$\theta = 100\,(R_\theta - R_0)/(R_{100} - R_0) + 0.01\,\theta\,(0.01\,\theta - 1)\delta$$

The constants R_0, R_{100}, and δ are determined by the calibration previously described.

The mean of the four thermoelement observations is reduced from microvolts to degrees temperature difference by use of the calibration factor determined as previously described. By combining this mean temperature difference between the water and the reference block, and the mean temperature of the block as determined by the thermometer, the temperature of the water, θ_w, is obtained.

The pressure observation, made at the middle of the series of temperature readings, corresponds with the water temperature determined as above. In reducing the pressure observation, the effective weight of the entire load supported by the oil acting on the effective piston area was computed as the sum of the masses of the weights, weight carrier, and the piston, corrected for calibration and air buoyancy. From this weight the resultant pressure was computed by use of the value of gravity at this laboratory (980.09 cm per sec per sec) relative to the standard value of gravity (980.665 cm per sec per sec) and the effective piston area, corrected for the effect of thermal expansion. To this component of pressure due to the load was added the observed barometric pressure corrected for temperature, difference in level, and for gravity, thus giving the total pressure at the bottom of the piston. From this pressure at the gage, the pressure at the level of the liquid in the calorimeter was found by applying the following corrections for the intermediate fluid columns: the oil column between the piston and the oil meniscus, the air column between oil and water, the water column between the water meniscus and the water level in the calorimeter, and the correction for the diaphragm position determined by the calibration at atmospheric pressure. The pressure contributed by the liquid water column in the calorimeter was calculated from the mass of water in the calorimeter, the dimensions of the calorimeter and the specific volumes of vapor and liquid water determined by Keyes and Smith.[11]

The total correction for fluid columns in the transmission line did not exceed 0.04 atm and was estimated to 0.0001 atm. The accuracy of this estimation may have limited the precision attainable at the lowest pressures measured. At the higher pressures, it was of less importance in comparison with several other factors.

V—FORMULATION OF RESULTS

Proceeding with the mean values of vapor pressure corresponding to even temperatures assembled in Table 1 as described above, the next step was to express the aggregate result of the entire series by means of a formula in order to smooth out irregularities caused by accidental errors of observation, and to provide a trustworthy method for interpolating intermediate values and for obtaining the derivative. The results of this formulation are given in Table 2. The constants of the empirical equation were determined by the method of least squares. Since the pressure

[1] Calculated from the equation

$$\Theta \log_{10} P = a\Theta + b + cx^3 + dx^5 + ex^8$$

where $\Theta = (273.1 + \theta)$, $x = \left(\frac{\Theta^2}{298{,}000} - 1\right)$, and a, b, c, d, and e are constants given in the table below for the two temperature ranges.

[2] Calculated from the equation

$$dP/d\Theta = 2.302585\, P \left(\frac{a - \log_{10} P}{\Theta} + 6cx^2 + 10dx^4 + 12ex^8\right)$$

which is the derivative of the above equation, using the same notation and constants.

TABLE OF CONSTANTS

	Range 100 C–275 C	Range 275 C–374 C
a =	+5.4247285	+5.4231165
b =	−2003.853	−2002.971
c =	+87.880	+109.54
d =	+107.35	−608.22
e =	−96.252	+1399.0

at the 100-deg point is fixed by definition, the formula was made to give the value of exactly 1 atm at this point. It was found necessary to apply the formula over two overlapping temperature ranges in order to secure a satisfactory fit. The agreement of the formula with observation is shown by the differences in columns 4 and 5 and graphically in Fig. 5. Since these differences in no case exceed the amount which experimental errors might cause, the formula is taken as a reliable representation of the aggregate results of the complete series of measurements. This formulation is the basis of a mutually consistent group of tables suitable for use as actual working tables. They are expressed in various appropriate units and arranged in convenient form to provide for intercomparison of current steam tables. The number of significant figures retained may be more than corresponds to the absolute accuracy of measurement, yet it was determined by considerations of consistency and precision of formulation, calculation, conversion of units, and comparisons. The derivative is included because this factor is important for making thermodynamic correlations and for interpolating intermediate values.

For the units which involve the value of the intensity of gravity the internationally accepted value of 980.665 cm per sec per sec or its equivalent in the English system (32.174 ft per sec per sec) has been used. Obviously it would be undesirable to complicate the tabulation further by taking into account the difference of gravity in different localities. It may be regarded as unfortunate that existing engineering practice still retains pressure units which involve local values of gravity, particularly since the difference is usually so small that the change to standard gravity could be made painlessly.

It should not be overlooked that the temperatures given in this group of tables are expressed either on the International centigrade scale or on the fahrenheit scale derived from it. For correlations involving the second law of thermodynamics, the departure of this temperature scale from the absolute or thermodynamic scale must be taken into account if it should be found to be significant.

Table 3 contains the values of the pressure of saturated water vapor and the derivative with respect to temperature at each degree centigrade from 100 deg to 374 deg. Values are given in each of the three units of pressure which are ordinarily used with the centigrade scale. The standard atmosphere is the standard international unit which has been used as the basis of reduction

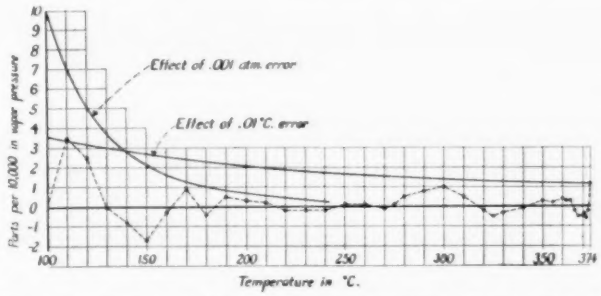

FIG. 5 DEVIATION OF MEAN OBSERVED PRESSURES FROM THE B. S. FORMULATION IN PROPORTIONAL PARTS

of the measurements. The centibar is a decimal subdivision of an internationally recognized unit of pressure.[12] This unit possesses several advantages for use as a practical working standard. It is derived directly from the fundamental units of length, mass, and time, independently of the properties of any substance or of the intensity of gravity. It may therefore be used in thermodynamic calculations with other current cgs units without requiring a conversion factor, a property possessed by no system of thermodynamic units used in current steam tables. This unit is of convenient size for practical use and has a convenient and unequivocal name, which is a unique combination.

The kilogram per square centimeter has a wide usage, particularly abroad and in scientific circles. Its chief disadvantage is that the intensity of gravity must be specified to make the unit definite. A second is that, lacking a name, it has frequently been confused with the atmosphere, having approximately the same value. The three units are used coordinately in this table to facilitate their use interchangeably and give the user a choice of unit appropriate for his purpose.

Table 4 contains values of the pressure of saturated steam in pounds per square inch at each degree fahrenheit. This pressure unit, like the kilogram per square centimeter, is indefinite unless the intensity of gravity is specified. Table 5 contains values of the derivative in the corresponding units.

Tables 6 and 7 are reciprocal to Tables 3 and 4 and express the same relation of vapor pressure to temperature arranged to indicate temperatures corresponding to integral values of saturation pressures.

[12] The "bar," equal to 10^6 dynes per sq cm, was approved as a unit of pressure by the International Meteorological Commission, Rome, 1913.

VI—ESTIMATION OF ACCURACY

Numerical values of physical quantities derived from measurements are never in exact accord with the true values. No matter how skilful and diligent the experimenter, there is a limit to the precision attained in each separate element of measurement and in the final result. The practical use of physical data is similarly subject to limitations of accuracy. The compiler of tables of properties of steam for practical use is obliged to choose from available experimental sources the definitive values which are to be used as a basis for formulation. This selection may be aided by the experimenter if, in addition to the record of methods, standards, and units used in his measurements, he includes also a judicious appraisal of the accuracy of the results.

By careful study of all the factors which enter into the measurements, an estimate may be made of the magnitude of the systematic error which may still remain in each factor after all known corrections for standards and calibrations have been applied. Having made these preliminary estimates, they may be used in a final estimate of the amount by which the results of the measurements might differ from the truth. Such an analysis has been made for the results of the present investigation by considering every apparent source of error, systematic or accidental.

The sources of systematic error which have been found significant include the calibration of the piston gage, the determination of the pressure corrections for the connecting line between the water sample and the gage, the difference of the scale of the thermometer used from the ideal international standard temperature scale, and the determination of the actual temperature of the free surface of the water sample relative to the thermometer. Each of these factors has been discussed earlier in its proper place. The magnitude of the accidental errors of measurement was deduced from the actual differences in the individual results.

Obviously the final appraisal of accuracy can be only approximate. If the facts were known on which an exact estimate of the systematic errors could be based, corrections could be applied for them and their effect eliminated. The element of judgment must enter in the figure which is deduced to indicate the uncertainty remaining after all known corrections have been applied. As such an approximate appraisal, it is believed that the values formulated for the pressure of saturated water vapor do not differ from the truth by more than 3 parts in 10,000, with the possible exception of the region near the critical where the rapidly changing properties of water make the measurements somewhat less trustworthy.

VII—ACKNOWLEDGMENT

The work presented in this report marks a further step in the effort to establish reliability and accord in steam tables, a project which has been promoted by The American Society of Mechanical Engineers through the material support of the steam-power industries. It is hoped that the results here given may prove an aid in attaining that object.

COMMITTEE PERSONNEL

The members of the Special Research Committee on the Thermal Properties of Steam are as follows:

Alex Dow, Detroit, Mich., Chairman; William L. Abbott, Chicago, Ill., Vice-Chairman; Reginald J. S. Pigott, Pittsburgh, Pa., Secretary; George L. Bourne, New York, N. Y.; Harvey N. Davis, Hoboken, N. J.; Hobart C. Dickinson, Washington, D. C.; Frank Dollin, Philadelphia, Pa.; Arthur M. Greene, Jr., Princeton, N. J.; Robert C. H. Heck, New Brunswick, N. J.; David S. Jacobus, New York, N. Y.; Joseph H. Keenan, Hoboken, N. J.; Frederick G. Keyes, Cambridge, Mass.; Lionel S. Marks, Cambridge, Mass.; Geo. A. Orrok, New York, N. Y.; Ernest L. Robinson, Schenectady, N. Y.

RP-55-5

Strength of Roll Necks

Report of the Special Research Committee on Heavy-Duty Anti-Friction Bearings

By W. TRINKS[1] and J. H. HITCHCOCK,[2] PITTSBURGH, PA.

The increasing use of anti-friction bearings for roll necks, which frequently necessitates a change in the customary proportions of roll body and roll neck, has made the question of roll-neck strength an important one. At the juncture between roll neck and roll body, stresses of high intensity occur which cannot be evaluated by the familiar formula of mechanics, and regarding which few directly applicable data were available. In order to evaluate the concentration of stress at this point, and to indicate the manner in which the stress concentration is affected by varying proportions of roll body, and roll neck, rupture tests were made with model rolls of gypsum plaster, having various proportions and several different sizes and shapes of fillet. The test conditions were made to correspond as closely as possible to those of actual rolls in operation. The experimental results are shown, and are compared with previous data. The effect of stress concentration in rolls made of various materials is also considered.

THE increasing use of anti-friction bearings[3] on the roll necks of rolling mills has given increased importance to the subject of roll-neck strength. Except in four-high and cluster mills, the application of anti-friction bearings frequently necessitates either an increase in roll-body diameter (compared to ordinary mills) or a decrease in roll-neck diameter, or both, in order to provide sufficient space for bearings of adequate capacity. This circumstance is particularly common in the case of two-high and three-high bar mills, where the available space between vertically adjacent roll necks, which is the significant dimension, is usually quite limited. The determining factor in such cases is the extent to which the roll-neck diameter can be decreased, in comparison with the diameter of roll body, without making the roll necks unduly weak.

The fact is generally recognized that a discontinuity of cross-section, such as that which exists at the juncture between roll body and roll neck, produces a concentration of stress at that point which cannot be evaluated by the familiar formula of elementary mechanics. Investigation has shown that the concentration of stress in such cases depends upon the extent and abruptness of the change of cross-section. In other words, the relative proportions of body diameter, neck diameter, and radius of fillet are involved in determining the actual intensity of stress which occurs in the roll neck. The relative length of roll body may also be suspected of having some influence in this connection. The significant factors may be expressed in terms of ratios, as follows:

1 The factor of stress concentration, which is defined as the ratio of the actual maximum stress at the roll-neck fillet, determined experimentally, to the apparent stress at the same point, as computed from the familiar formula of mechanics
2 The ratio of body diameter to neck diameter
3 The ratio of fillet radius to neck diameter
4 The ratio of body length to body diameter.

Because of the fact that the rolls of rolling mills are subjected to reversed bending, in which each element of material undergoes alternate tension and compression, the question of fatigue is also involved. Previous investigations of fatigue failure have shown that the effect of stress concentration in bodies subjected to alternating stress depends not only upon the proportions of the body but also to some extent upon the characteristics of the material. Seely[4] attributes this circumstance to the variable homogeneity of materials. Thus, a given external discontinuity of cross-section is found to have less effect in cast iron, which contains many minute internal discontinuities, than in a relatively homogeneous material such as alloy steel. In determining the strength of roll necks, it is accordingly necessary to consider not only the concentration of stress, but also the capacity of the roll material to withstand repeated alternations of concentrated stress. The factor of stress concentration and the actual maximum stress are considered as being independent of the roll material, while the properties of the material are taken into consideration by using a permissible stress (fatigue strength) which is considerably lower than that used for a static condition of loading.

---

[1] Professor of Mechanical Engineering, Carnegie Institute of Technology. Professor Trinks was educated at the Technische Hochschule at Charlottenburg, Germany, from which he graduated with honors in 1897, with the degree of M.E. From 1902 to 1905 he was chief engineer of the Wm. Tod Company, Youngstown, Ohio. Since 1905 he has been head of the Department of Mechanical Engineering at Carnegie Institute of Technology. Professor Trinks is the author of several engineering textbooks and of numerous technical papers. He has served on many technical committees of the A.S.M.E. during his long membership, and at present is chairman of the Special Research Committee on Heavy-Duty Anti-Friction Bearings, and a member of the Executive Committee of the Iron and Steel Division.

[2] Carnegie Institute of Technology. Mr. Hitchcock graduated from Case School of Applied Science, Cleveland, Ohio, in 1925. Since January, 1930, he has served as research associate of the Special Research Committee on Heavy-Duty Anti-Friction Bearings, conducting an investigation into the applicability of anti-friction bearings to roll necks. Mr. Hitchcock is a junior member of the A.S.M.E., and is also secretary of the Executive Committee, Iron and Steel Division.

[3] Anti-friction bearings as applied to roll necks are considered as constituting a class in which the coefficient of friction is less than some relatively low maximum value, perhaps a value of 0.007.

The members of the Special Research Committee on Heavy-Duty Anti-Friction Bearings are:

W. Trinks (Chairman), Professor of Mechanical Engineering, Carnegie Institute of Technology, Pittsburgh, Pa.

H. E. Brunner, Chief Engineer, SKF Industries, Inc., New York, N. Y.

W. R. Clark, Works Manager, Mill Products Division, Bridgeport Brass Company, Bridgeport, Conn.

G. C. Farkell, National Tube Company, Lorain, Ohio.

S. G. Koon, Associate Editor, *The Iron Age*, New York, N. Y.

H. H. Talbot, Chief Engineer, United Engineering & Foundry Co., Pittsburgh, Pa.

S. M. Weckstein, Industrial Equipment Engineer, Timken Roller Bearing Company, Canton, Ohio.

H. A. Winne, Industrial Engineering Department, General Electric Company, Schenectady, N. Y.

Contributed by the A.S.M.E. Special Research Committee on Heavy-Duty Anti-Friction Bearings and presented at the Annual Meeting, New York, N. Y., December 5 to 9, 1932, of The American Society of Mechanical Engineers.

[4] Seely, *Mech. Eng.*, Sept., 1930.

The stress-concentration factor can be evaluated for certain conditions from the results of numerous fatigue tests, in which cylindrical bodies of various materials, both with and without concentrations of stress, have been tested to failure in reversed bending. The results of these tests, however, are still too few, in comparison with the number of variables involved, to provide conclusive relations. The results of photoelastic observations in parallel-walled specimens have previously been applied to calculations of roll-neck strength, but there is no certainty that the ratio of stress intensity in cylindrical bodies is the same as that observed in specimens of rectangular cross-section. Because of these circumstances, the need for an experimental study of the concentration of stress in roll necks is evident. Tests were accordingly undertaken by the Committee,

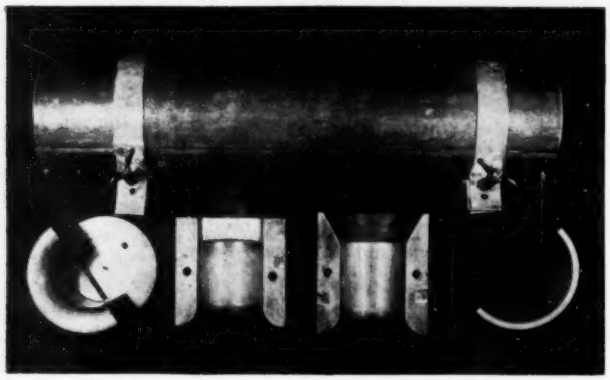

FIG. 1 STEEL MOLD USED FOR CASTING PLASTER MODEL ROLLS

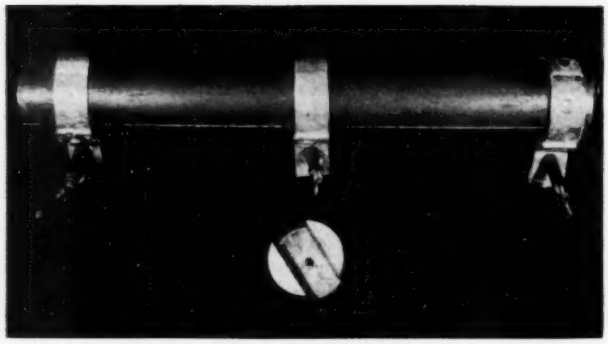

FIG. 2 CYLINDRICAL STEEL MOLD IN WHICH PLASTER COMPARISON SPECIMENS WERE CAST

in order to evaluate the stress-concentration factor for the common proportions of roll body, roll neck, and fillet radius which are encountered in practice. The influence of fillets of special design upon the concentration of stress was also investigated. The results of these tests were then compared with the results of previous fatigue tests, in order that the characteristics of different materials might be taken into consideration.

EXPERIMENTAL METHOD

The failure of a ductile material under a condition of alternating stress takes place in exactly the same manner as the failure of a brittle material under a single application of stress. Rupture tests of models made of a brittle material may accordingly be used to indicate the strength of ductile materials which are subjected to alternating stress, in so far as the strength is a function of the shape and proportions. This method of investigation has previously been used with marked success, a notable instance being the series of tests made by Seely and James[5] on models of curved beams. The conventional procedure is to construct two specimens from the same brittle material; one having the more or less complicated shape in which the stress intensity is to be determined, and the other having a simple shape in which the stress can be computed directly. Seely and James describe the ideal material for this purpose as one in which the strength in compression and shear are very high in comparison to the strength in tension. Pottery plaster was recommended as fulfilling this qualification, and this material was accordingly selected for the tests which are to be described.

PREPARATION OF TEST SPECIMENS

The customary limiting proportions of rolls for bar mills, in which the question of stress concentration is of greatest importance, are as follows:

	Minimum	Maximum
Ratio of body diameter to neck diameter...	1.65	2.00
Ratio of fillet radius to neck diameter.....	0.05	0.20
Ratio of body length to body diameter.....	1.45	2.50

Based upon these proportions, the dimensions of the plaster-model rolls were selected as follows:

Body diameter, inches.....	$3\frac{1}{2}$
Neck diameter, inches.....	2, $1\frac{3}{4}$
Fillet radius, inches.....	$\frac{3}{4}$, $\frac{1}{2}$, $\frac{1}{4}$, $\frac{1}{8}$, $\frac{1}{16}$
Length of roll body, inches.....	$8\frac{1}{2}$, 7, 6, 5

In order that the plaster model rolls might have smooth, uniform, and seamless surfaces, they were cast slightly oversize and machined to the proper dimensions after casting. A steel mold was constructed with a body diameter of $3\frac{5}{8}$ in., neck diameter of $2\frac{1}{8}$ in., and a nominal body length of $8\frac{1}{2}$ in. The mold was provided with $\frac{3}{4}$-in. fillets at the roll necks, and with facilities for adjusting the length of roll body. A photograph of the parts of the mold is reproduced in Fig. 1. A smaller cylindrical mold, $2\frac{1}{8}$ in. in diameter, shown in Fig. 2, was constructed for the comparison specimens of plaster.

Previous investigators[5, 6, 7] have found that the strength of pottery plaster is affected to a very great extent by the proportions of water and plaster used in preparing the castings, and by the details of treatment both before and after casting. For the preparation and seasoning of the model rolls, the following procedure, based upon previous information, was used throughout. Sufficient plaster and water for one model roll and one comparison specimen were carefully weighed in separate containers, the proportion selected being 40 per cent water and 60 per cent plaster. The plaster was poured into the water rapidly, but with care to avoid entrapping air, and the mixture was allowed to stand untouched for a blending period of ten minutes. After blending, the mixture was stirred by hand for five minutes, to mix the ingredients thoroughly and to remove the small quantities of air which were carried in with the plaster. The mixture was then poured into the molds, which had previously been coated with a thin layer of a water solution of soft soap, and the molds were jarred repeatedly for a few minutes to assist the escape of air bubbles. Agitation of the molds was stopped at the first sign of solidification of the plaster, and they were left motionless until solidification had become complete. After the plaster had set, the castings were removed from the molds and placed in a moist chamber, where they were stored

[7] Heath, "Plaster and Mold Making," Trans. Ceramic Society, May, 1930.

for forty-eight hours. The castings were then dried for a minimum of ten days in air which was circulated by means of a small blower. The containers for plaster and water were rigorously cleaned after the preparation of each pair of castings, in order to prevent the inclusion of small particles of hardened plaster and other foreign substances. The castings produced in this manner were dense, hard, and apparently homogeneous.

The castings were machined in an ordinary lathe with special tools which had been ground to the required radii. The tolerances in machining, with very few exceptions, were held to ± 0.010 in. in body diameter and body length, and ± 0.005 in. in neck diameter. In addition to the five previously mentioned sizes of plain-radius fillets, several fillets of special design were used. The complete dimensions of these fillets, a majority of which represent miniature reproductions of actual bar-mill rolls, are shown later in Fig. 20. In general, six identical models and six comparison specimens were constructed and tested for each set of dimensions, in order to avoid the effect of possible differences in the density and strength of different specimens. This precaution, as has been pointed out by Seely and James,[5] is essential if reliable results are to be obtained with this method of investigation.

Method of Loading

Effort was made to duplicate actual rolling-mill conditions as nearly as possible in the tests of these plaster models. The rolls and roll necks of rolling mills are subjected to reversed bending stress, as previously noted. One roll neck is also subjected to torsion, the torque being transmitted through the roll neck and part of the roll body to the point of application of the separating force. The opposite roll neck is free from torsion, if the torque which is due to roll-neck friction be neglected. Calculations have indicated that the lever arm of the separating force in bar mills varies from 0.05 to 0.15 times the roll diameter. The roll diameter in this case being $3^1/_2$ in., arrangement was made to apply the force eccentrically at a distance of $^3/_8$ in. (0.375 ÷ 3.5 = 0.11) from the vertical center line through the roll. This eccentricity can be seen in Fig. 3, which illustrates the loading arrangement for the model rolls. One roll neck of each test model was provided with a flat extension to fit a metal yoke which was attached to one roll-neck bearing, and through which the torque was transmitted. The flat extension also served the purpose of driving the casting during machining. The opposite roll-neck bearing was generously lubricated to prevent the application of torsional stress to the corresponding roll neck. By means of this arrangement, a close approximation to average rolling-mill conditions was achieved. The efficacy of the loading arrangement was attested by the fact that nearly every model broke at the neck which was subjected to torsion. The simple arrangement which was used for loading the cylindrical comparison specimens is shown in Fig. 4.

The castings were broken in a small testing machine in the Materials Testing Laboratory at Carnegie Institute of Technology. The stress at which rupture occurred in each comparison specimen was calculated by use of the familiar formula of mechanics involving the breaking load, the span, and the diameter of the specimen. The apparent stress at which rupture occurred in each model roll was calculated in the same manner, except that a graphical analysis was required to locate the point of rupture. The outline of each roll neck and fillet was drawn to a large scale, and the outline of a beam of constant strength having the same length of span as the roll was then drawn tangent to the fillet outline, as shown in Fig. 5. Obviously, the point of tangency in such a drawing represents the point at which the roll neck is apparently weakest, and because the drawings were made on a large scale, the distance from the bearing center line to that point could be determined quite accurately. This distance, of course, was slightly different for each value of fillet radius and neck diameter, and was used to compute the bending moment and the apparent stress at the point of rupture.

Typical drawings of this type are shown in Fig. 5 for plain fillets, and in Fig. 6 for fillets of special design. An interesting example of the effect of stress concentration is provided in the case of fillet No. 8, which has a tapered section leading to a cylindrical shoulder, and which is illustrated in the center section of Fig. 6. The models which were constructed with this fillet broke at the root of the cylindrical shoulder, rather than at the

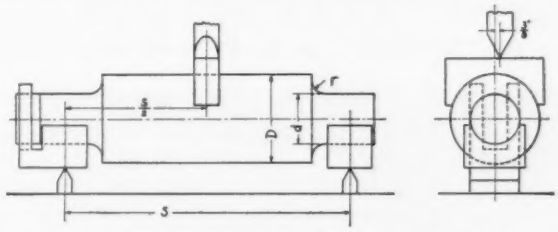

Fig. 3 Arrangement for Loading Model Rolls

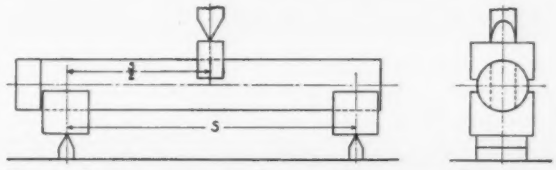

Fig. 4 Arrangement for Loading Comparison Specimens

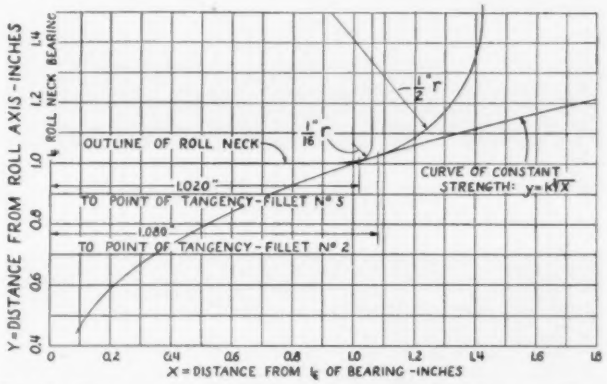

Fig. 5 Graphical Analysis to Locate Weakest Point in Roll Necks Having Plain-Radius Fillets

point of tangency where the roll neck is apparently weakest. This circumstance will be considered in detail later.

The torsional stress in the necks of the model rolls was not considered in determining the apparent stress at which rupture of the necks occurred. The torsional stress here, as in the necks of actual rolling-mill rolls, was very small in comparison with the bending stress, so that the combined stress differed in magnitude from the bending stress by only a very few per cent. The factor of stress concentration, as previously defined, was computed for each model roll as the ratio of the bending stress in the corresponding comparison specimen to the apparent bending stress in the neck of the model roll. The values of this factor in each group of identical models were then averaged. In general, the results obtained with identical models were quite consistent, although widely discrepant results were found in a few cases.

It is interesting to note that every model broke, as nearly as

could be determined, in accordance with the analyses shown in Figs. 5 and 6. These analyses indicate, in the case of plain-radius fillets, that the point of rupture must be located relatively far from the cylindrical portion of the roll neck when the fillet has a large radius, and very near the cylindrical portion when the fillet has a small radius. This contrast could easily be seen by comparison of the ruptured specimens, and may be visible in the accompanying illustrations. Fig. 7 shows a model roll and a comparison specimen, both unbroken; and Fig. 8 an identical pair of castings after rupture. Fig. 9 illustrates a broken roll which had a fillet radius of $^3/_4$ in., while broken rolls which had smaller fillets are illustrated in Figs. 10 and 11. Comparison of these photographs shows that rupture always occurs very near the cylindrical portion of the roll neck, on the side

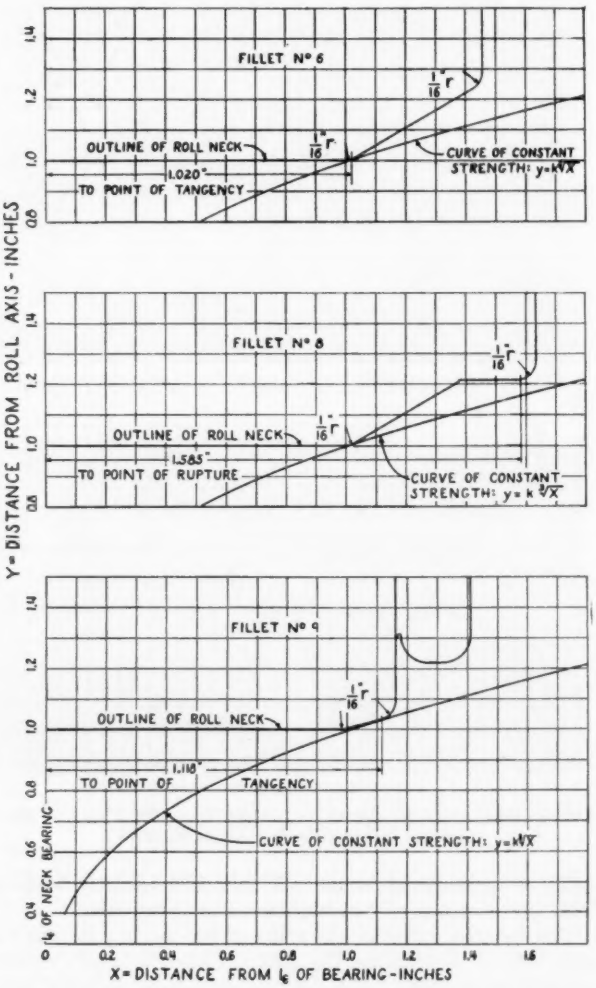

FIG. 6 GRAPHICAL ANALYSIS TO LOCATE WEAKEST POINT IN ROLL NECKS HAVING FILLETS OF SPECIAL DESIGN

which is subjected to tension, and that the point of rupture lies slightly farther from the cylindrical portion of the roll neck when the fillet has a large radius. Typical broken rolls which were constructed with special fillets are shown in Figs. 12–15. Fig. 13 is of particular interest, inasmuch as it confirms the previous statement regarding the location of the point of rupture in fillet No. 8. It is also interesting to note the agreement between Fig. 14 and the lower section of Fig. 6, with respect to the location of the point of rupture in special fillet No. 9.

TEST RESULTS

Study of the test results is facilitated by considering first those which apply to varying length of roll body. These results are shown graphically in Fig. 16; and indicate the somewhat surprising relation, shown by dotted lines, that the factor of stress concentration decreases slightly as the ratio of body length to body diameter increases. It will be observed, however, that the indicated variations of the stress-concentration factor with varying length of roll body are quite small in comparison with the discrepancies between different values in each group. The correctness of the indicated relations must therefore remain open to question. Each solid line of this illustration represents the weighted mean of all observed values in that particular group of tests. The maximum deviation of the indicated relations from the mean values is seen to be only a few per cent. It appears reasonable to assume, therefore, that within the range of the experiments with respect to the roll proportions, the factor of stress concentration is independent of the ratio of body length to body diameter. Subsequent analysis of the results is based upon this assumption.

All of the test results which were obtained with model rolls having plain radius fillets are shown graphically, in averaged form, in Fig. 17. The points marked by circles indicate the observed values of the stress concentration factor for rolls in which the ratio of body diameter to neck diameter was equal to 1.75, while the model rolls in which this ratio was equal to 2.00 provided the points marked by crosses. In accordance with the previous assumption, the small indicated effect of varying length of roll body is neglected, and the curves of this illustration are drawn through the points which correspond to the mean values shown in Fig. 16. With the exception of the points to which question marks are attached, and which will be dealt with later, rather definite relations are indicated between the value of the stress-concentration factor and the ratio of fillet radius to neck diameter. These relations may be expressed empirically by means of the following equation, which has been derived from the experimental results:

$$\eta = 1 + 3.5\ [0.01\ d/r]^{[1.968\ -\ 0.636\ D/d]}$$

In this equation, η represents the stress-concentration factor, d/r the ratio of neck diameter to fillet radius, and D/d the ratio of body diameter to neck diameter. Values of the stress-concentration factor which have been computed from this equation are shown in Fig. 17 by dotted curves. These values coincide with the experimental values for intermediate values of r/d, which is the region of greatest interest, and differ slightly from the latter curves for high and low values of r/d.

The points in Fig. 17 to which question marks are attached represent the results of tests on the first groups of castings which were prepared. Because of the obvious disagreement between these and later results, these tests were repeated with two additional groups of castings having the same dimensions. The supplementary tests provided reasonably consistent results, probably because of improved technic in the preparation of the castings.

For the sake of convenience, the experimental curves shown in Fig. 17 have been replotted in Fig. 18, in terms of the ratio of body diameter to neck diameter. The unbroken portions of the curves of Fig. 18 represent the results within the experimental range, while the dotted portions indicate the probable relations outside the experimental range. It is probable that each of these curves passes through the origin of coordinates, and their slopes indicate that such is the case; nevertheless, the fact should be emphasized that the dotted curves are purely hypothetical, and that the values which they indicate should be used in practice only with caution, if at all. It is improbable,

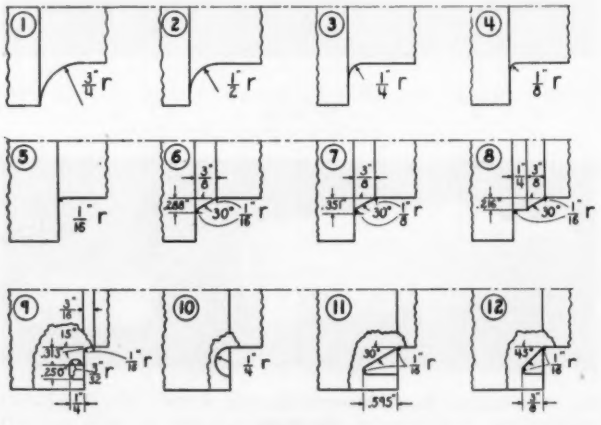

FIG. 20 SHAPES AND DIMENSIONS OF FILLETS USED ON PLASTER MODEL ROLLS

of course, that the proportions of roll bodies and roll necks in practice would require the use of values outside the range of these experiments.

The results obtained with model rolls having fillets of special design are shown graphically in Fig. 19. The number at each point of this illustration represents the type of fillet used on that particular group of specimens, and corresponds to the same number in Fig. 20. All model rolls having special fillets were constructed with the ratio of body length to body diameter equal to 2.43, and with the nominal ratio of body diameter to neck diameter equal to 1.76. The factor of stress concentration, it will be observed, is smaller in the case of any one of these special fillets than in the case of a plain fillet having the same radius. This fact indicates the desirability of using undercut or tapered fillets whenever possible. The use of undercut fillets, such as No. 10 or 12 of Fig. 20, is particularly advantageous because it allows the concentration of stress to be reduced without requiring the roll-neck bearing to be located far from the roll body.

The fact was previously mentioned that the model rolls which were constructed with special fillet No. 8 (see Fig. 20) broke at the root of the cylindrical shoulder rather than at the point of tangency of the constant-strength curve, where the roll neck is apparently weakest. This fact, far from being astonishing, is exactly what should be expected in the light of the other results of these tests. It has already been shown that the value of the stress-concentration factor is dependent upon the extent and abruptness of the change of cross-section. Considering first the point of tangency of the constant-strength curve in fillet No. 8, together with the dimensions of the fillet as given in Fig. 20, it is evident that the change of cross-section at this point is quite gradual, from the diameter of the cylindrical shoulder (2.43 in.) to the diameter of the roll neck (2 in.). The factor of stress concentration at the point of tangency must therefore be quite small. At the root of the cylindrical shoulder, however, the change of cross-section is not only greater in magnitude, but also much more abrupt, so that a higher value of the stress-concentration factor should apply at this point. The ratio of diameters at this section is 3.5/2.43, or 1.44; while the ratio of fillet radius to the smaller diameter is 0.0625/2.43, or 0.026. Applying these values to the curves of Fig. 18, it is observed that the probable value of the stress-concentration factor at this point is 1.58. According to the results shown in Fig. 19, a stress-concentration factor of 1.505 was determined experimentally for fillet No. 8. It is evident, therefore, that the experimental results obtained with rolls having fillet No. 8 are in close agreement with the other results of these tests, and that the weakest point in a roll neck is not always the point of tangency of the constant-strength curve.

COMPARISON OF RESULTS

Because of the fact that rupture of the plaster models was caused in these tests by combined torsion and bending stress, the foregoing results are not precisely comparable with previous data which involve only bending stress. Nevertheless, a comparison with the results of fatigue tests is essential, if the

varying characteristics of different materials are to be taken into consideration, and comparison with previous data obtained by other methods will be interesting. Such a comparison is shown graphically in Fig. 21. The curves A_1 and A_2 of this illustration are taken directly from Fig. 17, and indicate the experimental values which have just been discussed. Curve C indicates the results obtained by Peterson[8] in rupture tests of plaster cylinders in pure bending. Curve B represents the results of photoelastic observations made by Timoshenko and Dietz.[9] The remaining points of this illustration refer to the results of tests made by numerous other investigators with various materials. Data regarding the materials used and the proportions of the specimens in all of these tests are listed in Table 1.

TABLE 1 RESULTS OF PREVIOUS TESTS ON CONCENTRATION OF STRESS

Examination of Fig. 21 and Table 1 reveals the fact that fatigue tests of high-carbon and alloy steel (points b, c, and s) show approximately the same concentration of stress as the Committee's tests on plaster-model rolls, while the results of fatigue tests on low-carbon steel show somewhat less concentration of stress. It is evident also that photoelastic observations in parallel-walled specimens show greater concentrations of stress than are indicated by other methods. The lack of complete agreement between curves A_2 and C of Fig. 21, which appear to represent closely comparable conditions, may be due to several factors. Values on the former curve were obtained during the rupture of plaster specimens by combined torsion and bending stress, while the latter curve represents values obtained by rupture in pure bending. An equally significant difference is indicated by a comparison of the shapes of the specimens. Those used in tests C were supported and loaded through the portions of large diameter at the ends (see Table 1) so that bending stress only was applied to the specimens at the point of rupture. The model rolls to which curve A_2 refers, on the other hand, were supported by bearings at the roll necks and loaded at the center of the roll body, as shown in Fig. 3, so that the point of rupture was quite near the region of support.

As Frocht[10] has shown by means of photoelastic observations, the stress conditions near a region of loading or support are more or less indeterminate by ordinary methods, depending upon the degree of distribution of the load. Consequently, the conditions of stress at the point of rupture in the model rolls were undoubtedly not the same as those at the point of rupture of the plaster cylinders used in test C, and may have differed somewhat from the assumed conditions upon which curves A_1 and A_2 are based. This latter circumstance leads to the important point that the results of the tests made by the Committee, although perfectly applicable to the rolls of rolling mills, are not precisely applicable to other cases.

Mention should be made of the fact that the absolute dimensions of the roll-neck fillet, quite apart from the relative proportions, may have an influence upon the stress concentration. Earlier experiments with nicked or notched specimens have indicated that a very small notch in a small specimen is more injurious than a larger notch in a larger specimen, the relative proportions being the same in both cases. While this suspected effect cannot be evaluated numerically at present, it is probably safe to assume that the effect is not large in the case of rolls for rolling mills, where the absolute dimensions are usually quite large.

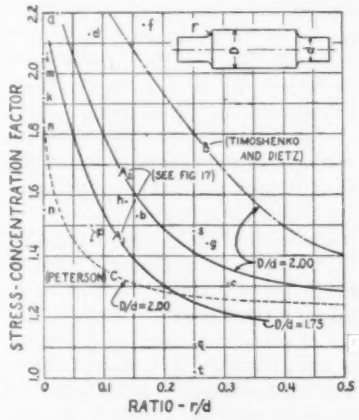

FIG. 21 GRAPHICAL COMPARISON OF RESULTS OBTAINED BY MEANS OF VARIOUS EXPERIMENTAL METHODS

(Data regarding test methods, materials, and proportions of specimens are given in Table 1.)

CONCLUSIONS

The results of these tests have confirmed and extended the conclusions of previous investigators with respect to this experimental method. Rupture tests of plaster models can be made with comparatively small expense; and provide consistent and

reliable results if the models are carefully prepared, and if the average of numerous observations on identical models is used. Single observations made with this method may be quite inaccurate.

The relation between the factor of stress concentration in plain fillets and the relative dimensions of roll body and roll neck has been clearly shown, and needs no further comment. With respect to the design of special roll-neck fillets, however, the following additional conclusion may be drawn. When such a fillet contains a tapered portion, the maximum strength for given dimensions of roll body and roll neck can be obtained by making the angle of taper equal to or slightly greater than the slope of the constant-strength curve at the point of tangency (see Fig. 6). Depending upon the proportions of roll body and roll neck, this slope may vary from 15 to 20 deg.

The intensity of stress in roll necks can now be computed, by use of the proper values of the stress-concentration factor. The intensity of stress, as previously stated, is considered as being independent of the characteristics of the roll material. The effect of concentrated and alternating stress, on the other hand, is a function of the fortuitous distribution of weak spots in the roll material. This effect must be taken into consideration in determining the permissible stress for each roll material. The available data which have been derived from fatigue tests are not sufficiently complete to provide final conclusions with respect to all roll materials, but some fairly definite tendencies can nevertheless be pointed out. From the results of previous fatigue tests, represented by the scattered points of Fig. 21, it appears that the permissible stress can safely be made equal to the fatigue strength in the case of alloy- or high-carbon steel rolls. For rolls of a more heterogeneous material such as cast iron, however, in which the effect of concentrated stress is less severe, the permissible stress might exceed the fatigue strength slightly, perhaps by 10 to 20 per cent. More definite conclusions in this respect are still needed, and will doubtless be provided by subsequent fatigue tests.

Concentrations of stress may occur at points in the roll body as well as in the roll-neck fillets, as a result of the grooves which are provided for rolling shapes. As Frocht[10] has shown by means of photoelastic tests, the presence of several notches or grooves close together in a stressed body, such as the numerous grooves in the roll body, introduces only mild stress concentrations in comparison with the concentration of stress caused by a single notch. For this reason, the concentrations of stress in the roll body are usually much less severe than those in the roll neck, but they may be appreciable and should be considered if the strength of the roll body is in question. The ratios of diameters at discontinuities of cross-section in the roll body are usually outside the range of these experiments. In the lack of adequate data which are directly applicable to such cases, prudent use of the extended curves of Fig. 18 may serve for rough approximation. The use of these extended curves, however, is not recommended in general.

The fact was previously mentioned, and should now be emphasized, that the data which have been shown are directly applicable only under certain specific conditions, particularly with regard to the relation between torsion and bending stress. This relation varies in the rolls of rolling mills, and although the variation is usually of very little significance from the standpoint of roll-neck strength, there are some cases, such as the small working rolls of four-high mills, in which torsion should be considered.

Grateful acknowledgment is made to the members of the Committee for their valuable advice in planning and executing the work. Acknowledgment is made also to the Department of Civil Engineering, Carnegie Institute of Technology, for their kind provision of facilities for preparing and testing the plaster specimens.

Discussion

W. R. Clark.[18] Roll designers have known for a long time that a roll having a large fillet where the roll neck joins the body would break less frequently at this point. Many rolls were therefore designed with large fillets, and neck diameters were made large enough, whenever possible, to prevent roll breakage outside the body of the rolls. The recent success of roller bearings on backed-up mills has encouraged attempts to apply roller bearings to two-high mills. This has made it necessary to reduce neck diameters to the point where neck stresses will balance permissible bearing loads, and in cold rolling mills, using chill iron rolls, the load-carrying capacity of the rolls has to be materially reduced or their diameters increased, in order to permit of increased bearing space necessary to carry the original loads. Generally, neck length must be increased, which in turn increases the neck stress near the roll body.

The problem can sometimes be solved by using an alloy-steel roll of the original diameter in place of the chill roll, and sometimes it is possible to apply roller bearings to existing alloy-steel rolls by redesign of the roll neck.

The data which the authors have presented will be of great assistance to roll designers in designing new rolls for roller bearings and in changing over existing rolls. The opportunities to save power and to roll more accurately with reliable anti-friction bearings are great. Recent developments of pressure-measuring gages, which can be readily inserted under rolling-mill screws, make it possible to accurately determine loads imposed on the bearings for the desired rolling operations.

The curves presented in this paper can be used to accurately design the roll necks and bearings for maximum safe loading possible in the space between the rolls, with balanced factors of safety allowed in necks and bearings.

About three years ago we changed over a 12-in. mill, having steel rolls, to roller bearings. In order to carry the same loads as before, it became necessary to reduce the roll neck diameter from 9 in. to 6.3 in., to increase the roll diameter to $12^{7}/_{8}$ in., and to increase the neck length from 7 in. to 11 in., in order to provide for proper bearings and bearing seals. It was found possible to incorporate these seals on a tapered section of the neck 3 in. long, 6.3 in. in diameter at the bearing, and $9^{1}/_{4}$ in. in diameter at the roll body. This was stressed less at the roll body than at the journal end and effectively prevented a weakness of the neck at the roll, due to stress concentration.

This change-over permitted a speed increase of 100 per cent; while the power drawn from the motor was generally less, so that the power cost per ton was cut in half.

S. M. Weckstein.[19] The information in the paper should help considerably in the design of suitable rolls. It would be interesting to obtain information on the same factors as related to built-up rolls. Quite a number of these special rolls are now being used, and information to check their design will be of value.

Authors' Closure

The only discussion calling for a reply is that of Mr. Weckstein, referring to the strength of built-up rolls. The stresses in that type of roll are so complex that their consideration in an appendix to the present paper is out of question. The built-up roll should be treated in a separate paper.

An Analysis of Crushing and Pulverizing Processes

By LINCOLN T. WORK,[1] NEW YORK, N. Y.

Different types of crushing and pulverizing mills are mentioned to show the diversity in operating characteristics. It is clear that different types of mills have been commercially adapted to similar products, and only rarely is one type of mill used to the exclusion of all others. The principles laid down illustrate the importance of grindability. A consideration of energy requirements shows that there is a large wastage of power over that needed to produce reduction in size. The earlier work of the author is confirmed on the difference in fineness-distribution curves produced under different grinding conditions and by different types of mills. Proper choice of mill, proper loading, and the application of separators offer the opportunity to produce material of specific size characteristics or to produce material below a given size at a minimum of cost.

Introduction

THERE have been brought together under the title or heading of crushing and pulverization a number of processes for the reduction in size of materials to constitute a basic operation useful to the engineering industries. This title represents the entire range of breaking of materials by machinery from the size of rocks leaving the quarry to the finest powders that are practically colloidal in nature. There are three terms which may be applied specifically to this group of operations; namely, crushing, pulverization, and disintegration. Crushing has been largely used as the terminology of the mining industries and may be used in the general sense of reduction in size of large pieces of material; it produces, essentially, coarser than sieve sizes. Pulverization is the term which may be applied to fine-grinding operations where particles are being broken from relatively fine sizes to powders or dusts. Both of these terms imply the actual fracture of a particle across surfaces which are tightly bonded. Disintegration is a term which may be applied to the reduction in size of particulate groups held together by relatively little force, and it may be said to imply that there is no actual change in the size of the inherent particles in the mass.

Crushing has been developed largely for the processing of minerals. Ores are broken to expose surface for roasting and oxidation and to minimize the amount of penetration needed in leaching, or to isolate individual particles of each kind for separating by flotation. Coal is crushed and sieved to various mesh sizes to render it suitable for firing on grates. Cement rock is crushed as preliminary to its final pulverization. Stone aggregates are crushed to various sizes for use as concrete aggregates or as material for macadam road. Pulverization is also applicable to minerals, but it is equally applicable to other substances which must be reduced in size for any special purpose. Rock minerals are pulverized to make them useful as fillers in rubber and in paints, and to create homogeneity of mixtures for ready reaction in the manufacture of cements, porcelain, and glass. Coal is pulverized to render it suitable for firing as a dust mixed with air. The fused clinker in cement manufacture is pulverized to render it reactive with water. Many other materials are reduced to powder to prepare them for further treatment or to prepare them in a suitable form for handling as a finished product. Disintegration may enter as a part of these crushing operations. In its purest form it may be illustrated by the breaking down of filter cakes such as dyes or pigments. This is accomplished with the same general type of machinery as is used in pulverization, but it is a special case in that the particle shape and size have already been established and the mill is used merely to separate particles from each other. Within recent years there has come into the field of fine sizes the colloid mill for the production of emulsions or of very finely subdivided solids.

The operations of crushing, pulverization, and disintegration utilize equipment of the same general character, specially designed of course to meet the diversified range of product and the varied range of particle sizes. These operations overlap and cannot be strictly differentiated. The nomenclature already defined will be used because different problems are presented, and yet all of these operations can be treated together and they represent problems of a somewhat similar nature. The objective in this reduction of materials may vary. In some cases it is desired to break large pieces to pass through a certain aperture. In other cases it is desired to crush for a maximum amount of a given sieve size. The same general requirements hold in pulverization. Sometimes a product that is uniformly of the same size is desired. In other cases it is desired to eliminate the coarsest particles, merely making the powder finer than a given specified size. In still different cases the best results are secured by a proper blending of coarse and fine sizes. Disintegration usually has for its objective the complete elimination of clusters or agglomerates and the production of individual particles of their own normal size. Thus it is not possible to select any one objective as the aim of grinding operations, but yet there stands out conspicuously from the others the production of surface as a primary objective, particularly in fine sizes.

These operations of crushing and pulverizing involve mechanical loading of a particle to reduce it in size. It is well to consider alternatives which may attain a similar objective. Dean and Gross[2] have investigated expandable substances which could be

[1] Assistant Professor in Chemical Engineering, Columbia University. Lincoln T. Work was Instructor in Chemical Engineering, Columbia University, from 1921 to 1929, since which time he has been in his present position. He has the degrees from Columbia University of A.B., 1918; Ch.E., 1921; A.M., 1924; and Ph.D., 1929. Dr. Work has been a consulting chemical engineer since 1921, his major fields being portland cement, active carbon, pigments, petroleum products, and grinding and particle size. During the summer of 1929 he was with the du Pont company in charge of the formation of the division of fundamental chemical engineering research. He was national secretary-treasurer of Phi Lambda Upsilon, honorary chemical society, from 1923 to 1929, and has been the national president since that time.

Presented at the National Process Meeting, Buffalo, N. Y., June 6 to 8, 1932, of The American Society of Mechanical Engineers.

Note: Statements and opinions advanced in papers are to be understood as individual expressions of their authors, and not those of the Society.

placed within the pores of a solid and which would disrupt the body upon rapid expansion. These agents fall into the classes of detonators and of superheated liquids. Their study has involved only the latter. Operating with superheated water at various pressures, they have broken galena of 4 to 6 mesh to produce predominantly an undersize in the range of 6 to 14 mesh with from 0 to 5 per cent under 200 mesh. A number of investigators have used the thermal expansion of the solid itself to produce disintegration. Rapid quenching of a very hot object will produce the stress needed to shatter the larger pieces. In this case, as in the former, the action is not predominantly on the fines, and these methods are likely to produce coarse materials. With high temperatures and a very rapid quenching, the second method may be extended into the sub-sieve range. For the production of very fine materials—in fact, usually finer than any ground product—solution and precipitation methods are most commonly used. For certain purposes spray drying of pulps, rather than mass drying with subsequent grinding, has been utilized to produce certain desired results and properties. With this brief consideration of the alternative methods of reducing particle size, the discussion of crushing will be resumed.

On account of its very complexity, crushing has not been amenable to fundamental scientific analysis. Exact methods of measurement have been lacking until quite recently, and practically every early approach to the subject has been limited by the fact that fineness below sieve size was not accurately evaluated. Furthermore, until recently it has been impossible to evaluate the resistance of any material to grinding, although it has been known that the performance of milling machinery varied with the grindability of the material. In fact, some mills which ground one material very well could not be used to grind another. Machines for crushing have been developed largely by empirical methods and keen observation. There is little tendency to standardize them, although they may be classified roughly into types for purposes of this discussion. The author has offered such a classification[3] into the five following types:

1 Direct-pressure mills—such as jaw crushers, gyratory crushers, stamp mill, and Symmonds cone crusher.

2 Roller mills—such as single- or double-roll crushers, differential rolls, Chilean mill, centrifugal roll mill, ball plate or roller plate mills.

3 Tube mills—such as ball or pebble mill and rod mill.

4 Beater mills—such as impact or hammer type, and cage mills.

5 Revolving plate mills—such as disk mills, buhr stones, and certain colloid mills.

The manner in which the mills apply load and the rate at which the particle is loaded differ between the types and even within the types. Then, too, these mills may be associated with liquid or air separators to remove a certain size of ground material from the finished product, and to return this to the mills for further grinding. While these differences between mills are apparent and will undoubtedly be emphasized in the discussion, it is the primary purpose of this paper to consider the grindability characteristics of materials, basic energy requirements for grinding, and the character of the finished product as it is affected by the entire processing.

Grindability of Materials

The properties of individual materials affect the rate and extent of their pulverization. With the increase in exactness of measurement and with the demands for greater fineness, measurement of the resistance of materials to pulverization has become significant. It is self-evident that a material like talc will grind differently from a material like quartz and that a mill which will grind talc to a certain fineness may not be capable of applying the necessary force to grind silica to the same fineness, or the mill itself may suffer from a prohibitive amount of wear in handling silica which would not be encountered in the grinding of talc. Then there is mica, which due to its plate-like nature offers very special problems in reducing it to thin particles rather than to rounded ones. Grindability of these materials has been largely estimated in the terms of the hardness scale or tested roughly by dropping a ball from progressive heights until the material breaks. A method has been devised for the estimation of the friability of coarse coal by dropping it to a surface of concrete and measuring the fineness of the resulting pieces.[4] Special materials like mica present a case where experience is necessary in the selection of the proper kind of mill to deliver a suitable product. These methods are not adequate. The industry recognizes this and is now calling for mills by number or by dimension rather than in terms of a general capacity figure.

In addition to the differences between different kinds of materials, the problem of grindability is significant within a group of materials. Take coal as an example, and the differences between anthracite and bituminous are sufficient to create a serious problem in the selection of a mill or in the estimation of its capacity. The differences are so pronounced that a mill which will adequately meet the demands with bituminous coal may not even produce a combustible powder when grinding anthracite. In one case, the capacity of the mill was actually reduced more than half by a change from bituminous to anthracite coal. Noticeable differences in mill capacity and in power consumed per ton of product are to be observed with different samples of bituminous coal. It is therefore necessary to evaluate grindability in some quantitative terms. First, it must be known quantitatively whether the material can be ground by a given milling action and at what approximate rate and power consumption, and then it must be known what is the nature of the resulting fineness obtained from this mill action.

Some effort has been made to evaluate grindability by measuring the change in the fineness of a material after a definite mill action. Hardgrove[5] accepts the Martin proof of Rittinger's law that the work done in grinding is proportional to the reciprocal of the particle diameter, and uses a mechanical mortar and pestle or a revolving ball crusher to create surface as a measure of energy. The original material is prepared in the range of 16 to 30 mesh, and the material after crushing is compared by sieving. Many coal and coke samples are compared as to grindabilities, and the values for coal range from the low 20's for anthracite to 119 for bituminous. He has discussed the bearing of grindability on mill capacity, and has indicated that with complete scavenging of fines from the grinding parts, mill capacity is very nearly proportional to grindability.

The author has used a laboratory jar mill for a comparison of this same property in abrasives. In this case it was important to know not only the change in surface, but also how rapidly the coarse material is eliminated and how much fine dust is produced.

TABLE 1 GRINDABILITY DATA ON ABRASIVES, IN PERCENTAGES

Mesh	Sample 1		Sample 2		Sample 3

[5] Hardgrove, R. M., "Grindability of Coal," Trans. A.S.M.E., vol. 54 (1932), paper no. FSP-54-5.

This may be illustrated by data on three samples of abrasive (see Table 1).

The initial materials are essentially of the same size, being chiefly in the 16–20-mesh interval. Sample 2 shows much more pronounced elimination of the coarse material than samples 1 and 3. Yet after grinding it contained less material finer than 50 mesh than did sample 3, which had resisted breaking. Such a method of test might be used to compare several samples as to their probable power consumption in a mill. It would not determine whether a special mill type was suitable for the original material. In a general way, as has been noted here, the differences in friability where coarse particles are broken through the grain and in abrasion where fine grits or impalpable powder is produced may be estimated by an observation of the shape of the final fineness curve. An exception may be noted where sharp materials are being compared with rounded materials as to abrasion resistance. The initial roughness may be significant and the particles may have to be subjected to a preliminary trial grinding to bring them to the same surface condition.

It is not alone in the manner of disintegration that grindability is significant. Mill capacity, power consumption per ton, and the quality of the product may be affected by moisture, the plastic nature of the material, and its susceptibility to heat. These factors may necessitate special types of mills or special processing procedures if they would not altogether prevent the reduction of the materials. Surface moisture increases mill power. For example, a certain pulverizing mill when fed coal of 6 per cent moisture requires an energy consumption of 15 kwhr per ton; when fed coal of 9 per cent moisture, uses 16.5 kwhr per ton; and when fed coal of 12 per cent moisture, uses 18.3 kwhr per ton. Thus moisture correspondingly decreases mill capacity, and it also limits the fineness to which grinding may be carried before there is cloggage of the mill through agglomeration of the particles. Drying is often effective in correcting these troubles. It is frequently done in a preliminary drier, but may also be done by the passage of warm air through the grinding mill. Often it is desirable to add more water and to grind wet. Some materials become plastic with increase in temperature, more particularly those materials which are near their melting points, such as sulphur and asphalt, and their grindability will change rapidly with mill temperature. Salts containing water of crystallization may be decomposed on heating, and the water which is evolved acts to impede crushing. Organic dyes may be injured or decomposed by elevation of temperature during the milling procedure. These difficulties are usually met by the practical common sense of the mill operator, and there is no quantitative method of estimating when they will occur or of evaluating their magnitude. The mill may be chosen of such a type to deliver the desired fineness with a minimum of heat. Refrigeration of the mill has been proposed to increase the grindability and to lessen the effect of heat. The material may be passed through the mill rapidly, so that it does not heat up. Then it may be further cooled, and there may be removed from it the portion which is sufficiently fine, using sieves or air separation. The cooled product or the oversize may be returned to the mill for further reduction.

It may thus be seen that the problem of grindability is one which has not been treated quantitatively, save with the possible exception of mill tests for evaluating this property. There is need for a thorough study and the actual correlation of this with crushing data. Such a study is particularly necessary in those fields where milling costs are a large proportion of the total cost, such as pulverization of fuel and the manufacture of portland cement. Through the present lack of knowledge on that score, purchasers have not been able to specify proper sizes of pulverizers and have depended on the guarantees of the mill manufacturers. As these guarantees have been largely based on experience, there has been considerable uncertainty and grief which might be avoided by quantitative evaluation of the grindability of the material to be processed.

Energy Requirements

The actual energy required for crushing or pulverization depends upon the ease with which the material may be broken, the fineness of the ultimate product, and the effectiveness of the mill in converting its energy input into grinding effort. With respect to the first two of these factors, the inherent nature of the material has been discussed under grindability. In any consideration of crushing, the basic energy required to produce the disintegration is of considerable interest.

For a long period, during which fineness measurements were largely in the range of sieve sizes, a dispute raged as to whether the Rittinger or Kick concepts of breaking energy were correct. Rittinger developed the idea that each new unit of surface produced in grinding required a fixed amount of energy to separate like material from like and to expose this new surface. From this concept he showed mathematically that the work of crushing is proportional to reduction in diameter. While the treatment is illustrated in terms of a cube, irregularities in actual surface of ground material may be taken care of by a surface factor. On the other hand, Kick's concept may be stated as follows: The energy required for producing analogous changes of configuration of geometrically similar bodies of equal technological state varies as the volumes or weights of these bodies. In other words, for any unit weight of particles the energy required to produce a desired reduction in volume of all particles in the mass is constant, no matter what may be the original size of the particles. This relation is based on the idea that elastic deformation of the particle takes place under loading and that the actual energy required to produce sufficient deformation for breakage is the theoretical energy. Stadler[6] and Taggart[7] have supported Kick, while Gates[8] and Bell[9] have supported Rittinger. Gates has developed the crushing-surface diagram to show graphically the relative efficiencies of crushing. The cumulative per cent undersize is plotted against the reciprocal of diameter for both the feed into the mill and the discharge from it. The area between the two curves is a relative measure of the energy expended in crushing, based on developed surface.

With respect to the Kick versus Rittinger dispute, the consensus of opinion among mining men has been formulated to the effect that the Rittinger law applies very closely to the actual performance of pulverizing mills. Kick's law has appeared to measure the performance in coarse grinding. The solution to this question has been regarded as uncertain because the measurements were practically all on sieve sizes, and the assumptions which were made with respect to sub-sieve size were open to great variation. With new tests available, the question has again been revived, and several contributions have recently been made. Martin[10] has compared the energy consumption in a ball mill with the new surface developed. An 18-in. by 18-in. mill with 1-in. steel balls and batch charges of silica sand was used for test-

ing. A method was devised to measure the rate of solution of the silica in hydrofluoric acid. The energy required for driving the mill with and without a charge of sand was considered as energy input. When energy input and these surface values were compared, he concluded that "in ordinary tube mill grinding the surface produced is accurately proportional to the work done." It has generally been conceded that the actual work of grinding may be but a small portion of the work required of a mill, and to avoid this possible error Gross and Zimmerley[11] have utilized the energy of a freely falling body to crush sand. They have modified the hydrofluoric-acid solution method to compensate for change of surface with time, and they too have found that the new surface produced varies with the energy input. Their conclusion is that, "when crushing quartz, the new surface produced is in direct proportion to the work input in accordance with the Rittinger law of crushing." It should be borne in mind that these crushing methods measure the overall energy accompanying disintegration and that the dissolution test has not yet been rigidly proved to measure surface. It is to be noted that in the exact measurement of surface the same essential method was used by both Martin and by Gross and Zimmerley. It has been suggested by some who have discussed these results that the rate of etching of sand by hydrofluoric acid may vary with the conditions of stress to which the particles have been subjected. These theoretical considerations, therefore, throw some doubt upon the apparent conclusiveness of the Kick versus Rittinger dispute, although a great amount of valuable information has been added in these investigations.

In connection with some recent work, effort has been made to determine the actual energy needed to develop new surface. The assumption is made that the theoretical minimum is the surface energy of the material in its given state of pulverization. Values of surface energy calculated by Edser at 920 ergs per sq cm and by Martin at 310 ergs per sq cm are somewhat divergent. But if these values of surface energy be considered as an order of magnitude, the calculated crushing efficiency is still exceedingly low.

TABLE 2 SURFACE ENERGY AND CRUSHING EFFICIENCY

Observer	Mill	Surface energy — Calculated by	Surface energy — Value, ergs per sq cm	Crushing efficiency, per cent
Gaudin	Rolls	Edser	920	1.3
Martin	Ball	Martin	310	0.06
Gross and Zimmerley	Stamp	Edser	920	3.0
Gross and Zimmerley	Stamp	Martin	310	1.0

The data in Table 2 are by Gross and Zimmerley,[12] and their comments are quoted briefly: "As the values for the surface energy of solids are unsatisfactory at present, some doubt is cast on the value of theoretical efficiencies. The foregoing efficiencies indicate that a large portion of the energy input in the crushing operation is dissipated in the form of heat. . . ."

Fahrenwald, Hammar, Lee, and Staley[13] have discussed the calculation of crushing efficiency and have given a critical treatment of the derivation of surface energy, introducing surface wetting as an important factor in grinding energy. They have developed a thermal method and carried out experiments which indicate mill efficiencies from 6 per cent to 25 per cent, approximately ten times those derived by surface-energy calculations: Even these values still leave from 75 per cent to 94 per cent of the energy input of the mill to be accounted for.

The investigations upon the energy consumption in grinding have shown, first, that overall energy input in crushing quartz is proportional to its rate of dissolution and probably to the new surface developed and, second, that the actual energy needed to develop new surface is a small proportion of that which is applied to the mill to obtain the crushing.

Fineness Characteristics of Ground Materials

Other investigators have studied the fineness of the ultimate product and have measured the fineness below sieve ranges by microscopic or elutriation methods. Thus, in addition to calculations of surface, the nature of the fineness-distribution curve is also known. These investigations have made possible further study of the nature of the crushing action in any mill. Heretofore such terms as compression, beam action, shear, impact, abrasion, attrition, and others have been used to define mill action in cases where no marked characteristic of fineness can be seen in the ultimate product. The fineness-distribution curves which have been obtained after careful measurement are not amenable to simple mathematical analysis, but rather may be treated with probability or statistical formulas. Martin, Blythe, and Tongue[14] have measured with the microscope quartz ground in a ball mill and have proposed an exponential relation of the type $N = ae^{-bx}$, where N equals the number of particles in a unit interval of average diameter x, and a and b are constants for each condition of grinding. Gaudin[15] has reported data on jaw crusher, rolls, rod mill, and ball mill, using quartz, galena and granite, in terms of graded sieve apertures and the percentages included in the sieve intervals. The sieve apertures have followed the Tyler scale, using either the fourth root of 2 or the square root of 2 as the constant interval. Below sieve size he has used sedimentation and has added those values to the sieve values. When per cent in a sieve interval and sieve aperture were plotted on a logarithmic scale, he found a constant paraboloid loop in the coarse range and a straight-line relation in the fine. He has expressed only the latter relation mathematically, as he has used it for calculations into the finer ranges of size:

$$y = Cx^k, \qquad dz = (C/p - 1)x^{k-1}dx$$

In these formulas y is the percentage by weight in the sieve interval x to px mm, and dz represents the amount in a uniform interval from x to $(x + dx)$. C and k are constants. He has noted a consistent exception to this straight-line relation when the materials are not homogeneous. In such a case breakage takes place preponderantly at crystal size, a point which he has checked by measurement of that crystal size in the original rock.

The author has investigated the situation by an experimental study in laboratory equipment and by an analysis of data already in the literature. Tables 3 and 4 present the test data obtained on dry grindings and on grindings in different fluids in a laboratory jar mill. These values were determined by combination sieving, elutriation, and microscopic sizing, and the smoothed distribution curves are presented in Figs. 1, 2, 3, and 4. As these small millings represent qualitatively the general action of a ball mill, there are some observations to be made as to the progress of grinding in such a mill. This mill action involves the gradual

elimination of feed material to produce particles ranging between feed size and zero diameter. As time goes on, the particles are further broken, with the ultimate elimination of the coarser sizes. The drift of the weight curve into the fine regions is progressively slower with time, as the number of breakings to produce a unit shifting is increased.

Differences may be noted in the dry grindings in which the weight of charge is varied. In the first case, 1100 g practically filled all the interstices between the balls. In the D series, the 400 g did not fill the interstices, and the charge was subject to freer ball action and greater ball load. Elimination of coarse material was more rapid in the D runs. However, for equal removal of coarse material, greater quantities of finer material were produced in the first series. (See Figs. 2, 3, and 4, and com-

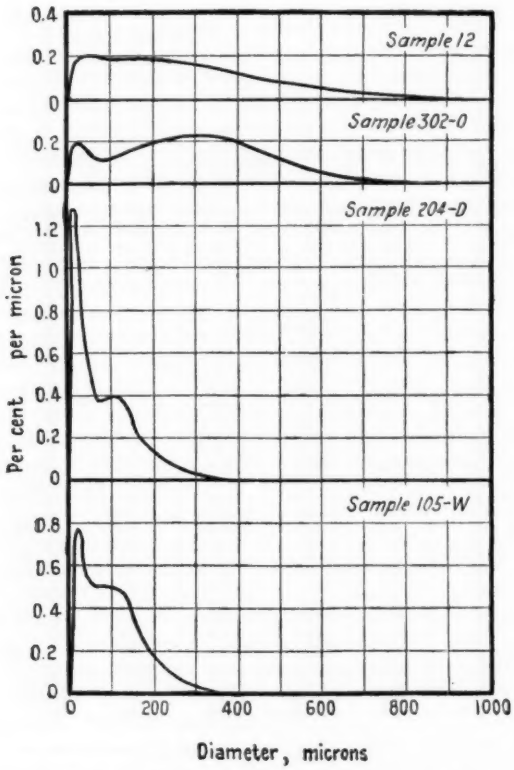

FIG. 1 CURVES FOR SAMPLES GROUND 1 HR

pare 205-D with sample 8 and 202-D with sample 7.) The grinding time to approximately equivalent fineness was on the order of the weight of the charge. This is not safe as a general conclusion.

Similarly, differences may be noted between the D, W, and O runs (400 g sand, dry, in 1200 cc of water and in 1200 cc of linseed oil). Increasing viscosity of fluid slows down elimination of coarse material. That the difference is not more marked between the D and W runs is probably due to the liquid dispersing the solid more widely. The action of elimination of particles seems to be a combination of the tendency to hold the particle in place for action and the slowing of the ball velocity. The O series was dissimilar to the first, but of the same order of time for equivalent grinding.

Grindings in the liquids gave a lesser content of extremely fine material. This is suggestive of a lubricating action which changes the predominance of wear to a larger size. In addition, the mill wear was greater with the dry grindings.

The data submitted in Tables 3 and 4 have been subjected to graphical and statistical analysis to determine the nature of the breaking of homogeneous solids. The same treatment has been used to fit values from other ball mills and also other types of mills.

Some of the samples tested by Weigel[16] and by Klein and Parrish[17] represent the products of direct grinding. Data on other mills submitted by Gaudin[18] and Haultain[19] have also been checked. It was observed from the large mass of evidence that the grinding of a homogeneous solid follows a relation involving at least two functions. The analysis of the relation requires consideration as to whether these functions are similar in all types of grinding operations and what is the basic nature of each of these functions. Beyond that, the problem is one of resolving the curve forms into these two functions, to study their variation with time of grinding and to show the application of the composite function for grinding operations.

A study of the relations as they occur in a large variety of fineness curves indicates the likelihood of purity of one function in the coarse range of sizes. In general it would seem that the other function which is predominantly for fine particles cannot be appreciable above one-third to one-half of the entire diametral range in which the particles occur and that it is actually significant only below one-quarter of the maximum diameter. It is thus possible to analyze the primary function over three-quarters of the diametral interval and to estimate its influence over the remaining interval.

This primary function is the "paraboloid loop" of Gaudin, when the data are plotted according to the sieve scale. In the per cent-per-micron plot it is the peak form in the coarse range. The frequency curve is much more illuminating. When the logarithm frequency is plotted against the corresponding particle diameter, the values fall on a straight line over the coarser three-quarters of the diametral range. Very small values in the extremely coarse sizes may appear to contradict this, but that is due to an overemphasis of insignificant values in the logarithmic plot or to unused feed. Ranging from the point of departure of the curve from the rectilinear down to zero diameter, there is a rapid rise which is considered indicative of the secondary function.

[19] Haultain, H. E. T., "A Contribution to the Kick Versus Rittinger Dispute," University of Toronto, School of Engineering, Res. Bull. No. 4, p. 145 (1924).

It is evident that the general statistical relation which fits this primary function is the exponential proposed by Martin, Blythe, and Tongue[20] as the law of grinding. Their experimental work was done on silica sand in an 18-in. by 18-in. mill with steel balls. Sizing tests were made under the upper three-quarters of the diametral range. These data, added to the other, are contributory evidence as to the nature of this as one function.

The residual frequency or weight may be considered to represent the secondary function. Typical curve forms are given to show how the primary function fits the total figure. (Fig. 5.)

In view of the graphical representation of the primary relation, attention was directed toward graphical representation of the secondary action. An adequate basis was found when total increments of the logarithm frequency above the primary line were plotted as a straight line with the logarithm of the corresponding particle diameter as abscissa.

The data submitted earlier in the paper have been tested with these relations. (Fig. 6.) Lest there be confusion due to the orders of magnitude of the frequency logarithms, and lest slight

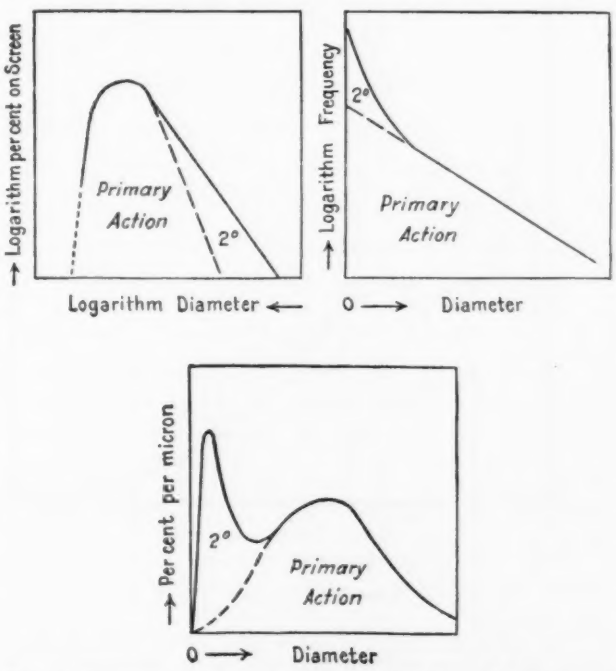

FIG. 5 DIVISION OF TYPICAL GRAPH FORMS INTO PRIMARY AND SECONDARY ACTION

variations of the points from the line be large on the weight basis, the frequency values taken from the straight-line relations have been calculated back to the per cent per micron, and the discrepancies have been noted there. This also has been done for a few curves taken at random from the experiments of Haultain[21] and of Gaudin[22] on the rolls and of Weigel[23] on the tube mill. (Fig. 7.)

Discrepancies occur at either end of the curve form, if at all. In the region of zero to two microns, they are usually small, being attributable to mill wear, dusting loss, and errors in the assumption of the mean diameter. The last factor is very important only when there is a great change in frequency across the range of the class interval. It was impossible to diminish the intervals sufficiently below 2 microns to eliminate this error.

[20] Loc. cit.

[21] Loc. cit.

[22] Loc. cit.

[23] Loc. cit.

The count in the lowest size range may be low, as the limits of visibility were close. These discrepancies have been so reduced in importance by the conditions of sizing that they need not be further considered.

Of greater significance are those few variations occurring at the coarse end of the curve. They have not been noted in the ball-mill tests, but are observed in some of the roll-mill data. They

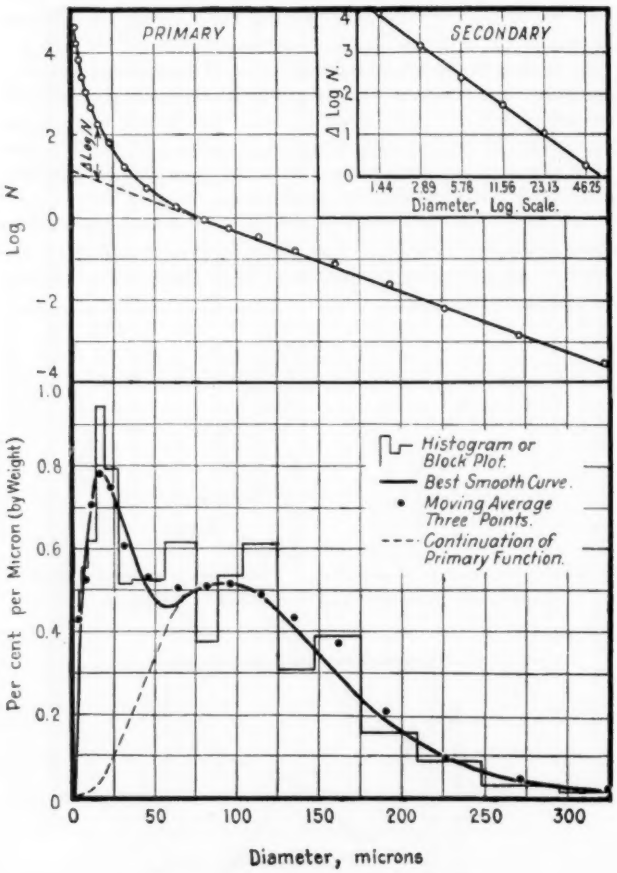

FIG. 6 RESOLUTION SAMPLE 105-W

show a greater elimination of coarse particles than the primary relation will permit. While some portion of this may be attributable to the effect of the roundness factor on the diametral measurement, the controlling factor is the positive sizing action of the rolls. Later analysis of the statistical formula will show how that can be.

There will be considered at this time a simple picture of the action which takes place in crushing to show how the general concept can fit the relations which have been proposed. The film of Haultain on the action of rolls in crushing shows that a particle may be disintegrated to produce a continuous function of size distribution from the maximum, near feed size, down to finer powder. It makes apparent the fact that the primary function may legitimately cover the full range from feed size to impalpable powder. The accumulation of such breaking action gives the general expression of the primary action in crushing. (Fig. 8.)

At the start of grinding there are N_d particles of feed size d. After a certain time, A_d particles of feed size will have been eliminated by breaking.

$$N_d - A_d = F_d$$

In breaking, one particle of size d will generate a statistical frequency in each of the finer ranges, as follows:

N'_{d-1} particles of size $(d-1)$
N'_{d-2} particles of size $(d-2)$
. . . . . .
N'_3 particles of size (3)
N'_2 particles of size (2)
N'_1 particles of size (1)

Each of these frequencies multiplied by A_d will give the total frequency in the respective size ranges, which are the result of the breakdown of feed size. (See Table 5.)

Similarly, further breaking will cause to be eliminated some of the particles of size $(d-1)$ to form finer particles, according to the law for the breakage of this size. The addition of the total of each of these breaking actions will give the resulting frequency for each size of particle in the total product of breaking.

From this relation, it is possible to observe the limitations of the exponential relation found to hold so generally and to analyze further the primary action in other types of grinding operation.

$$F_d : F_{d-1} : F_{d-2} : \ldots : F_3 : F_2 : F_1 = K$$

If the elimination factor A is a relatively small portion of the total, it may be neglected from the total of most of the frequency values. In addition, it is likely to be present in the same ex-

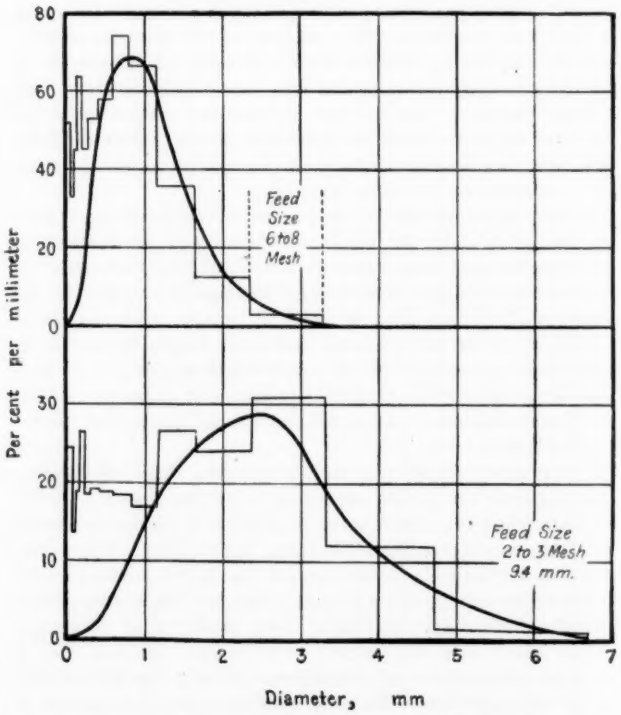

FIG. 7 HAULTAIN ROLL-MILL DATA; FITTED WITH CURVES OF PRIMARY ACTION

ponential relationship, as striking, and presumably breaking should be a function of the frequency of each particle size. It becomes suggestive that a unit-breaking action, such as the first, follows the exponential relation. A sized feed put through rolls, at not too great a reduction in size, would give that condition. There would be, however, a positive sizing action (the factor $-A_d$) of elimination.

The curves from Haultain's work fit well over a long range,

TABLE 5 SUMMATION OF PARTICLE BREAKINGS

Number of breakings	Size ranges: d	$d-1$	$d-2$	***	3	2	1
Feed	N_d						
First	$-A_d$	$+A_dN'_{d-1}$	$+A_dN'_{d-2}$	...	$+A_dN'_3$	$+A_dN'_2$	$+A_dN'_1$
Second	...	$-A_{d-1}$	$+A_{d-1}N''_{d-2}$	...	$+A_{d-1}N''_3$	$+A_{d-1}N''_2$	$+A_{d-1}N''_1$
Third	...	.....	$-A_{d-2}$	...	$+A_{d-2}N'''_3$	$+A_{d-2}N'''_2$	$+A_{d-2}N'''_1$
*****	...	.....	*****	...	*****	.....	.....
$d-2$	...	.....	.....	...	$-A_2$	$+A_2N_2{}^{d-2}$	$+A_2N_1{}^{d-2}$
$d-1$	...	.....	.....	.....	.....	$-A_2$	$+A_2N_1{}^{d-1}$
Total	F_d	F_{d-1}	F_{d-2}	***	F_3	F_2	F_1

while one of Gaudin's, carrying a high reduction ratio, shows the sizing action of the mill. When the rolls are set to less than minimum size of feed, each particle must be subjected to at least one breaking, and $N_d = A_d$. It may also chance that $A_dN'_{d-1} = A_{d-1}$, thus eliminating size $d-1$. The maximum particle size is controlled by this sizing action, and the elimination factor is necessary in such a formula as will express these cases. In ball milling, when the feed is eliminated and the accumulated fines are significant, the elimination factor and the feed factor are unimportant and the curve approaches more nearly its pure form. In that case, the elimination frequencies may well be proportional. If the breaking action is sufficiently positive so that each strike means the fracture of a particle, the frequency of breakage would be a function of the frequency of particle occurrence.

It has been observed that the secondary relation appears appreciable only below one-quarter of the maximum diameter. The lack of continuity with feed precludes its being directly the outcome of breaking. It seems likely that this is an action in which one particle loses a small corner without appreciable change in its own diameter and with the formation of a smaller particle. Until evidence is submitted to justify calling this action wear, this concept must be regarded as that of pulverization associated not alone with attrition, but possibly a secondary or even a different character of particle breaking.

For this action there has been found a straight-line relation between the logarithm of frequency above the primary value and the logarithm of diameter which is capable of analysis to a statistical formula. Log N_1 (representing primary relation) + $\Delta \log N$ (representing secondary relation) = log N (total).

$$\log N_1 + \Delta \log N = \log N$$

$$(N_1) \times \log^{-1} (\Delta \log N) = N$$

If $\Delta \log N$ versus $\log x$ is a straight-line relation,

$$\log x = q - p\,(\Delta \log N)$$

where

$$q = \text{value of } \log x \text{ when } \Delta \log N = 0$$

$$p = \text{slope } d(\log x) \div d(\Delta \log N)$$

$$\Delta \log N = -(1/p)\log x + (q/p)$$

$$\log^{-1}(\Delta \log N) = 10^{(q/p)}\, x^{-(1/p)}$$

Substituting

$$N = a(10)^{-bx}\,(10^{(q/p)}x^{-(1/p)})$$

$$N_1 = a(10)^{-bx}$$

Therefore

$$N_2 = a(10)^{-bx}\,(10^{(q/p)}\,x^{-(1/p)} - 1)$$

The statistical relation for secondary action may be taken as:

$$N_2 = (mx^{-n} - 1)\,a\,(10)^{-bx}$$

$$W_2 = (mx^{-n} - 1)x^3a_1(10)^{-bx}$$

where

$$m = 10^{(q/p)}$$

$$n = (1/p)$$

W_2 being the weight per unit diameter due to the secondary action.

The statistical relation which has just been expressed in mathematical terms has the significant feature that the secondary action is a function of the primary action and an exponential function of the particle diameter. This is to be expected from the concept which has been given. It may be assumed that, as the result of the secondary action, each particle gives the same number of finer particles of a specified diameter, which is to be a definite proportion of the original particle size. In such a case, the frequency curve for the secondary action would be an exponential, differing only in its constants from that of breaking. But though such a piece may statistically be the source of the same number of particles, they will actually be quite different in size. In addition, the frequencies observed at any one time are the accumulation of an earlier period, as well as those just produced. Breakage will gradually eliminate these, but account must be taken of the time effect. This leads to the conclusion that the expected relation is one dependent upon the primary function, with or without time lag, and upon the behavior of the individual particle in secondary action just pictured. The statistical relation is a reasonable expression of that concept.

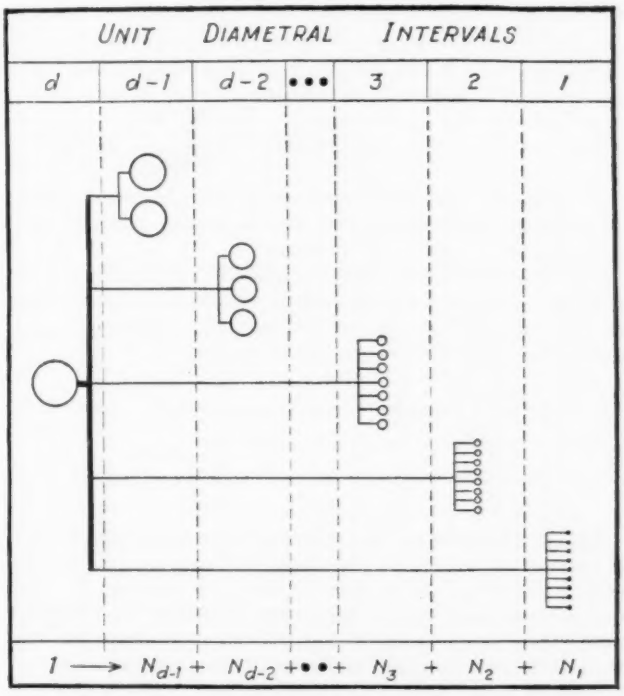

FIG. 8 GENERAL CASE OF BREAKING OF SINGLE PARTICLE

The formula may be limited where the exponential is not established for breaking, and possibly for excessively great wear. Variations will normally be introduced into these portions of the curve when non-homogeneous solid is ground. The graphical method is a simple means of determining the critical constants, and these in their turn are of use in defining the grinding action. The secondary function will be used between the limits of $x = 0$ and $x = \log^{-1}q$, to avoid negative values. The breaking function might better be used between feed size and zero to avoid an accumulation of small quantities between feed and infinity.

In themselves, the formulas derived from the graphical study are of use to secure the several values so frequently derived from fineness data. The materials which are both coarser and finer than 200 mesh are calculated by the weight basis for correlation, but ground products finer than sieve mesh or material sized microscopically over the range may be resolved directly. The constant corresponding to a will be erroneous, but that may be determined by resolution of the formula to the weight basis and making the total weight equal to 100 per cent:

$$100 \text{ per cent} = \sum_0^{\text{feed}} W = \sum_0^{q} 10^{(q/p)}\, x^{[3-(1/p)]}\, a(10)^{-bx} + \sum_q^{\text{feed}} a(10)^{-bx}\, x^3$$

Considering $W = dw/dx$, the form may be integrated, values of x substituted, as well as q, p, and b, and the constant a obtained for unit weight of the material.

Instead of performing a laborious calculation of surface at each diameter to secure the total surface, calculation may be made directly from this formula, by setting up the equation of unit surface and integrating to get the total surface.

$$\int_0^{\text{feed}} ds = \int_0^{q} (q/p)\, x^{[2-(1/p)]}\, a(10)^{-bx}\, dx + \int_q^{\text{feed}} ax^2(10)^{-bx} dx$$

The establishment of the constants also makes simple the calculation of any of the several diameters, based on weight, surface, or frequency, and what may prove to be more significant as well as more exact, the mean diameter of each of the functions independently. Take the weight basis as an example. If the mean diameter falls below $\log^{-1} q$ (or Q), the first portion of the summation will be divided, and that from zero to x equated to the second portion from x to Q, plus the breaking function from Q to feed. If it is greater than Q, the breaking function will be divided. Indications as to which one it is will occur in the signs of the summation. The same type of calculation may be used for calculations of mean diameter based on surface and frequency. (Table 6.)

Through the courtesy of Columbia University, the services of Dr. T. H. Gronwall were utilized in effecting the integration. The method involved expansion of the exponential, and an evaluation of the integral by Simpson's rule.

This analysis of the fineness characteristics of ground materials presents quantitative data on the trend of fineness in a small ball mill and a statistical treatment of the fineness distribution curves obtained in milling. There are shown to be two functions: the exponential of Martin and a secondary relation containing this exponential. The first of these relations represents the formation of relatively coarse pieces through direct breaking of the particle. The second represents the production of excess fines, either during or subsequent to breaking. Further analysis may show more exactly the origin of these laws and variations of the product with any mill type.

Physical Concept of Crushing and Pulverization

Innumerable terms have been used to define the actions of mills in the reduction of materials. These terms are in many cases the same as those used in a physical testing laboratory for the testing of specimens. It may be well, therefore, to consider grinding as a random physical test upon a peculiarly shaped specimen. Such factors as the nature of the substance, the shape of the piece, and the manner of loading will have an important bearing on the fineness of the resultant product.

The nature of the material under a testing machine will give some indication as to the manner of breaking in a mill. Take a metal like steel and subject it to compression. It will bulge slightly and finally break, probably into two pieces at an angle of approximately 45 deg with the direction of loading. Thus a ductile material is not easily crushed and does not easily produce dust. Take a more brittle substance like glass and subject it to compression after fracture. There will be the base cones or pyramids, some large pieces which will have broken from the sides, and a scattering range of sizes down to dust. The elastic deformation of material in the larger piece apparently produces several fractures, due either to multiple paths of breakage or to elastic recovery after breakage. A non-homogeneous material like concrete will furnish a similar fracture, but there may be less dust due to the fact that fracture tends to avoid the aggregate and passes around it. The analogy in grinding is shown in the work of Gaudin[24] where crushing disintegrates preferentially to the grain size of the material. There is another type of material which has either very easy cleavage or very weak bonding between grains. This finally disintegrates into an excessively large amount of uniformly fine material. Thus does the nature of the substance in the testing machine illustrate the wide differences in fineness distribution and in ease of breakage which may be obtained by compression loading in a mill—factors which have already been partially evaluated as grindability.

The illustration just presented covers only compression loading, and that under the conditions of flat, restricted ends. In grinding, the particles are usually round, and it is only by rare chance that a flat particle face meets a flat grinding face, but still a great amount of breaking is effected by direct pressure on these irregular specimens. The shape of the initial piece has a distinct bearing on the character of the fines which may be produced. A short investigation carried out by Norman Cudworth Cohn under the author's direction will show this difference. Silica gravel was sieved between $^1/_2$ in. and $^3/_4$ in., and the pieces falling within that interval were divided into three classes:

(1) Round or flat particles which in crushing between plane faces would have one point of contact on each face.

(2) Pieces which would have one point of contact on one face and two points of contact on the other face—bridge loading.

(3) Pieces which would have one point of contact with one face and three points of contact with the other.

Each individual stone was subjected to breakage in a small receptacle in a hydraulic press. The receptacle was stopped in its advance as soon as rupture had occurred. When the dust

[24] Loc. cit.

had settled, qualitative observation was made of the breakage, and the broken pieces were stored with the others of their kind. Table 7, of sieve percentages, will show a noticeable decrease in the finer sizes with a bridge support; in other words, the tension break produces less dust.

TABLE 7 SHAPE OF PARTICLE

—200.....	— 0.074	0.856	1.208	0.607

It has just been shown that the manner of loading may produce tension, and that tension tends to produce less fines. Grinding mills introduce other factors in the manner of loading which are predominantly selective with respect to size. There is a type known as impact or beater mill in which a piece of material is thrown from a revolving paddle at a high velocity and forced to impinge on a fixed wall. In such a mill the finer particles are likely to follow the revolving air stream and not strike the wall directly. The harder coarse particles may strike the wall, but not at sufficient velocity to produce fracture. It is further conceivable that the type of fracture produced is that caused by rapid loading where the stress is highly localized and preceded the fracture with but little deformation of the entire specimen. In a physical testing laboratory the impact machine would bear the closest analogy to this action, but it must be remembered that most impact machines produce a wedging action with corresponding fracture in tension. Impact breakage produces a minimum of dust. Another selective action which is well known is that of the ball mill. A very coarse feed may not be subjected to sufficient loading by the tumbling of the balls or the compression within the mill to produce initial fracture. Smooth rounded pieces occasionally remain for long times with the grinding elements.

Thus it may be seen by analogy with the testing machines that there are wide differences in the manner of particle breakage which are inherent in the nature of the material and in the manner in which the load is applied. Shape of the particle may, within the same mill, produce differences in the manner of loading. The mill action may be selective, tending to load the specimen in such a way as to produce breakage to predominantly coarse sizes or by failure to act on specific sizes of particles.

Effect of Separating Devices

Separating devices are quite commonly used with mills in what is known as closed-circuit grinding. The charge is run rapidly through the mill, and then goes to a separator, which removes the oversize and returns it to the mill, allowing the undersize to pass on as finished product. This separation may be effected by the use of an air classifier or a liquid classifier, depending upon which is the medium for grinding. The purpose of closed-circuit grinding is largely one of economy. It also permits the production of fine material free of coarse grits. This may be important in the burning of portland cement, where large grits may introduce free lime or insoluble residue in the final product, and in the burning of powdered coal, where coarse particles pass rapidly through the flame without burning completely. Thus closed-circuit grinding is commonly used in the production of fillers for rubber or paint to eliminate particles coarser than 300 mesh which would be objectionable in the finished product.

These advantages are not to be gained without some compensating loss with respect to fineness characteristics of the finished products. It would be a mistake to assume that a product obtained by classification had the same surface as one obtained by direct grinding. This may be illustrated by a comparison of samples 11, 8, and 7. Sample 11 has been ground for two hours, and approximately one-quarter of the material is finer than 50 microns. This would be more uniform than that of either sample 8 or sample 7, and there would be much less exceedingly fine material. Sample 8 having been ground 5 hours is much finer, and approximately 15 per cent is over 50 microns. This could be eliminated by a classifier, with a resulting fineness distribution which would show an appreciable amount of fines, but an amount not equal to the fines of sample 7, where the

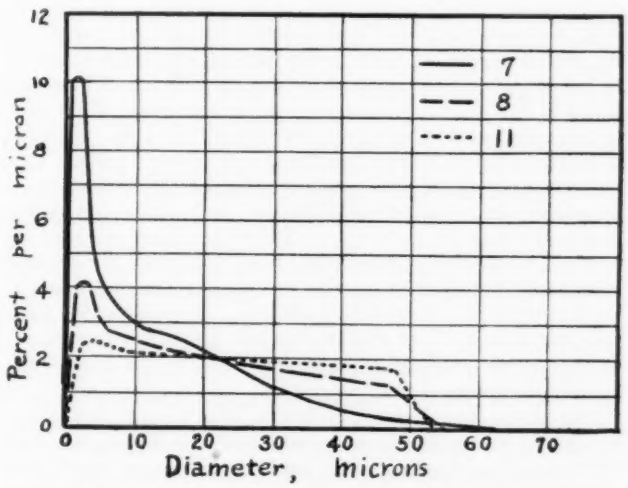

Fig. 9 Action of Classification on Ground Sand

product is ground to 50 microns. The distribution of the fineness of the final product is illustrated graphically in Fig. 9.

Separating devices permit of a marked economy of power and maintenance in the production of a material below a given upper limit of size, but the product is, at the same time, considerably coarser than one brought within the same size limits by direct grinding.

Practical Considerations

Sufficient mention has been made of the different types of crushing and pulverizing mills to show the diversity in operating characteristics. It is also clear that different types of mill have been commercially adapted to similar products, and only rarely is one type of mill used to the exclusion of all others. For example, in the pulverization of coal, hammer mills, roller mills, and ball mills all have their advocates, whereas in the final pulverizing of cement it is almost exclusively a tube-mill operation. At the present time there are not sufficient quantitative data to make easy the selection of mill types, or even of mills within a type, for a definite grinding problem.

The principles which have been laid down here illustrate the importance of grindability. A material which is difficult to grind should be reduced in a mill having extended wearing surface, parts which can be easily replaced, and a relatively slow and positive grinding action. The higher-speed mills with correspondingly less wearing surface find their application with materials offering less difficulty in grinding.

A consideration of energy requirements has shown that there is a large wastage of power over that needed to produce reduction in size. Therein lies an opportunity to improve the present milling procedures as well as an opportunity to compare the actual mill power with basic energy.

The statistical treatment of fineness curves and the analysis of the nature of breaking confirm the earlier work of the author on the difference in fineness-distribution curves produced under different grinding conditions and by different types of mills. Proper choice of the mill, proper loading, and the application of separators offer the opportunity to produce material of specific size characteristics or to produce material below a given size at a minimum of cost. The principles of closed-circuit grinding which have been used for years in mining industries are applicable in the finer range of sizes and offer a still greater economical advantage.

Discussion

R. M. Hardgrove.[25] Too frequently we take the product as it happens to come from the pulverizer, without much effort to fit the products to the needs of the process. For most purposes the ideal product would all lie in a very narrow range of sizes, as both oversize and undersize are usually objectionable. In some processes—as for example, pulverized coal for burning and pulverizing cement clinker—a large surface is desired; but even in cement, too large a percentage of the very small sizes is considered undesirable by some authorities. Efforts are being expended to produce a product approaching a uniform size, eliminating objectionable oversize and saving power and increasing capacity by minimizing the amount of undersize. A control of the fineness distribution in dry grinding can only be obtained by classification, either combined in the mill by air or screens, or external to the mill by screens or air separators.

Pulverizers are extremely inefficient, as is brought out in the paper, and this is largely so because not enough attention has been given to scavenging. If finished product is allowed to remain in the mill, it cushions the grinding action decidedly, and the more thoroughly we remove the fines as soon as they are produced, the higher the efficiency.

Batch grinding is extremely inefficient for that reason, and in open-circuit tube mills the bulk of the work is done in the inlet end where the charge is not cushioned by finished product.

The improvements made in the last few years in capacity, power consumption, and efficiency of pulverizers have all been produced by more recirculation and scavenging and lead us to believe that no pulverizer in use today is producing more than a small fraction of the work that it is really capable of doing, if the material were introduced to the grinding zone without having useless work done on it, and removed as soon as it was pulverized to the required size.

The paper quotes a pulverizer efficiency of 3.0 per cent based on the Gross and Zimmerley constant of 17.56 sq cm per gm of surface per kg cm of work when pulverizing quartz. While this method may not be entirely correct, we can use it in comparing the efficiency of more modern pulverizers.

Mills of the ball-bearing principle using air classification within the mill are daily indicating an efficiency of over 4 per cent, including motor and gearing losses, compared to the 3 per cent for open-circuit tube mills.

Another mill of this ball-bearing principle installed in a cement plant in closed circuit with an air separator is daily showing an efficiency of 5.7 per cent, including motor and machine losses, or nearly double that of the tube mills on open circuit commonly used for grinding cement rock. These results are possible by the use of a grinding principle which applies the force directly to the particles to be pulverized without lifting any unnecessary dead weight, by the low friction losses, due to the true rolling action of the balls, and by the high recirculating load and efficient scavenging. The laboratory method of determining grindability has proved to be extremely useful and reliable, and the more general use of this will enable us all to speak the same language, and eliminate one of the unknowns from the pulverizing problem.

The life of the pulverizer parts, however, seldom has any relation to grindability. Wear is a result of the combined abrasive and erosive action of the material being pulverized. In an impact mill the action is largely erosion, while in a tube mill it is largely abrasion. In mills having a true rolling action it is a combination of both, but is largely erosion. There is a vital need for a reliable index of the abrasive and erosive action of the various materials to be pulverized.

Metallurgical developments have contributed to the pulverizing art by supplying metals at a reasonable cost that have a relatively slow rate of wear, so that it is no longer necessary or good economy to choose a bulky and inefficient pulverizer even for cement rock or clinker.

Horace C. Porter.[26] As a member of Sub-Committee 7 on Pulverizing Characteristics, of Committee D-5 on Coal and Coke, American Society for Testing Materials, the writer would call attention to the work and objects of this sub-committee. As Dr. Work points out, the power requirements and the pulverizing results obtained are very different with different coals. Different types of mill are required for different coals. In burning coal, the surface exposed per unit weight (and also per unit volume, which has to do with density of the cloud) is of paramount importance. This surface factor is dependent upon fineness and shape of the particle.

Dr. Work brings out the effect of closed-circuit grinding on the size-distribution curves for the resulting material. This is very important with coal and is quite generally put into practice. The power requirements are affected thereby, and it is only necessary to produce such a degree of fineness as will permit of complete combustion under the conditions pertaining in the furnace used. There is always the question, however, whether finer pulverization, requiring more power, may not be justified by the better results to be obtained in burning rate and furnace capacity.

Coal is a non-homogeneous material. There are present not only mineral inclusions, most of them harder than the coal substance, but also physically different layers in the coal substance itself. These layers have been found to vary a great deal in hardness and grindability. Friability and grindability are not the same. The former, it has been proposed to determine by a drop or shatter test which by impact produces with different materials a different proportion of fines. Grindability, on the other hand, introduces the different function of abrasion or rubbing of surfaces in addition to the impact function.

It has been thought best in this A.S.T.M. sub-committee to concentrate on a testing device which will introduce both impact and abrasion—namely, the ball mill, with suitable proportion of balls to total space. Any test of this kind, however, is necessarily an arbitrary one and cannot duplicate exactly the conditions of practice.

The moisture in coal, as Dr. Work mentions, is of great importance in affecting its grindability. It may be added that the manner of moisture combination is also extremely important. Some of the moisture in coal is free, and other parts are in combination or physically retained in capillary pores. These

[25] Research Engineer, Babcock & Wilcox Company, Bayonne, N. J. Mem. A.S.M.E.

[26] Consulting Chemical Engineer, Philadelphia, Pa.

forms of moisture have different effects on the brittleness and grindability of the material.

The coking power of a coal, sometimes called cokability, has an influence on its grinding characteristics. A well-known rough indication of cokability is the packing together of fine coal during the grinding process in a mortar or in some types of mill. Temperature, of course, has a large effect on such plastic materials as pitch and wax, possibly also on some kinds of coal.

It may be of interest, in connection with determination of total surface exposed by fine particles, to mention the work of Ralph A. Sherman and C. E. Irion at Battelle Memorial Institute, Columbus, Ohio, who are attempting various physical methods (other than microscopic counting and calculation therefrom) for the determination of surface. Among these are the adsorption of dyes, which depends essentially on the surface exposed, and the adsorption of radioactive material. It has been the writer's opinion that such methods would be complicated by the fact that total surface within the capillary pores might be indicated rather than the exposed surface of the particle as a whole.

The work of the sub-committee has not yet resulted in a standardized method of test, but it is believed that one will be developed as a result of the various studies, such as these of Dr. Work and others in this field.

Anthony Anable and B. J. Larpenteur.[27] Theoretical studies such as these are the greatest advantage, as in the final analysis all improvements in the technique of practical grinding are based upon the application of such theories as Dr. Work has deduced in this paper. In comparing various grinding devices and in comparing one method of grinding with another, Dr. Work has based his comparison on the amount of energy liberated, all of which he measures on the basis of Rittinger's units of total surface produced. While this is entirely satisfactory from the theoretical standpoint, we doubt whether this is of prime importance to the practical plant operator whose chief concern is the producing of the maximum amount of material just through a given mesh per unit of cost.

It is true, as Dr. Work has noted, that closed-circuit grinding produces a material which does not contain as large a percentage of fines as does an open-circuit grinding installation with both handling the same amount of material and both grinding it so that all of it passes a given mesh. This is due to the fact that closed-circuit grinding, through the rapid elimination of finished material from the system, does not tend to overgrind to the same extent.

It is the writers' contention that this very fact, the reduction of overgrinding, is a distinct benefit and one of the chief advantages of closed-circuit grinding. The practical operator in both the metallurgical and industrial fields has generally found, from tests or experience, the exact degree, measured by meshes or microns, to which his particular material must be ground in order that it may be treated efficiently in the next processing step. Any production of material finer than this critical mesh may be of interest to him from the theoretical standpoint, but nevertheless it has very little practical significance, since this finer product is not needed and has consumed power and grinding media which cannot be justified from an economic standpoint.

It is a widely known fact that closed-circuit methods of grinding have become practically universal practice in all metallurgical operations as well as in many operations in other fields where the tonnage to be handled is great and where one of the chief manufacturing costs is that of fine grinding.

Experience has shown that an open-circuit cylindrical mill will consistently produce more and more material of a certain fineness and will liberate more and more energy measured by Rittinger's surface units and Kick's energy units, as the rate of feed to the mill is progressively increased. This relationship was shown by E. W. Davis as a result of studies at the Minnesota School of Mines. In order, however, to take advantage of this progressive increase in output and liberation of energy, it has been found necessary to close the circuit by means of a separating device or classifier so that only material of the desired critical size may be released from the circuit for subsequent processing. The large amount of oversize which obviously is carried through the mill, due to the heavy load, may be returned for further grinding, and thus retained within the circuit until it has reached the point where it can be used economically in the next step. In addition, then, to the elimination of objectionable overgrinding, greater tonnage production results from the increase in the amount of material being passed through the mill at any one time.

When grinding in closed circuit, the mill is fed at several times its "open circuit" rate, the material races through the mill in a fraction of the usual time, and the product entering the classifier may contain as little as 30 to 40 per cent of finished material, with some material almost as coarse as the new feed. No attempt is made to finish the reduction in a single pass through the mill, but rather every effort is made to remove the material from the system just as soon as it reaches the required fineness, thus allowing the balls to work unhampered on the unfinished particles. The fact that capacity increases without corresponding increases in power is attributable to the more rapid elimination of fines, the reduction of uneconomical overgrinding, and the increased amount of coarse material which may be exposed to the cascading balls at one time. In practice the ratio of circulating load to new feed is generally in the neighborhood of 2 or 3 to 1, while in some instances the circulating ratio has been carried to 10 to 1 advantageously. Many engineers feel that the economic limits as regards circulating load ratio have not been reached with present practise. A new Canadian installation will employ an 18-to-1 circulating ratio for grinding a hard gold ore.

The practical and commercial aspects of fine grinding must not be lost sight of, even in the case of such an excellent theoretical paper as this of Dr. Work. The production of a very fine product, the liberation of energy, and the producing of increased surface are of definite interest to those who are working out the theoretical concepts of fine grinding. However, these are generally of only secondary importance to the practical man who is not especially concerned with any material ground finer than his own particular critical mesh, and is inclined to regard the presence of "superfines" as definite evidence that he is wasting his power unnecessarily and that his grinding system is not operating at the maximum economic efficiency, although it may be operating at the maximum theoretical efficiency.

G. F. Metz.[28] While the author has set forth much of theoretical interest to engineers interested in grinding, it is believed that a few comments, as the result of our own laboratory and field experience, would be of interest. We have found that the use of a jar or batch mill to determine the grindability of various materials is a step in the right direction, but that it is wrong to use the capacity information from this size mill in figuring capacities of larger diameter mills, or as Martin has worked out in his paper entitled, "The Science of Grinding." In this paper he takes an 18-in. by 18-in. ball mill using 1-in. steel balls and from the work of this small machine calculates the amount of power required to grind 3 tons per hour of silica sand from approximately minus 20 plus 30 mesh to 99 per cent through 200 mesh. We have found that the larger diameter mills are

[27] Engineers, The Dorr Company, Inc., New York, N. Y.

[28] G. F. Metz, Division Engineer, Hardinge Company, Inc., York, Pa.

much more efficient than the smaller sizes. For instance, a 10-ft conical ball mill will grind 15 to 20 per cent more tons per horsepower through a certain sieve mesh than the 8-ft mill. This we attribute to the tremendous mass action in the larger diameter mill. It is this same mass action which allows us to adjust our ball charge to the particular reduction required rather than to the coarsest particle fed to the mill. Due to the tremendous drop of the charge in a 10-ft mill we can use smaller balls than, for instance, on the same material in an 8-ft mill when attempting to grind to the same fineness.

The batch mill is no indication of actual power required in modern grinding equipment, as no provision is made for the removal of finished material, which in itself cushions the grinding charge and prevents efficient reduction. In continuous mill operation, where the mill is operated in conjunction with a classifier, regardless of whether it is wet or dry grinding, there is a continuous removal of fines from the grinding circuit, leaving the mill charge free to work on coarse and granular material.

Referring to the author's quoting of Gross and Zimmerley, it is the writer's opinion that all energy input in a ball mill is dissipated into heat, except that portion which is stored in a deformed particle as potential energy, which in itself would be released by a slight additional blow in the form of heat. The author states that grinding in liquids gave a lower content of extremely fine material. We have found that it is not true generally in practice, and that it is just as easy to obtain superfine material in wet grinding as in dry. All our experience has been that the wear on the parts is greater in wet grinding mills than in dry grinding. For instance, on limestone, the total steel consumption is not over $^1/_4$ lb per ton in a conical ball mill equipped with air separation, when grinding to around 90 per cent through 200 mesh. On the other hand, wet grinding on this same material in a conical ball mill shows a ball wear of $^1/_4$ lb per ton and a lining wear of $^1/_4$ lb per ton, making a total steel consumption of $^1/_2$ lb per ton. The same is true in ore grinding. The steel consumption in wet work is at least two to four times as great as for the same reduction in dry grinding.

In a paper entitled "Modern Grinding" by J. C. Farrant, before the Chemical Engineering Group at Derby, England, on January 23, 1931, the author classifies mills as follows:

1 Low speed (attrition and impact): Pan mills, buhrstones, Hardinge conical ball and pebble mills, cylinder ball and pebble mills, tube mills, rod mills.

2 Medium speed (compression): Ball ring mills, multiple-ring roll (horizontal ring), multiple-ring roll (vertical ring), single-ring roll, vertical emery mill.

3 High speed (impact and shearing): Hammer mill, cage disintegrator, impact mill, shredders.

Based on actual operating data he has listed various materials as being applicable to this list of grinding machines, and in a great many cases some machines which will pulverize the harder materials will do equally as well on the softer ones as even those machines which are designed primarily for soft materials. In Mr. Farrant's paper he has listed considerable actual operating data on modern installations, and it is believed his paper would be of interest to any one having grinding problems.

Laboratory results in grinding experiments, as far as ball and pebble mill tests are concerned, show lower capacities per horsepower input than commercial operations. This is due to the absence of mass action. The height of ball drop on the same size particle in a commercial grinding mill causes much greater impact and considerably more fines on the initial break. Also for a fineness to a given mesh, a commercial mill will show considerably more superfines than the laboratory mill, which we attribute to the foregoing mass action.

MARTIN FRISCH.[29] The statistical method devised for analyzing the performance of crushers and pulverizers, especially for predicting size distribution and for searching out the meaning of the results of sieve analyses, will prove useful to many interested in pulverizers and pulverizing processes.

Unfortunately, so complex are the processes with which this paper concerns itself that even a method of such as introduced by this paper cannot be applied at once to meet the requirements of every one. The requirements of each industry employing pulverizers differ. Size distribution may be all important in one industry, whereas in another, color or specific weight of the product may be the criteria which determine whether or not the performance of a pulverizer is satisfactory. The problems of those who pulverize coal for combustion are probably simpler than those of the chemical engineer. Size distribution as such is of relatively small importance provided the product has a minimum fineness as measured by some one sieve. This minimum fineness is not the same for all coals. The design of the furnace in which the coal is burned is also an influence. Since the performance of most pulverizers sold for the purpose of preparing coal for the firing of furnaces is defined as so many tons per hour at a particular fineness, through say a 200-mesh screen when the size of feed is such that all will pass a screen of a certain size, and when the feed of a given grindability contains not more than a given maximum per cent of moisture, it becomes obvious that particle-size distribution is not as important to either the seller or the user as are such things as the effect of size of feed, initial moisture content, grindability, and ultimate fineness of product on the capacity.

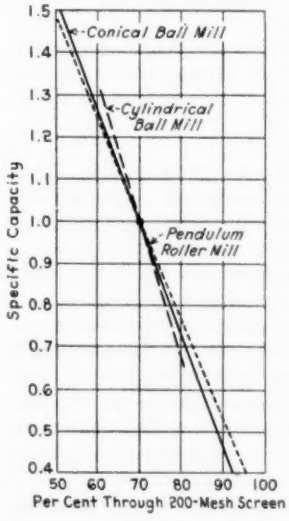

FIG. 10 EFFECT OF FINENESS ON PULVERIZER CAPACITY
(Capacity at 70 per cent through 200 mesh = 1.0.)

Much work has been done to determine the relation between combustion efficiency and fineness. It has been found that greater fineness means more complete combustion and hence higher efficiency. But it has also been found that even with relatively coarse grinding the combustion efficiency is so high that little is to be gained from finer pulverization that could be justified by the increased expense for obtaining the increased fineness. The capacity of each pulverizer drops off very rapidly with each per cent increase in fineness as measured by the standard screen, which happens to be the 200 mesh. Hence initial investment in pulverizing equipment increases quite rapidly. For example, a study has been made of the effect of fineness on the capacity of pendulum roller, cylindrical, and conical ball mills. As shown by Fig. 10, the reduction in capacity with increase in fineness was very marked for each, and of about the same magnitude. Tenney, in his paper, "Pulverization and Boiler Performance," dated February 11, 1931, has shown that the most economical fineness for Illinois coal is approximately 57 per cent. For other coals the most economical fineness may be greater or less, depending on whether the coal is of a coking or free-burning variety.

A pulverizer may be expected to yield from 25 to 50 per cent greater capacity, all other conditions being the same if the size of feed is reduced from all through 1 in. to, say, all through $^1/_4$ in.

[29] Foster Wheeler Corporation, New York, N. Y. Mem. A.S.M.E.

This principle has been tested in the cement-clinker-grinding field as well as in plants pulverizing coal for firing boilers. Whether or not such precrushing is justifiable depends on economic factors generally peculiar to each particular installation.

The effect of moisture on capacity is also very marked, as the author has suggested. Moisture is one of the most serious factors to be contended with in the pulverization of coal. In the early days the use of coal driers was deemed a necessity, because it was found that if the moisture exceeds a certain critical value, depending on the kind of coal and on the type of pulverizer used, the capacity of the pulverizer may be so reduced as to make the pulverizing equipment inadequate to meet the load requirements. In some cases the capacity might disappear entirely. In general, it may be said that for most pulverizers each per cent increase in surface moisture reduces the capacity of the pulverizer from 3 to 7 per cent. The detrimental effects of moisture in the feed have been partially offset by the use of preheated air for carrying the coal out of the mill. The preheated air partially or entirely dries the coal during the pulverizing process and materially increases the capacity with wet coal.

Of all the factors influencing the performance of a pulverizer, grindability is one of the most important. Unfortunately, no standardized method has yet been developed for determining the grindability of coal which all may use as a basis for reporting their findings to the same scale. Due credit must be given to Mr. B. J. Cross, who first developed the laboratory method now most generally used, and to Mr. R. M. Hardgrove, who later developed an improvement on this method. Grindability as defined by Cross and Hardgrove unfortunately does not measure the capacity of a pulverizer directly, because the output of a pulverizer is not directly proportional to the grindability. However, a relation can be established by experience between the output of a pulverizer and any grindability scale. Some doubts have been cast by many on the value of grindability tests because the performances of pulverizers sometimes do not seem to be consistent with the laboratory grindability determinations. These doubts should disappear when the results obtained with commercial pulverizers can be properly interpreted and reduced to a common basis. It is obvious in view of what has already been said as to the effect of initial feed size, moisture, and fineness of the ultimate product that in order to be comparable the results of tests with commercial pulverizers must be corrected to a common basis as to feed size, initial moisture content, and fineness. The company with which the writer is connected has determined the grindability of a large number of coals in its laboratory, and after comparing the results of these tests with actual performance of its pulverizers when grinding those coals we have found that if the results are corrected properly the pulverizer performance is accurately predictable on the basis of the laboratory grindability.

These remarks are offered because, in the writer's opinion, the field of those who would study pulverizing processes mathematically is still unexplored and full of possibilities. Obviously, in the present state of our knowledge a mathematical analysis is of very little value, except to a restricted few. Materials to be pulverized so lack homogeneity and the yardsticks by which we measure whether a given treatment for these non-homogeneous materials yields satisfactory results vary so widely that for a long time to come little may be expected of a purely mathematical study. Statistical analysis of the final product described by the author may help us to understand better what happens in a pulverizer if used in conjunction with experience. But experience must be relied on more for the present.

H. P. Reid.[30] The writer will limit his comments to four general subjects, as follows:

[30] Special Engineer, Universal Atlas Cement Co., Chicago, Ill.

1 In the classification of the general type of machines for reduction of the size of materials, the author has failed to mention the jet impact type of pulverizer. This machine has been used relatively little in this country but it has possibilities and characteristics which may bring it into service for certain desired material reduction. In general it may be said that the jet impact mill may be subdivided into two types—first, that with the use of a target or wear plate or wear body against which the material to be reduced is jetted or blasted, and, second, that with several jets of the material and gaseous or fluid vehicle impinging or impacting each other.

2 In the production of surface exposure, it may be possible with some materials to obtain, by selected milling processes, particles which vary decidedly from spheres or cubes. Where such is possible, the desired chemical reactions may be obtained with apparently coarser particle sizes or more complete chemical reactions may result with a given particle size, as measured by sieves, than would result were the material broken to near-spheres or near-cubes. This may decidedly change the type of mill selected.

3 Fahrenwald, Hammar, Lee, and Staley have, according to the author, carried out experiments which indicate grinding-mill efficiencies from 6 to 25 per cent. With 75 to 94 per cent of the energy input to be dissipated in some useless way, one wonders just how this dissipation takes place. It must be mostly to heat and sound energy. That part which is dissipated as heat must tend to raise the temperature of the material load of the mill. Apparently very little study has been made of the effect of this temperature rise on the grindability of the material. The author enumerates several materials whose properties would be injured by temperature rise, but has not pointed out the possible loss, from even the 6 to 25 per cent grinding efficiencies, which might and in fact evidently do result with many ores and stones. Particularly does this temperature effect appear to be detrimental with extremely fine grinding. There seems to be a greater tendency for the extremely fine particles to cohere, to coat the grinding media, and to build up cakes which cushion the grinding action as the temperatures rise. The exact nature of the heat action and the temperature limits for optimum grinding conditions apparently have not been fully investigated. It may be possible to reduce the amount of the energy dissipated as sound by proper design of mill and of its foundation, etc. But were this accomplished, what would be the net result? Would any more energy be made available for particle reduction with the random action of the grinding media, especially with tube and ball mills? If the energy now dissipated as sound were transferred to heat, the net results would very likely be higher temperatures and increased coating and cushioning actions, which in turn would probably mean still lower mill efficiencies.

4 The author refers to various methods which have been suggested, some of which are in use, for determining the relative grindabilities of materials. He has also pointed out the serious effect of moisture on grindability of coals. Apparently, very little is known of those properties which affect grindability. May it also be that we know relatively little about measuring grindability? Hardgrove has reported some very interesting studies on the grindability of coal. His work has placed a large question mark on the entire subject as he finds coals which have nearly the same general chemical and physical characteristics that differ widely in grindability. What are the factors which govern grindability? Can these factors be economically altered by methods used in drying, treating, storing, etc., of materials which are to be pulverized? Portland cement clinker is produced by heating finely ground raw materials to approximately 2700 F. The methods used in cooling of this clinker to grindable temperatures apparently greatly affect its grindability. Quick quench-

ing of the clinker fractures the lumps by innumerable hair cracks, thus simplifying the crushing. Again the age of the clinker when ground apparently affects its grindability. If this is true with portland cement clinker, may there not also be controllable factors or pretreatment of other materials which could be economically used to reduce the costs of pulverizing?

It thus appears that there is a need for much more research on particle-size reduction of materials in general.

G. H. KAEMMERLING.[21] Probably the most striking fact brought out in the paper is the great discrepancy between the maximum and minimum figures on crushing efficiency. It has been recognized for some time that available pulverizing processes are very inefficient with respect to the utilization of the energy supplied, and even the maximum figure proposed for crushing efficiency leaves a wide margin for improvement. It does not seem likely that ordinary refinements in current pulverizing methods will go very far toward closing the gap between actual and theoretical efficiency. Once given a mark to shoot at, in the form of a generally accepted basis for estimating the theoretical energy requirement for any degree of reduction of a given material, engineers may be expected to investigate more closely the mechanism of the energy losses in present pulverizing methods, with the purpose of developing new and more efficient methods. The determination and satisfactory establishment of such a basis will constitute a very valuable research work.

In the case of a non-homogeneous material, such as coal, there are differences in resistance to crushing among the particles of a given size produced during the pulverizing process, due not only to cleavage planes containing ash, but also to the variation in crushing resistance of the constituents of the coal compared with the constituents of the ash. In the commercial process of pulverization the coarser particles are retained in the mill, or removed and returned to the mill, until sufficiently reduced. This results in building up a charge in the mill of greater average hardness than the feed. It is possible that this effect is not important with ordinary Eastern coals. In the case of coals containing a high percentage of abrasive ash, however, a laboratory investigation of the rate of reduction of the different constituents would produce interesting information regarding the effect of ash content and character on power and maintenance requirements.

[21] Research Director, Erie City Iron Works, Erie, Pa. Assoc. Mem. A.S.M.E.

AUTHOR'S CLOSURE

The discussion represents an effective supplement to the aspects of the problem developed in the paper. One point needs further clarification to avoid apparent contradiction, and that is the comment by Mr. Metz on the relative fineness obtainable when grinding dry or wet. The illustration given in the paper relates to the extremely fine particles up to 3 or 4 microns in size, while the comments offered by Mr. Metz relate to a larger portion of the sub-sieve range. The action described in the paper illustrates the fact that grinding forces cannot be applied to extremely fine particles when the fluid medium is sufficiently viscous to carry the particles with it as the fluid is expelled from beneath the grinding faces. The discussion as a whole has brought out fully the importance of accurate sub-sieve measurement and the very limited amount of data now available.

High-Pressure Steam-Generator Research

Progress Report of Investigations at Purdue University by the A.S.M.E. Special Research Committee on Critical-Pressure Steam Boilers

By H. L. SOLBERG,[1] G. A. HAWKINS,[2] AND P. A. WILLIS,[3] LAFAYETTE, IND.

This is a progress report of the investigations with the high-pressure steam generator at Purdue University which have been carried on since January 1, 1932, and are mainly concerned with the measurement of the enthalpy of steam by the use of a condensing calorimeter designed for pressures up to 3500 lb per sq in. The heat leak was determined by assuming that the Keenan Tables were correct within the range at which the calorimeter was calibrated. Thirty-nine tests were carried on at pressures varying from 1900 to 3500 lb per sq in. and temperatures of 709 to 780 F. The results were compared with those of Keenan, Knoblauch, Callendar, and the International Tables. The Purdue University figures are in close agreement with those of Keenan, Knoblauch, and the International Tables, but show considerable variance from Callendar's results.

H. L. SOLBERG

G. A. HAWKINS

P. A. WILLIS

IN A PAPER that was presented at the Annual Meeting of The American Society of Mechanical Engineers on December 1, 1931, entitled "Characteristics of a High-Pressure Series Steam Generator,"[4] results were given of the operation of a high-pressure steam generator at a variety of capacities, pressures, and final steam temperatures. The behavior of the unit on a swinging load under automatic control was also demonstrated. Since these preliminary tests were reported, the following studies have been undertaken:

1 The laws governing fluid friction of steam at pressures up to 3500 lb per sq in. and temperatures up to 830 F have been studied. The results to date are insufficient to allow any definite statement; however, it is expected that these studies of fluid friction will be completed within the next year.

2 Major attention since January, 1932, has been devoted to the design, construction, calibration, and use of a condensing calorimeter in order to determine the enthalpy of steam at the conditions under which the steam generator is being operated.

The High-Pressure Condensing Calorimeter

A condensing calorimeter of the steady-flow type was designed to measure enthalpy at pressures up to 3500 lb per sq in. and temperatures up to 800 F. A simplified diagram of this type of calorimeter is shown in Fig. 1. Steam is condensed in a coil of tubing sufficiently heavy to withstand full steam pressure. The rate of condensation is controlled by a regulating valve on the condensate discharge. The cooling water on entering the calorimeter flows through a passageway entirely surrounding the condensing chamber. It then enters the section which contains the coil, receives heat from the steam, and is discharged.

The details of this calorimeter are shown in Fig. 2. Steam is condensed in 60 ft of extra-heavy $^1/_4$-in. iron-pipe-size seamless-steel tubing, coiled on an average center-to-center diameter of $12^3/_8$ in., the total external surface being about $8^1/_2$ sq ft. The coil chamber and water jacket were formed by four coaxial cylinders constructed of 16-gage sheet steel. All joints were made by oxyacetylene welding. For insulation between the condensing chamber and the water jacket, 85 per cent magnesia was used; also for covering the outside of the calorimeter. The inlet and outlet ends of the steam coil, as well as the water-discharge tube, were all brought out through the water jacket in circular openings of sufficient diameter to provide an inch or more of insulation between the jacket and each of the tubes.

Inlet and outlet cooling-water temperatures were measured with mercury-in-glass thermometers. Tycos thermometers graduated in 0.1-deg divisions were used. The two inlet thermometers had a range of 32 F to 120 F, while the outlet thermometer range was 0 C to 100 C. A centigrade thermometer was used

for the outlet-water temperature measurement as no fahrenheit thermometer with a suitable range and with proper graduations was available. The inlet-water thermometer bulbs were in direct contact with the water, the thermometers being held in position by corks in the pipe tees provided for that purpose. The same arrangement was tried at first with the outlet thermometer, but due to rapid temperature fluctuations it was later abandoned and a thermometer well was used. The thermometer well was screwed into a counterbored cork and was thus insulated from the pipe and tee. Details of the thermometer well and also of the baffles for mixing the outlet water are shown in Fig. 2. By using magnifying glasses in reading the thermometers, it was possible to estimate the readings to the nearest 0.05 deg. Stem corrections were made for all tests. The temperature of the surrounding air was measured by thermometers on either side of the calorimeter.

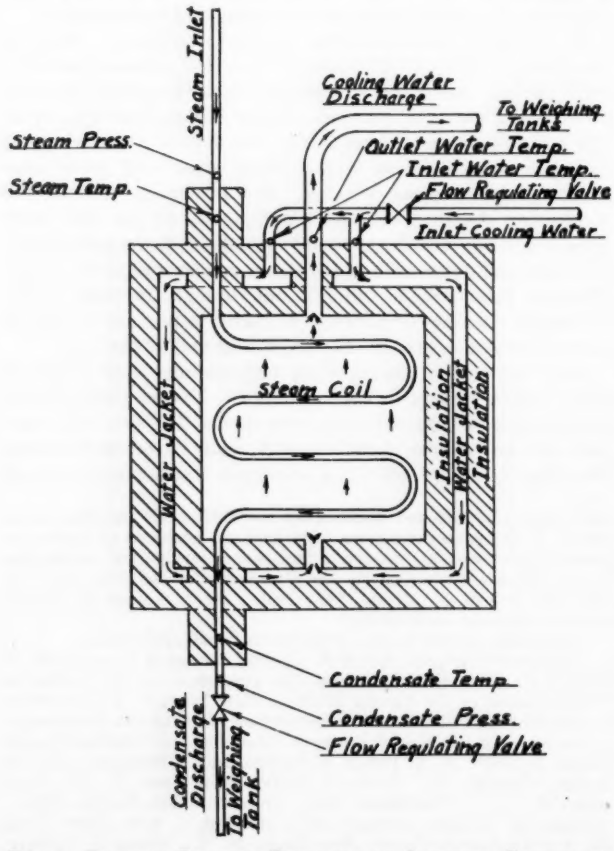

FIG. 1 DIAGRAM SHOWING PRINCIPLE OF JACKETED CONDENSING CALORIMETER

During the calibration tests Crosby bourdon-type test gages were used for steam and condensate pressure measurements. For the high-pressure tests the entering steam pressure was measured by the Bailey dead-weight pressure-measuring device installed as part of the high-pressure steam-generator equipment. Thermocouples, constructed as shown in Fig. 3, were used to obtain the steam temperature at entrance to the calorimeter and also the condensate temperature at discharge. Flaked mica was used for packing, and fused-quartz tubes were employed to insulate the leads from the thermocouple body. The distance from the hot junction to the end of the thermocouple body was approximately 1 in. The steam and condensate thermocouples were constructed of standard iron-and-constantan thermocouple wire, and the millivolt-temperature tables used were those provided by the manufacturers. Both thermocouples were connected into the entering steam line and tested with saturated steam at different pressures. Their readings were found to agree and to check the corresponding saturation temperatures within the limits of accuracy possible with the potentiometer.

Millivolt readings were obtained by Leeds & Northrup potentiometers. For the calibration tests an instrument was used that was capable of being read to the nearest 0.1 mv in the steam-temperature range and to 0.02 mv in the lower or condensate-temperature range. For the experiments with high-pressure steam greater accuracy in steam-temperature measurement was required due to the rapidity with which enthalpy changes with temperature at high pressures. Accordingly, a potentiometer having a sensitivity of 0.02 mv in the upper range was used in most of these tests. Cold junctions were maintained at 32 F by means of crushed ice.

The weight of the cooling water was obtained by use of two 800-lb-capacity tanks mounted on standard Fairbanks platform scales. The scale beams were graduated in $^1/_2$-lb increments, and the scales, after careful calibration and adjustment, were found to be sensitive to variations of about $^1/_4$ lb. The condensate was weighed in a tank of about 200 lb capacity set on a calibrated Fairbanks platform scales of 250 lb capacity. The scales had beam graduations of $^1/_4$ oz and was sensitive to variations of about 0.2 oz over its entire capacity range. A double-pipe heat exchanger, supplied with steam from the laboratory header, was inserted in the cooling-water line to provide for control of the temperature of the cooling water entering the calorimeter.

CALIBRATION OF THE HIGH-PRESSURE CALORIMETER

With proper adjustment of the inlet-water temperature, the heat leak from a jacketed calorimeter can be made negligible

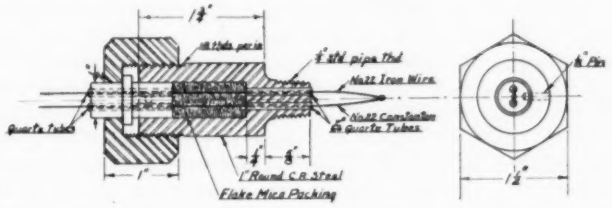

FIG. 3 THERMOCOUPLE FOR STEAM AND CONDENSATE TEMPERATURES

except at three points: (1) steam entrance, (2) condensate discharge, and (3) cooling-water discharge. The greatest loss of heat will occur at the first point, since there the temperature difference is much greater than at either of the other two places. With the inlet cooling water maintained at room temperature and with a constant temperature rise of the cooling water, the heat leak from the calorimeter per unit of time was assumed to be a function of steam temperature only. Changes in condensate temperature with different rates of flow will introduce a slight error, but if the calorimeter is provided with sufficient condensing surface, the condensate will be cooled to within a few degrees of the inlet-water temperature and variations in the heat leak at the condensate outlet will be very small.

On comparing recent steam tables it was found that there is now very close agreement on all the thermal properties of steam at pressures below 350 lb per sq in. It was decided, therefore, to calibrate the calorimeter for the heat leak by subtracting each calculated value of enthalpy, as obtained from test data, directly from the corresponding value in the Keenan Tables. The heat leak is then this difference multiplied by the weight of steam condensed and divided by the duration of the test. In order to avoid the expense of operating the high-pressure steam generator for the calibration tests, it was decided to utilize steam from the laboratory header at about 200 lb per sq in. A special gas-fired superheater was used to permit adjustment of the steam temperatures to any desired point between saturation and about 900 F. The arrangement of the equipment is shown schematically in Fig. 4.

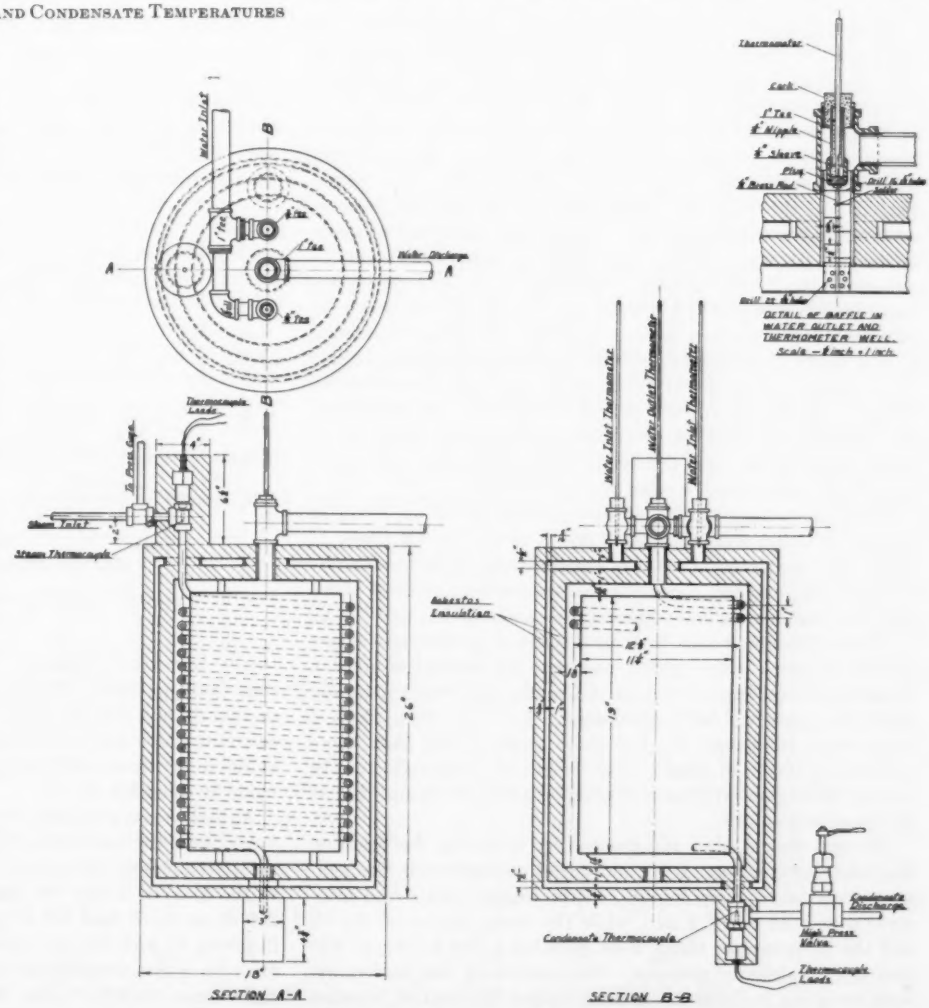

FIG. 2 HIGH-PRESSURE CONDENSING CALORIMETER DETAILS

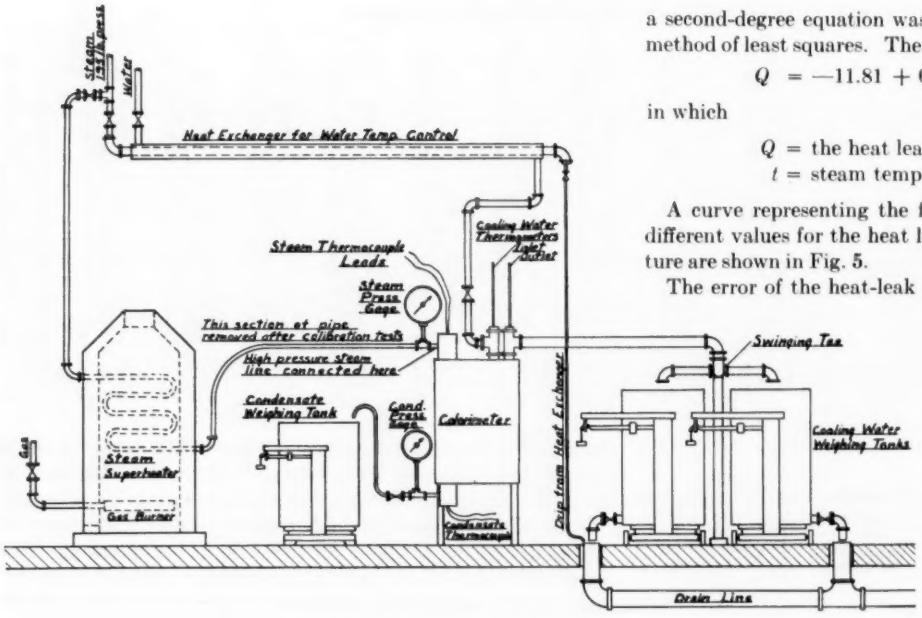

FIG. 4 ARRANGEMENT OF EQUIPMENT

Since the specific volume of steam at low pressures is about 30 times that of the high-pressure steam for which the calorimeter was designed, large pressure drops occurred in the condensing coil during the calibration tests. With steam at 195 lb per sq in. pressure and 700 F, the maximum capacity of the calorimeter was found to be 4 lb per min. At this rate there was a pressure drop of about 25 lb between the inlet and the outlet of the superheater, and the remaining drop down to atmospheric pressure occurred in the calorimeter coil. At the maximum rate of steam flow of 4 lb per min, a steam temperature of about 700 F could be obtained with the superheater. At 2 lb per min the temperature could be raised to 850 F, while at a rate of 1 lb per min temperatures of 900 F and above were obtainable. By proper manipulation of the heat-exchanger steam and condensate valves, changes of less than $^1/_2$ deg could be made in the water temperature. When condensing steam at a rate of 4 lb per min, the condensate temperature at discharge was found to be about 3 deg above room temperature, and the temperature difference was correspondingly less at smaller rates of condensation.

There were altogether 20 calibration tests carried on, covering a range of steam temperatures of 564 F to 884 F. Of these, 11 tests were conducted at rates of condensation of approximately 2 lb per min, and the remaining 9 were made at rates of about half this amount. It had previously been found that a test of 20 to 30 min duration would, in general, yield as good results as one extending over a longer period, and that the amount of error in weighing the cooling water and the condensate was apparently much less than had been anticipated. Tests in which 25 lb of steam were condensed did not show greater error than those condensing 100 lb of steam. The weight of condensate for the tests at the higher rate was accordingly fixed at 50 lb and that at the lower rate at 25 lb.

All tests were started and stopped by balancing the beam on the condensate scales. Inlet and outlet cooling-water temperatures were taken every minute, thermocouples and steam pressures were read every 2 min, while the temperatures of the air and the thermometer stems were recorded every 6 min, as was also the condensate pressure. The results of the calibration tests are given in Table 1. In order to find the relation between rate of the heat leak from the calorimeter and steam temperature, a second-degree equation was derived from the test data by the method of least squares. The equation so obtained is:

$$Q = -11.81 + 0.03227t - 0.0000144t^2$$

in which

Q = the heat leak in Btu per min
t = steam temperature, deg F

A curve representing the foregoing equation and also the 20 different values for the heat leak plotted against steam temperature are shown in Fig. 5.

The error of the heat-leak equation was calculated and found to be 2.32 Btu per min. Since the heat leakage at 900 F is only 5.5 Btu per min, as calculated from the equation, it is apparent that the combined effect of the errors of observation is almost as great as the amount of heat lost from the calorimeter. The error contained in the heat-leak equation, however, does not have a very great effect upon the final result for total enthalpy. The highest rate of heat leakage indicated by the calibration tests (Table 1) was given by test No. 1 as 9.05 Btu per min. If this were entirely neglected, the difference between the enthalpy obtained from the Keenan Tables and the enthalpy as calculated would be 4.1 Btu per lb, an error of 0.28 per cent. From Fig. 5 the heat leak for test No. 1 is found to be 5.2 Btu per min. Multiplying this by the total time and dividing by the weight of steam condensed gives 2.4 Btu per lb to be added

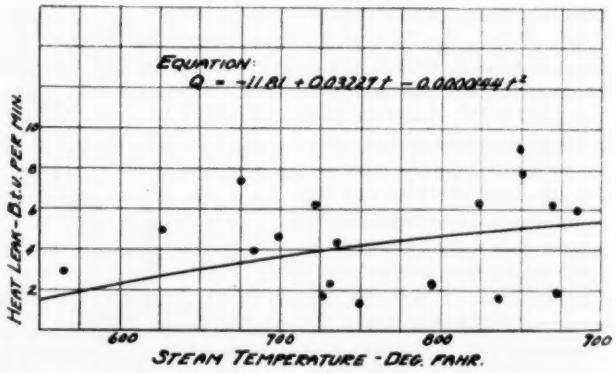

FIG. 5 VARIATION OF CALORIMETER HEAT LEAKAGE WITH STEAM TEMPERATURE

to the calculated enthalpy. The final value for the enthalpy then becomes 1449.6 Btu per lb, producing an error of 1.7 Btu, or slightly less than 0.12 per cent. This indicates the degree of accuracy which may be obtained with this calorimeter with steam at 200 lb per sq in., after the correction for the heat leak has been made by using Fig. 5.

At high steam pressures the final effect of all errors of measurement, with the exception of that of steam temperature, should be approximately the same as at the lower pressure. According to the Keenan Tables the specific heat of superheated steam at 200 lb per sq in. and 725 F is approximately 0.52, while at 3300 lb per sq in. and the same temperature it is about 4.2. A given error in steam-temperature measurement will thus have over eight times the effect upon the calculated value of enthalpy at the higher pressure than at the lower.

Preliminary Enthalpy Determinations at High Pressures

A test procedure with the condensing calorimeter quite similar to that developed for the calibration tests (Table 1) was used for the preliminary enthalpy measurements at high pressures. The same method was employed in starting and stopping the tests and the same observations were taken. The desired steam pressure and temperature were obtained by proper adjustment of the controls of the high-pressure steam generator. The operator of the steam generator held the pressure and temperature as steady as possible during each test and also recorded the steam pressure as indicated by the Bailey dead-weight pressure gage. The steam-thermocouple millivolts were read at 2-min intervals for all tests except the last three, when they were recorded each minute during the test. There were 20 preliminary enthalpy measurements made at high pressures. The rate of steam condensation for the first six tests was adjusted to approximately 3 lb per min, and for the remaining tests a rate of about 4 lb per min was used. The total steam condensed in most of the tests was either 70 or 75 lb, the duration ranging from about 17 min to 26 min, with an average of about 20 min.

The rate of the heat leak from the calorimeter was obtained from Fig. 5. The enthalpy of the condensate was found by adding to the enthalpy of saturated liquid, corresponding to the condensate temperature, the increase in enthalpy due to compression to the condensate pressure. This gain in enthalpy was obtained by a large-scale graphic interpolation of the Keenan Compressed Liquid Water Table published in 1931. During all of the high-pressure tests, steam from the laboratory main was condensed to supply the small amount of make-up feedwater required for the steam generator, using trisodium phosphate for conditioning this water. The water in the hot well was maintained at or near the boiling point, and the hot well was vented to the atmosphere in order to eliminate the non-condensible vapors as completely as possible. The results of the preliminary enthalpy measurements are summarized in Table 2. In Fig. 6 these data are plotted on pressure-enthalpy coordinates. Eight superheated-steam isotherms, plotted from the Keenan Tables (1930), are also included for comparison.

The results of tests 7 to 15 inclusive are not reported as they were inconsistent in themselves and were at wide variance with published steam-table data. The difficulty was traced to a defective steam-temperature thermocouple. The fused-quartz insulators, shown in Fig. 5, had been dissolved under the influence of the high-pressure steam and had corroded the thermocouple wires. The thermocouple was rebuilt without these insulators, and the results of tests 16 to 20 were then obtained. The accuracy of the data in test 6 is also open to question due to the possible failure of the original thermocouple at this point. It is seen that while the calorimetric measurements in tests 16 to 20 are all below those of Keenan, the difference is in no case greater than three-tenths of 1 per cent. At 3510 lb per sq in., where the divergence might be expected to be greatest, the two values agree

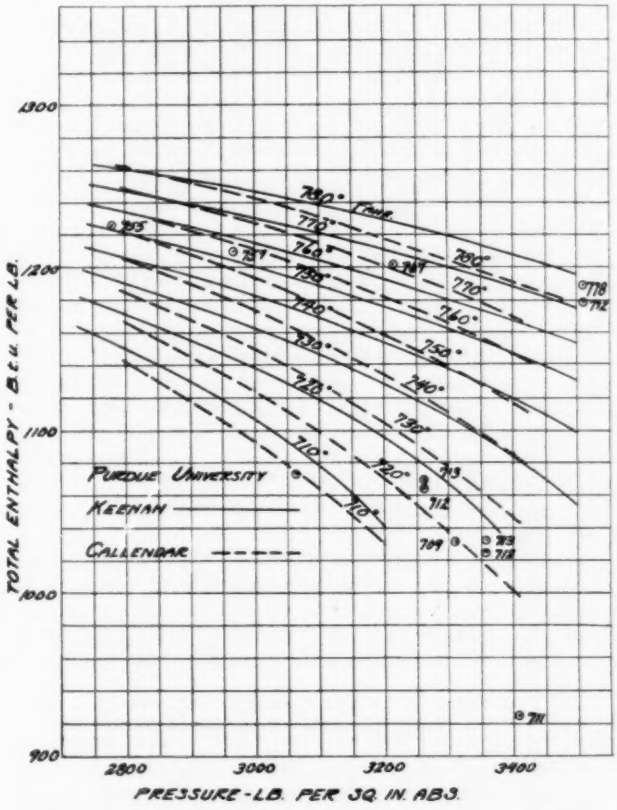

Fig. 6 Enthalpy Values From Preliminary Tests

within about one-tenth of 1 per cent. Tests 1 to 6 are outside of the range of the Keenan Tables.

Determination of Enthalpy at Pressures From 1900 to 3500 Lb per Sq In.

Supplementing the preliminary results which are recorded in Table 2 and Fig. 6, 30 tests were conducted along isotherms of 730, 750, and 775 F and at pressures varying from 1900 to 3400 lb per sq in. The results are reported in Table 3 and Fig. 7.

In general, the testing procedure included during any one day a series of tests at a constant steam temperature and with different pressures. Consequently, after establishing steady temperature conditions, the time required between tests was determined by the ability of the operator to change and to stabilize the operating conditions on the steam generator. The flow rate through the calorimeter was held as constant as possible and the total steam condensed per test was about 70 lb. With this operating procedure, the heat-leak correction was reasonably constant for all tests conducted during the particular day in question.

The differences in the total enthalpy of steam between the observed results and those of Keenan (1930), as interpolated from the Steam Tables, varied from —0.4 Btu per lb to 9.3 Btu per lb, corresponding to a maximum of 0.79 per cent. Only seven of the 28 tests recorded in Table 3 indicated a divergence from the Keenan values of more than one-half of 1 per cent, the average for all tests being about one-third of 1 per cent. Two of the determinations were slightly below the corresponding Keenan values, one was in exact agreement, while the remaining 25 gave values somewhat higher. The results of tests 12 and 39 were not recorded in Table 3, as they were conducted under unsteady steam-generator operating conditions.

Conclusions

The determinations of the enthalpy of steam reported in this paper were undertaken at the suggestion of an organization which was largely instrumental in making possible the installation of the high-pressure steam generator at Purdue University. The main object of these determinations was the comparison of the data secured with the values of Callendar, Keenan, Knoblauch, and the International Tables.

The results of the Purdue University tests are apparently in close agreement with those of Keenan. Due to the fact that the Purdue University tests do not go below 700 F or above 800 F, it is not practical to make comparisons with the values of Knoblauch, Callendar, or the International Tables other than throughout the range of the 752 F isotherm from 2100 lb per sq in. to 3556 lb per sq in. abs pressure. The results of the Purdue University tests are slightly lower than those of Knoblauch, but higher than the values in the International Tables. The values of Callendar are higher than the Purdue University results from 2100 lb per sq in. to about 2800 lb per sq in. abs, but lower from 2800 lb per sq in. to the end of the test results. Fig. 7 indicates that the results of the Purdue University tests are in fairly good agreement with the values reported by Keenan and Knoblauch, but seem to vary in the higher pressure ranges from the Callendar 750 F isotherm. It is recognized that the condensing calorimeter is not a primary device for the direct measurement of the enthalpy of steam, since it requires calibration for heat leak, and reliable data on the enthalpy of saturated and subcooled water at temperatures between 70 and 140 F are necessary. Data now available should eliminate errors from the causes named. The Purdue University tests may be criticized by reason of the fact that pure steam was not used. The authors believe that any appreciable error from this cause should be reasonably constant if feedwater conditions are properly controlled.

It is desirable that further refinements be made in the measurement of steam and cooling-water temperatures. This is particularly true when working with steam near its critical pressure and temperature because of the high specific heat. The generation of high-pressure steam in a unit of semi-commercial size, with close control of temperature and pressure, and its condensation in a calorimeter involve apparatus that must be handled with great care if the accuracy of the physics laboratory is to be approached. It is hoped that the close agreement of the results

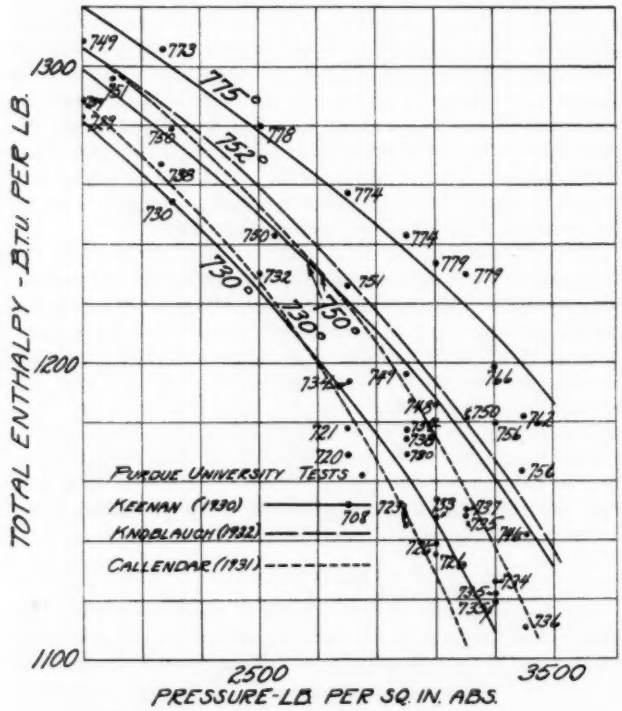

FIG. 7 ENTHALPY OF HIGH-PRESSURE STEAM

presented with the published values of the Keenan and Knoblauch tables over the pressure and temperature range investigated may prove of interest and value. Difficulties with some of the auxiliaries for the high-pressure generator prevented a more complete investigation with the condensing calorimeter. Accordingly, the authors invite suggestions as to the advisability of extending these tests to include a more comprehensive survey of the enthalpy of steam at pressures between 1500 and 3500 lb per sq in.

Discussion

ROBERT C. H. HECK.[5] In general method of heat measurement—that is, in using a water calorimeter to absorb and measure the heat of a sample of steam—these experiments go back to the method of Regnault. Modern steam research, especially in the latter half of its 25-year period, has preferred the alternative scheme of supplying heat in the primary form of closely measured electrical energy. Chiefly, the electrical-supply method offers possibility of more completely isolating or insulating the process.

However, both mechanical and thermal difficulties increase, as the apparatus with electrical supply must contain very high pressure. For this reason, a return to the older method is justified by the rugged simplicity of the steam coil in the calorimeter here described. Present use of the water-absorption method is not novel with the Purdue investigation, since it has been employed in recent years by Callendar in England and by Havlicek in Czechoslovakia. With an equally high grade of skill in physical measurement, there is no inherent reason why this method shall not give correct and reasonably precise results.

As noted by the authors, it is highly important that both pressure and temperature of the entering steam be measured precisely and simultaneously. Consider the region near the critical point in a plot of enthalpy h in pressure p for superheated steam. Not only are the isotherms so widely spaced that specific heat c_p is very high, but they also have such slopes that h varies quite rapidly with pressure. Thus at 3200 lb abs and 750 F, a difference of 1 Btu in h will be caused by about 0.5 deg of temperature or by 7.5 lb per sq in. of pressure. Close to the critical point the pressure influence becomes very strong.

A question arises as to the velocity and kinetic energy of the steam at the place where the entrance observations are taken. In the full-pressure experiments, velocity is so slow that this effect is insignificant, but in the calibration tests it may rise to an appreciable size. Thus at 195 lb abs and 750 deg, and at 2 lb per min of steam flow, the writer figures a velocity in the tube of about 266 ft per sec, equivalent to 1.4 Btu of kinetic energy. This will of course be modified by enlargement of passage and turbulence of current around the thermocouple.

To the writer's mind, the plot of heat-leak tests in Fig. 5 shows a degree of erraticity that will have to be rather strongly suppressed, by more complete insulation, if dependably accurate results are to be obtained.

The rather high range of cooling-water temperature, about 60 F, is favorable to accuracy of heat measurement. However, an error of 0.1 deg in this difference, or of 1 part in 600, is equivalent to more than 2 Btu in the enthalpy per pound of steam. From the scattering of results a probable error is inferred of as much as 0.2 deg in the temperature difference. Even to express the enthalpy of low-temperature water to but one decimal place is to fall below a precisely determinative value of this factor in heat absorption—but perhaps that is a mere tabular condensation from the justified two-place expression in the Keenan table.

To sum up, the investigation here described is a piece of high-grade work in the engineering laboratory, but it does not at all measure up to the accuracy of the work of the steam research program. To the more precise experimentation it makes a broadly confirmatory but not a closely determinative contribution. If the investigation is to be continued and is to give really valuable results, it must be graded up in the accuracy of the physical measurements made.

N. ARTSAY.[6] The paper shows the correctness of measuring instruments installed with the boiler and the dependability of their readings as checked by the condensing calorimeter. The authors should be congratulated on the close results they obtained with the relatively crude apparatus at their disposal. This preliminary work brings the whole installation in readiness for a series of experimental runs which might tackle the host of difficult problems so far poorly investigated or not touched at all.

The authors ask for suggestions on the advisability of extending further the enthalpy determinations. The data given in the paper show that a satisfactory reliance can be placed on the measuring instruments of the boiler, and a further checking of them seems to be superfluous for all practical purposes. So the following suggestions for the future work with the boiler are in order:

1 A definite program to cover several years of semi-commercial

[5] Professor of Mechanical Engineering, Rutgers University, New Brunswick, N. J. Life Mem. A.S.M.E.

[6] Mechanical Engineer, New York, N. Y. Mem. A.S.M.E.

experimental work with the boiler should be prepared, widely spread, and discussed to attract interest and support of the manufacturers of high-pressure steam equipment and operating companies. Without their experience and support this undertaking cannot be of lasting practical value. It should be borne in mind that the Purdue installation offers the greatest chance of doing valuable work on a practical semi-commercial scale, and in planning the program any work properly belonging to a laboratory should be avoided.

2 Assuming that in a not so distant future the drumless boilers with forced circulation will make their logical appearance in the industrial and central-station field, the Purdue boiler and its set of instruments and apparatus should be made a center of experimental development work intended to solve the many practical difficulties inherent to the apparatus using extreme pressures, temperatures of steam, and actual feedwater. Scale formation, carry-over effects, instability of tube materials, valve troubles, resistance to flow—all this could be investigated. These results could be valuable not only for the coil boilers, of course.

3 The extremely important paper by De Baufre deals with the strength of boiler tubes; this problem needs experimental verification. Short lengths of tubes should be welded in the boiler coil in the spot of highest heat absorption, the tubes be selected of various diameters and thicknesses, the hours of service and operating conditions be recorded, and the shape of tubes be checked for ascertaining their relative behavior in a long service.

4 The failure of boiler tubes versus stresses and heat transfer has never been properly ascertained. A steel-protected refractory-lined chamber may be built and arranged to be fired with an independent gas burner. Tubes of various thicknesses and materials then could be tested to destruction and the question of the optimum thickness and material settled.

5 Efforts should be strengthened to develop a sensitive differential-pressure gage to investigate pressure drops through various pipes and fittings. The boiler coil, for this purpose, should be tapped and valved in several places to get different proportions of water and steam in the mixture or steam at various temperatures. The writer can offer some ideas for such an instrument.

6 Pieces of tubes of various steel should be tested for creep in the region of superheated steam to check the laboratory tension-creep rates versus actual behavior of the metal in the tube form and under compound stress.

7 A bypass tube should be arranged from a spot near the boiling point leading to the valve of a test set built to investigate the scale formation. A removable test stretch of a tube fixed in the set should be subjected to a high rate of heat transfer by firing a separate gas burner. Concentrated solutions of different salts could be then continuously injected in the bypassed flow and the scale formation investigated under varying pressures, temperatures, concentrations, mass velocities, and rates of heat transfer. The test tube must be easily removable for inner inspection. Observation of metal temperature would give actual data on heat conductivity of scale.

8 Manufacturers of high-pressure equipment and operating concerns should be polled on their individual problems and needs in experimental work. There is still a lot to do; for instance, in pipe and tube welds, flanges, flange bolts, gasket material, and so forth.

A wealth of valuable practical information could be gained through the tests of the Purdue boiler, but the success will depend much on the planning and cooperation of all concerned. The start has been made in the right direction, but much strenuous work is yet ahead.

W. F. Ryan.[7] The second paragraph of this paper states that a study is being made of the laws governing the fluid friction of steam at high pressure and at high temperature. This work will fill a very serious gap in the reliable data required by designers of steam plants and steam equipment. Further work on steam tables research can only make minute corrections to the data now available within the range of pressures and temperatures in practical use. Determination of the viscosity of high-pressure, high-temperature steam, however, will supply needed data in a field where there is practically no information whatever avilable.

The viscosity of superheated steam is the one remaining unknown factor which affects friction in pipe lines, turbine nozzles, turbine blades, etc., and a rational calculation of pressure drop or heat transfer, where high-pressure, high-temperature steam is involved, is now quite impossible. The empirical equations which have been developed by various manufacturers unfortunately lack universal application. The data which the authors intend to produce in this field are therefore of the greatest importance.

Perhaps the chief value of this paper is that it shows the accuracy with which measurements can be made with this apparatus, as Professor Heck has pointed out. This paper cannot be regarded as a check on the work of the Steam Tables Research Committee, but certainly the Keenan Tables can be regarded as a check on the accuracy and consistency of the work done by these authors with the existing apparatus. Therefore, when information is offered in regard to the laws affecting fluid friction of steam, the data will be received with the greatest confidence by all engineers.

Authors' Closure

The authors wish to express their appreciation of the many valuable suggestions that have been made relative to a program of experimental work which should be carried out on the high-pressure steam generator at Purdue University.

Progress in Railroad Mechanical Engineering

IN COMMON with the experience of recent years, the railways are being called upon to consider and introduce many innovations which are profoundly changing their past methods of operation. While the field cannot be entirely covered in this survey, a number of the more widely known recently acquired practices are referred to under the various headings which follow.

Motive Power

The few new locomotives that have been placed in service are capable of hauling full-tonnage freight trains at unusually high sustained speed or they may be employed to handle extra-heavy passenger trains and thereby maintain the regular schedule. These units are so designed as to be best fitted for operation on long non-stop runs, the tenders having a capacity of at least 18,000 gal of water and 20 tons of coal. Four-wheel trailing trucks are used, together with booster, to accommodate large firebox arrangements and assist in starting heavy trains.

Multi-Pressure Locomotives. The first two multi-pressure-boiler locomotives placed in service on the American Continent are the Canadian Pacific 2-10-4-type wheel arrangement and the New York Central 4-8-4-type wheel arrangement, both of the three-cylinder-compound formation. The steam generation and utilization principles employed in the two locomotives have been employed in three locomotives in Europe, with what are described as giving very satisfactory results in fuel saving and overall efficiency, but the largest European unit of the type is only 42 per cent of the weight and develops only 36 per cent of the power of the Canadian Pacific multi-pressure one. These locomotives use steam at a pressure of 850 lb per sq in. in the high-pressure cylinder, whereas the best of our conventional form of locomotives use steam at 275 lb, so there is an increase in steam pressure of over three times. There are two superheaters, one for a steam pressure of 850 lb and one for 250 lb; there are two boiler-feed pumps, one for feeding to the low-pressure boiler and one from the low-pressure into the high-pressure boiler. There is the ordinary exhaust-steam feedwater heater for heating the water that is drawn from the tender before it goes into the first boiler.

Water Glasses. There have been some interesting departures from usual practice in water glasses used on the closed circuit and on the high-pressure boiler, carrying 1700 and 850 lb, respectively, on the Canadian Pacific and New York Central multi-pressure locomotives. Glasses in one shape or another have been used almost exclusively on locomotives and boilers for other purposes, but with increasing steam pressures, the tubular glass has gradually been replaced by thick "bull's eye" or heavy flat glasses, referred to in railroad practice as "Klinger." Glasses for these still higher pressures were ordered, but the manufacturer furnished what was to the railroads an innovation in that the glass was replaced by a thin sheet of mica. The manufacturer advised that experiments with high steam pressures had indicated that the thin mica sheets were more durable than the glass. While the flat glasses were deemed safer than the tubular glass they would break when the water level was no longer visible, although the glass held and did not shatter. Mica "glasses" have been in service now for over a year with very good results.

Poppet Valves. A departure of more than ordinary interest has been the application of Lentz and Caprotti poppet valves, fitted with both oscillating and rotary valve gear, to several hundred locomotives abroad and a number of test applications in this country. There appears to be a realization that the losses due to mechanical friction are much less in the case of poppet valves than in that of the piston type. In like manner, less energy is absorbed in actuating the valves, so that not only a theoretical but a practical gain of some degree is recorded. To determine the extent of this gain would necessitate the employment of a locomotive testing plant; otherwise the feature as to the degree of energy conservation must continue to remain a matter of judgment. Aside from any disposition to credit a better distribution of steam, an economy in maintenance cost realized thereby would be a further reason for the consideration of this construction, in view of its greater initial cost as compared with conventional designs. Long valve travel has been widely adopted for use on modern high-pressure locomotives in order to allow a relatively short cut-off to be employed.

Roller Bearings on Locomotives. A number of railways, chief among which are the New York Central and the Delaware, Lackawanna & Western, are successfully operating locomotives fitted completely with roller bearings on all axles. Prevailing opinion indicates that anti-friction bearings will make greater progress in the next few years on motive power than they will on cars, but it will be by reason of their contribution to reduced maintenance and freedom from attention rather than from any possibility of locomotive redesign which they may offer.

The valve motion and rods present a peculiarly well-adapted field for roller-bearing applications, since the absence of wear in them guarantees that the valve setting will remain exactly as initially intended when the locomotive was turned out of the shop. So far as the rods are concerned, it is found that anti-friction bearings materially reduce the need for bearing attention and there is no tendency toward that pounding which develops in the ordinary plain bearing locomotive and with the costly effects with which railway mechanical officers are thoroughly familiar.

The reduction of locomotive maintenance expense through the careful selection and adaptation of new ferrous-metal products has progressed with considerable success. Oftentimes with a change in material a modification design is necessary in order to improve a given part and minimize the risk for defects, due to improper or improperly controlled manufacturing practices. Increases in strength and ductility are obtained through the use of alloy elements of steel which are largely applicable in railway service. During the year a number of Diesel-electric locomotives were built with the cab, underframe, and trucks fabricated from structural-steel shapes and plates and arc welded. Bolts were employed only for those parts requiring occasional removal or renewal. It was found advisable to weld the body bolster directly to the side sills, the joint surfaces being reinforced with heavy gusset plates and brace plates, all welds being continuous.

The use of large high-tensile-strength steel castings has become general for the understructure of the locomotive and tender. The elimination of highly stressed bolts and rivets in locomotive parts has been a potent factor in this accomplishment. These cast-steel structures are really assembled in the mold in liquid

---

Presented at the first session of the Railroad Division, Monday morning, December 5, 1932, during the Annual Meeting, New York, N. Y., December 5 to 9, 1932, of The American Society of Mechanical Engineers.

Compiled by L. K. Sillcox, Chairman of the Survey Committee of the Railroad Division.

Personnel of the Executive Committee of the Railroad Division for 1932: T. C. McBride, Chairman; M. B. Richardson, Secretary; G. W. Rink, L. K. Sillcox, C. B. Peck, and C. E. Barba.

form, and the metal can be placed in the right proportion exactly where it is needed for strength, thus securing weight economy and uniformity of fiber stress. This method of assembly permits the incorporation of the numerous necessary brackets, which in many cases are utilized to provide not only much greater strength for the detail part itself, but often to add to the value of the entire unit. Until eight years ago the cast-steel frame acted solely as a bedplate for the separate tank which it supported. With the increased demand for coal and water capacities, the length of tender increased to an intolerable limit, to say nothing of the weaving and buckling of such tanks causing leakage and cracking of the sheets. This led to the introduction of the water-bottom tender, which in addition to permitting more coal and water storage, provided a strong tender unit that combined the tank and frame with the solid corrosive-resistant bottom face of the frame, which in turn forms the lower member of a deep box-type girder. This construction permitted a lower center of gravity and eliminated not only the bottom tank sheet maintenance, but because of its greater rigidity added the necessary strength to the tank structure as a whole to permit of economical maintenance. The steam locomotive bed was first made with separate cylinders, which was followed with the cylinders being made integral with the locomotive frames.

Rolling Stock

The Pennsylvania Railroad placed in service a new type of motor car for the Long Island Railroad. It is a double decker and will seat 44 more persons than the suburban passenger coach now in use, with its capacity of 76, the new type carrying 120. This car has two tiers of seats, one level being above the other. The cars have a center aisle, as in cars now used, and on each side of this aisle seats are placed, facing forward, each seat being roomy enough for two persons. The floor board of this lower tier of seats is 14 in. below the aisle, so that the seats are almost flush with the aisle floor. Passengers will descend one step to the lower-tier seats. The floorboard of the upper-tier seats is above the central aisle. Passengers mount two steps to the higher seats. These pairs of seats are not directly above the lower ones, but the upper and lower pairs are staggered, one lower-tier pair of seats being succeeded by an upper-tier pair as the passenger walks down the car. The sunken seats in the lower tier permit the upper-tier seats to overhang, with still enough space for headroom. Windows are so placed that each seat, upper and lower, has its window.

Further attention has been given to passenger-car design to meet special conditions. Combination cafe-parlor cars have been used for some years, but now there are being built various other combinations, such as cafe-coach, coach-parlor, and sleeper-club cars, where one combined will take the place of two separate cars when traffic is light.

In the fast-freight line, baggage cars have been built fitted with tanks for the shipment of live fish.

Air Conditioning. In recent years there has been considerable experimenting with air-conditioning equipment for railway passenger cars, and there is a rising demand on the part of the traveling public for this travel comfort. Although the art is undoubtedly in a formative stage, tested equipment for this purpose is available. Close attention is being given, not only to improvement in quality of service and to better adaptation of types of accommodation to customer demand, but also to popularization of travel facilities.

Rail Cars

During the year oil-electric rail coaches were built in Germany to operate at 93 mph, which is probably the first effort of a railway company to meet the competition of air services, there being a regular service of the latter type between Berlin and Hamburg. The equipment is made up in two parts joined by gangway bellows. Each of the outer ends is supported on a four-wheel truck having a wheelbase 11 ft 6 in. long, and the inner ends are carried on a common truck with the same wheelbase. Since the designed speed is 93 mph, air resistance is of primary importance, and model tests were carried out in the wind tunnel of the Zeppelin works to determine the most suitable form for the body construction. The outer ends are streamlined, and in addition the overall height of the cars has been kept as low as possible, and any projecting fittings have been avoided, the doors and window frames being flush with the outer surfaces. To avoid eddy currents under the cars, the whole of the underside is incased in metal sheeting. The cars are driven by two 12-cylinder, 410-bhp, 1400-rpm engines directly coupled to a generator. The current generated is supplied to two electric motors geared to the driving axles. The seating capacity in the unit is 102 passengers and there is a compartment for baggage, a small section in the center of the cars being reserved as a buffet. The question of braking on a service operated at such high speed was recognized as being most important, since with constant brake resistance the stopping distance varies as the square of the velocity. Owing to the special design of the brakes employed, however, it is anticipated that it will be possible to bring the cars to rest from full speed in a distance of approximately 3600 ft. The cars are equipped with two braking systems, one oil and the other air operated, the car wheels being provided with special brake drums and the brakes being of the outside type, lined with an asbestos composition. In order to avoid long and heavy levers, a number of small brake cylinders were installed, designed to operate in the usual way. The total length of the combined articulated unit is 138 ft, with a light weight of 77 tons.

The introduction of the pneumatic rail car, with the practicability of its adaptation to railway service, is of special interest alike to the railways and the traveling public. This new unit of equipment involves a modified view of railway service and a radical departure from the heavy equipment which has been generally employed. The pneumatic rail car, as its name implies, is a light-weight unit, approaching automotive practice to a greater extent than conventional railway usage, with its light-steel construction, pneumatic tires, and internal-combustion engine. It was developed in Europe by engineers working in collaboration with railway men, who sought relief from the growing traffic loss attending many of the operations of the uneconomic steam units. The pneumatic tire, with the conventional type of rail flange, provides riding comfort not possible in any other type of rail equipment now in use, and the adhesion of this tire on the steel rail, which is three times greater than that obtaining for the conventional type of steel wheel, insures maximum acceleration and braking qualities. Weight, which is a limiting factor in the construction of this equipment, has been met by the utilization of stainless steel and a patented process of shot welding. The average dead weight, empty, of 337 lb per passenger capacity, makes possible the utilization of a relatively small internal-combustion engine, which is nevertheless sufficiently powerful and flexible even when acting through a straight mechanical drive to serve the purposes desired.

Car Trucks. With increasing train speeds, very serious attention has been paid and exhaustive tests have been run to determine the effect on passengers and lading from the periodicity of spring oscillation. Remarkable discoveries were made as regards the disturbance and damage to lading in the case of present standard-coil freight-truck designs of conventional pattern. It was quickly evident that coil springs can be em-

ployed to advantage to provide sensitive response to small changes in load, and elliptic springs for the purpose of dampening spring oscillations and amplitudes of oscillation, one desirable combination appearing to be that of coil and elliptic springs arranged in series. In such cases the elliptic spring is permitted the greater part of the admissible springing and the coil springs the smaller part. The small changes of load, which the elliptic spring transmits without oscillation, due to friction between the leaves, can then be easily taken up by the coil springs.

During the year test reports were issued regarding 100-car freight-train operation, with and without roller bearings, on a comparative basis, such equipment having been tested under the auspices of the Timken Roller Bearing Company. Ten 70-ton hopper cars, with bodies made from aluminum, were placed in service, with a saving in weight of 21,200 lb, as compared to the use of steel as ordinarily employed.

Tank cars handling dry granular commodities with practically the same convenience and efficiency that standard tank cars now handle liquids were perfected after nearly two years of research and road tests by the General American Tank Car Corporation and are designed for bulk movement of such dry materials as cement, lime, silica sands, sulphur, fertilizers, soda ash, pottery clays, and fuller's earth.

A car is being designed by the Standard Steel Car Company for the quick freezing of perishable foods. This car is not unlike the all-steel baggage car, inasmuch as it has a central door opening, with a partition beyond the center door which forms a small compartment for refrigerating machinery operated by electric motors. The large compartment is equipped with two 8-stage frosters, the combined capacity being equal to 40,000 tons of frosted foods every 24 hours.

This car is unique in the sense that it is planned to send it to various sections of the country during the growing season and have it collaborate with packing plants, so that the food is first prepared by the packing plants and is then turned over to this car, where it is packaged and quick-frozen. These packages are than put into cartons, sealed, and placed in refrigerator cars for shipment to warehouses and final distribution. In other words, it is a manufacturing plant on wheels, from which emanates considerable tonnage during a year's service.

The same company is also designing a new type of refrigerator car to handle frosted foods that must be transported at low temperatures. This design is unique in that there is practically one car body built within another, with heavy insulation on the sides, floor, and roofing, the inner shell being absolutely insulated from the outer shell, thus eliminating as far as possible the transmission of cold or heat from without and within.

Determined to adopt every possible means of coordinating railway and truck service and of meeting highway competition, a number of railways are offering an adaptation of the ferry-truck plan, which consists of the movement of entire motor trucks and trailers, loaded with merchandise, by flat cars.

Containers have also proved a most valuable acquisition to the railways in meeting highway competition.

Horsepower and Tractive Effort of Steam Locomotives (Locomotive Ratios)

By A. I. LIPETZ,[1] SCHENECTADY, N. Y.

Cole's Ratios, by the use of which the tractive-force curves of locomotives can be calculated and plotted, knowing certain of the locomotive dimensions, have been successfully used for the past 15 to 18 years. The Type E superheater, the feedwater heater, long-travel valve motions, and certain changes and refinements in proportion and design have tended to increase the power of steam locomotives built since 1920. The power calculated by Cole's method does not therefore accurately represent the actual power of modern steam locomotives. In his paper the author reviews the work of Cole and others, checking it against available test-plant and road-test data, and finds that some of Cole's constants still hold good in a great many cases. Others he finds it necessary to modify not only as to the figures, but also as to the method itself.

He develops constants for a new, easily applied method, based on boiler evaporation and a factor depending on the number of revolutions of the driving wheels, for use in connection with modern locomotives, and suggests the continued use of Cole's Ratios for locomotives in the design of which the modern factors are not included.

BY the term "locomotive ratios" are commonly understood formulas and tables which permit the calculation of tractive efforts of steam locomotives from their dimensions. F. J. Cole, late chief consulting engineer of the American Locomotive Company, devised a method for plotting tractive-effort curves of locomotives,[2] which has been used for the last 15 to 18 years with great success. His figures were based on locomotive test data available in his time, and even now they still represent fairly accurately the power and tractive effort of locomotives of the designs known up to the end of the World War.

Since 1920 a number of improvements has been made tending to increase the power of the steam locomotive, the most outstanding of which are type "E" superheaters, feedwater heaters, and long-travel valve motions. Changes and refinements introduced into the designing and proportioning of locomotive parts have also increased the power of the locomotive. Consequently, when Cole's method is applied to modern locomotives, built since 1920, there is a discrepancy between the calculated and the actual power of the locomotive. It was therefore thought necessary to revise Mr. Cole's figures and recommend new ones instead which would apply to modern locomotives.

The author was fortunate enough to have access to Mr. Cole's basic working sheets. He could therefore go over all the information on which Cole's method and figures were based, and critically review them. He was struck by the correctness of some of his constants, which still hold good in a great many cases, but in others he found it necessary to modify not only the figures, but the method itself. Especially have Cole's evaporation figures been found to be very accurate, and applicable to modern locomotives. However, slight corrections to care for changes in design are sometimes required. As regards the underlying Cole idea of figuring the tractive effort on the basis of cylinder sizes and factors depending upon piston speed, it was thought better to base the calculation on boiler evaporation and a factor depending upon the number of revolutions of the wheels.

It should be borne in mind, however, that no one method or formula can express the tractive effort of all locomotives. So many variables affect the performance of a steam locomotive that attempts to devise a universal formula have never been successful. As an example, it suffices to say that in designing steam cylinders the proper dimensioning and shaping of steam ports and bridges, and the relative location of exhaust- and live-steam passages, are of great consequence as regards the question of losses caused by wire drawing and condensation. No formula can express the ability of the designer to provide an economical cylinder. The most that can be done by a formula is to express the average results of a well-proportioned locomotive of a design that is characteristic of a certain period of locomotive development, and to give an idea of the power of a steam locomotive under ordinary working conditions with a degree of accuracy sufficient for practical purposes.

With this end in view, the author attempts in what follows to provide means of quickly and fairly accurately evaluating the horsepower and tractive effort of a modern two-cylinder, simple-expansion locomotive equipped with a superheater of sufficient size, with or without a feedwater heater, with a proper valve motion, and with other parts characteristic of modern locomotive design.

---

[1] Consulting Engineer, American Locomotive Company. Nonresident professor, Purdue University. Mem. A.S.M.E. Mr. Lipetz was educated at the Warsaw (Poland) Polytechnic Institute, from which he received the degree of Engineer Technologist (mechanical engineer) of the first grade in 1902. In 1903 he entered railway service in Russia as an apprentice on the Moscow-Kiev-Voronesh Railway, later serving as fireman, locomotive driver, inspector, and assistant master mechanic. From 1906 to 1909 he was assistant professor of thermodynamics and railway mechanical engineering at the Kiev Polytechnic Institute, passing examinations preliminary to degree of Doctor of Engineering. For three years he held administrative positions on the Tashkent Railway, and for the three years following was chief of the locomotive department, Ministry of Railways, Russia. From 1915 to 1920 he served the Russian Railways in the United States, first as representative of the Russian Ministry of Railways and then as assistant chief and, later, chief of the Russian Mission of Ways of Communications in the United States. Since 1920 he has been connected with the American Locomotive Company, first as European representative at Paris, and since 1925 as consulting engineer at Schenectady, N. Y. Since 1927 he has also been nonresident professor of locomotive engineering at Purdue University. He was granted a number of early patents on Diesel locomotives and was the designer of the Russian Decapod locomotives of the war period. He is the author of many papers on steam and Diesel locomotives, and was the reporter for America on locomotives of new types at the International Railway Congress held at Madrid, Spain, in 1930.

[2] "Locomotive Ratios," by F. J. Cole, American Locomotive Co. Bulletin No. 1017, 1914.

Contributed by the Railroad Division and presented at the Annual Meeting, New York, N. Y., December 5 to 9, 1932, of THE AMERICAN SOCIETY OF MECHANICAL ENGINEERS.

NOTE: Statements and opinions advanced in papers are to be understood as individual expressions of their authors, and not those of the Society.

For locomotives of an earlier period, Cole's formulas are sufficiently accurate, and although the method about to be explained could also be extended to cover all locomotives, no attempt has been made to supersede the Cole method for locomotives of prewar design.

Tractive Effort

The basis of all tonnage and speed-time-distance calculations is the tractive effort of a steam locomotive. Of the different tractive efforts that are sometimes being used, the basic one is the "indicated tractive effort," which is the direct result of the work of steam in the cylinders. For a two-cylinder, simple-expansion locomotive it is usually expressed by the formula

$$T_i = p_i \frac{d^2 s}{D} = \alpha p_b \frac{d^2 s}{D} \quad \ldots\ldots\ldots\ldots\ldots [1]$$

in which

T_i = indicated tractive effort, lb
p_i = mean indicated pressure in the cylinder, lb per sq in.
d = diameter of cylinder, in.
s = piston stroke, in.
D = diameter of driving wheels, in.
p_b = boiler pressure, lb per sq in.
$\alpha = p_i/p_b$ = mean indicated pressure ratio.

The "rail tractive effort," which is the imaginary force applied to the rim of the wheels, and the drawbar pull on the tender drawbar, can be found from the indicated tractive effort, if the engine friction and total locomotive resistance are known. The object of this paper is to establish a method and figures for the calculation of indicated tractive effort as a function of speed.

As can be seen from [1], the tractive effort depends upon the boiler pressure, size of cylinders, and diameter of the driving wheels. At starting and low speeds, when the capacity of the boiler is able to supply the cylinders with steam at maximum cut-off, the enumerated factors are the only ones that need be considered. In this case the mean effective pressure is from 85 to 93 per cent of the boiler pressure, and the tractive effort is easily calculated from Formula [1]. By making $\alpha = 0.85$, the formula gives what is known as the "rated tractive effort" of a steam locomotive, namely,

$$T = 0.85 p_b \frac{d^2 s}{D} \quad \ldots\ldots\ldots\ldots\ldots [2]$$

Ordinarily it is assumed that this tractive effort does not depend upon the speed, which is more or less correct for low speeds. However, as the speed increases, the tractive effort drops for the reason that losses due to steam friction in the steam ports and passages (wire drawing) decrease the mean effective pressure. The tractive-effort curve at the maximum cut-off (85 per cent), or as it is sometimes called, the "cylinder tractive effort," varies with the speed, as shown by the curve $RAA'M$, Fig. 1.[3]

If the maximum cut-off should be maintained for some time, a speed (V_1) will be reached beyond which the boiler evaporation is not sufficient at that cut-off for sustained performance. The boiler pressure will begin to drop. Just before this speed is reached, the cut-off should be reduced, say, to 81 per cent, when the cylinder tractive effort will be represented by a new curve, BB', which will also have a sloping characteristic similar to that of the maximum cylinder tractive effort. At a certain speed (V_2) the boiler evaporation limit will again be reached and the cut-off will have to be further reduced, and so on. Accordingly, there will be a whole series of curves which will represent tractive efforts at different cut-offs. Points A, B, C, D, E, etc. if connected, will form a border line for all possible tractive efforts below the evaporation limit. In other words, it will represent the maximum tractive effort of the locomotive, limited by the boiler evaporation, or the "boiler tractive effort."

Curve RA and curve $ABCDE$ together form what is called the tractive-effort curve of the locomotive. One portion, RA, is part of the maximum cylinder tractive effort, while the remainder, $ABCDE$, is the boiler tractive effort. Two locomotives with the same cylinder sizes, boiler pressures, and wheels, but with different boilers, would have cylinder tractive efforts that were practically alike, but the boiler tractive efforts would differ, as shown by curve $A'B'C'D'E'$. It is therefore evident that a knowledge of cylinder sizes and other parts of the machinery is not sufficient for establishing the tractive effort of a locomotive.

As the horizontal portion of the maximum cylinder tractive effort is the rated tractive effort, which does not vary with speed, it can be stated that the tractive-effort curve of a locomotive is limited on the one hand by the rated tractive effort, which is a horizontal line, and by the boiler tractive effort, which is a curve of hyperbolic shape.

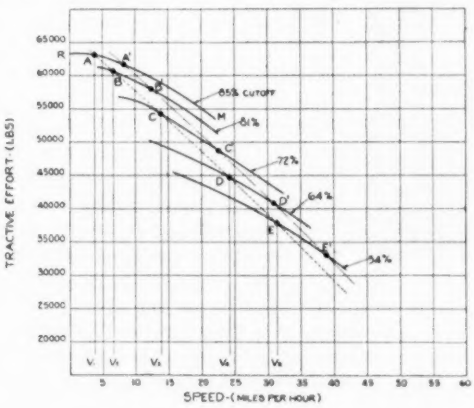

Fig. 1

A method of plotting the tractive-effort curve on the basis of cylinder sizes only, using the rated tractive effort and certain factors, irrespective of the size of boiler, is in principle incorrect. Nevertheless, in practice, it can give good results for the reason that in a locomotive of a certain period and of conventional proportions, the sizes of the locomotive boiler and cylinders are in a certain ratio to each other. However, as with improvement in locomotive design the boiler becomes larger in proportion to the engine, in order to meet the increased speed requirements of traffic, the formulas based on cylinder sizes and Cole's factors begin to give too low values.

Mr. Cole himself introduced the idea of boiler horsepower. He determined it to be equal to the maximum evaporation in pounds per hour divided by 20.8 for superheated steam, this figure representing the consumption of steam in pounds per horsepower-hour, including auxiliaries.[4] This made it possible to determine what is called the boiler percentage, which means the ratio of maximum cylinder horsepower (at 1000 fpm piston speed) to the boiler horsepower, the maximum cylinder horsepower being found from the Cole formula, and the boiler horsepower as stated above. Cole recommended designing locomotives with boiler percentages as close to 100 per cent as possible. In this case his method of plotting the tractive-effort curve would be correct, strictly speaking, at least for one point, namely, 1000 fpm piston speed. However, for locomotives with larger or smaller boilers, the boiler

[3] Compare with Lomonossoff, "Locomotivversuche in Russland," Berlin, 1926, p. 84; also "On the Calculation of Drawbar Pull of Steam Locomotives," by R. Nakamura, part iii, Tokyo, 1931, p. 4.

[4] "Locomotive Ratios," p. 9; also "Locomotive Handbook," American Locomotive Co., 1917, p. 64–65.

percentage had no effect on plotting the curves. Therefore some locomotive builders and railroads have already found it necessary to make corrections in the Cole factors in relation to the boiler percentages. This in fact is a roundabout way of figuring the correct tractive effort for a piston speed of 1000 fpm, and an approximate value for other speeds.

Direct Methods of Establishing Tractive-Effort Values

There are at least two possible direct methods for establishing the tractive-effort values for different speeds—one, which might be called the analytical method, and the other, an empirical method.

The first, the analytical method, is logical and seemingly very simple; however, in order to give good results, it requires a number of corrections, which can be determined only from actual experience. It would seem very simple, if the evaporation of the boiler and principal dimensions of the locomotive engine are known, to calculate the amount of steam per stroke for each speed and the tractive effort for that speed resulting from the work of the figured amount of steam. Knowing the diameter of the driving wheels D in inches, we can find the number of revolutions per minute n from the formula

$$n = \frac{336.134\ V}{D} \quad \ldots\ldots\ldots\ldots\ldots\ldots [3]$$

V being the locomotive speed in miles per hour.

Denoting the clearance volume of a cylinder in relation to the swept volume of the piston by l; the cut-off, or admission, in relation to the stroke by a; the compression in relation to the stroke by c; the swept volume of a piston, in cubic feet, by U; the specific volume of steam, in cubic feet per pound, at the moment of cut-off by v; the specific volume of steam, in cubic feet per pound, at the beginning of compression by w; the total evaporation of a locomotive boiler in pounds per hour by E; and the amount of steam spent on auxiliaries in relation to the total evaporation by x, the enumerated quantities for a two-cylinder simple locomotive are tied together by the following formula

$$E(1-x) = U \times 4n \times 60\left[\frac{a+l}{v} - \frac{c+l}{w}\right] \ldots\ldots [4]$$

from which the admission a can be found by the method of approximation.[5]

If we know the boiler pressure, the admissions thus found for certain numbers of revolutions corresponding to certain speeds, permit the plotting of indicator cards for these speeds and thus establishing the mean effective pressures p_i of steam in a locomotive cylinder, also for various speeds, which in turn will make it possible, by using Formula [1], to figure the tractive effort of the locomotive as a function of its speed.

This method was proposed and used in the early years of locomotive development, and for a long time it was considered to be the only possible method in view of its comprehensibility. It is rational in principle, and therefore had a great many adherents. The difficulty with the method, however, lies in the fact that two important and very complex factors are neglected: first, the cooling of steam in the cylinder, and second, the distortion of indicator cards due to speed, both of which cause considerable losses.

The cooling of steam in the cylinder, or what is known as the heat exchange between the steam and the cylinder walls (and heads), cannot be expressed by any theoretical formula. A large number of studies has been made, some of them employing very complex forms of mathematical analysis,[6] in order to establish the cooling effect of the cylinder, but none of them has given practically satisfactory results, as too many variables are involved. With highly superheated steam the conditions are slightly better and some formulas can be established, but even then, resort must be had to empirical figures from tests, as will be shown later.

The second factor, distortion of indicator cards, depends upon the valve-motion characteristics, steam-port dimensions, and steam passages, as all of them entail drops in pressure, depending upon the speed. These laws are also very intricate and do not easily lend themselves to mathematical expression; and when formulas are used, they must also be corrected by test data, which of course are only approximate.

The best example of such a theoretical study in recent years is that made by the late Professor Strahl of the German State Railway in his book "Der Einfluss der Steuerung auf Leistung, Dampf- und Kohlenberbrauch der Heissdampflokomotiven."[7] He bases his calculations on superheated steam at 300 C (572 F), and assumes for such steam a contraction of volume equivalent to a cooling of 60–80 C (108–144 F). For higher superheats he further assumes that each 5 deg C (9 deg F) increase in superheat decreases the steam consumption by 1 per cent. These constants are recommended as approximate general results from tests.

For the mean effective pressure p_i he gives the formula

$$p_i = bp_s - p_d\,(b - 0.6a) - p_e$$

where p_s is the steam-chest pressure, a is the admission, and b, p_d, and p_e are expressed by long and very intricate formulas embodying a number of experimental constants.[8]

Professor Strahl shows that for the German standard locomotives used in 1917, his method gives fairly good results. The author tried to apply it to an American 4-6-4 locomotive for which test data were available. It took an experienced calculator two days to determine three points—three tractive efforts for three speeds—and these were not in agreement with the test results.

It is possible, however, that if tables were worked out for the constants and common principal dimensions of American locomotives, the calculations could be simplified, and that certain modifications would make the formulas more suitable for American locomotive proportions.

The main difficulty, however, is that a number of assumptions has to be made for the derivation of these formulas, and in order to make them conform to actual practice, the constants must be taken from test data, which, of course, are good only for locomotives of approximately the same principal dimensions; in other words, these complicated formulas do not eliminate the need of using empirical data, and therefore the question arises whether it would not be better to base a method on empirical data only, taking into consideration the principal dimensions of the locomotive, and thus save the amount of work involved in these intricate calculations.[9]

The second method, which is an outcome of just this consideration, was suggested also years ago by locomotive investigators. Frank, von Borries, Richter, and others tried to establish empirical tables and curves for the horsepower of locomotives of different types as a function of the locomotive speed expressed in number of revolutions per minute. Table 1 gives the figures

[5] This is necessary in view of the fact that c is a function of a.

[6] "Steam Power," by W. E. Dalby, New York and London, 1915, p. 243.

[8] See pp. 9, 11, 12, 25, and 27 of Professor Strahl's work just cited.

[9] In his doctor's thesis, Achterberg suggested calculating the losses due to heat exchange in cylinders instead of using Strahl's empirical constants, but had to introduce other constants based on test results. See "Kurzes Lehrbuch des Dampflokomotivbaues," Dr.-Ing. F. Meineke, Berlin, 1921, pp. 66, 68–69.

TABLE 1

	Revolutions per minute					
	90	120	150	180	210	240
Horsepower per square meter of gas heating surface (inside)	4.7	5.2	5.5	5.7	5.7	5.5
Horsepower per square foot of evaporative heating surface (outside)	0.39	0.43	0.46	0.48	0.48	0.47

which von Borries recommended for plotting horsepower curves for two-cylinder simple-expansion locomotives operating with saturated steam.[10] They are referred to one square meter of gas fire-side (inside) heating surface and given in relation to the rpm of the driving wheels.

The last line of the table represents the same horsepowers referred to outside heating surface in square feet, in order to make them comparable with data on American locomotives. They are from 25 to 35 per cent lower than corresponding figures of our modern locomotives with superheated steam, but the general character of power increase with speed is the same.

As soon as the law of the horsepower curve was established, the tractive-effort curve could be easily figured by the known formula

$$P = \frac{T \times V}{375} \quad \ldots\ldots [5]$$

where P = indicated, rail, or drawbar horsepower
T = corresponding (indicated, rail, or drawbar) tractive effort, lb, and
V = locomotive speed in miles per hour.

Similarly, in 1901, the author while a college student, found that the parabolic shape of the horsepower curves suited very well the then existing types of locomotives. He published an article[11] in which he suggested the use of formula

$$\frac{P_i}{H} = \frac{A\sqrt{n}}{1 - B\sqrt{n}}$$

in which A and B are functions of the principal dimensions of the locomotive, mainly heating surface and grate area.

These formulas are also out of date, but it might be possible to establish new constants even for the most modern locomotives, as all horsepower curves seem to follow the same general law.

The advantage of the empirical method, expressed either by tables or formulas, lies in the idea of basing the calculations on horsepower rather than on tractive effort, as the former depends upon a smaller number of variables than the latter. If the locomotive is built in accordance with certain standards of perfection and refinement, the horsepower depends mainly upon the amount of steam generated by the boiler. If, in accordance with previous notations, the amount of steam available for the engine is

$$E \times (1 - x)$$

and if the properly designed locomotive engine requires S_h lb of steam per ihp-hr, the indicated power of the locomotive is evidently

$$P_i = \frac{E \times (1 - x)}{S_h} \quad \ldots\ldots [6]$$

The sizes of cylinders do not come directly into consideration. If they vary within a limited range, as is the case in locomotives, and if the proportions are correct, they should not influence S_h. As is known from the theory of steam engines, the important factors are the cut-off and the number of revolutions per minute (rpm).[12] The first factor determines the expansion ratio and the thermodynamic efficiency of the steam cycle, while the second affects the condensation and steam-friction losses.

Some investigators think that steam consumption depends on piston speed, and so Mr. Cole found in his investigation of locomotive data, but the majority of steam-engine authorities refer steam losses to the rotary speed of the crank and not to piston speed. Steam-consumption figures based on recent locomotive test data also show more uniformity when they are referred to crank speed rather than to piston speed.

However the case may be, the advantages of referring the steam consumption to piston speed, or to the rpm, cannot be great, as the piston strokes do not differ much in modern locomotives, being between 28 in. and 32 in. On the other hand, as the cut-off depends on the rpm and not on the piston speed (see [4]), it seems to be more practicable to consider S_h as depending on the rpm.

It cannot depend on linear speed of the locomotive as this would be equivalent in stationary practice to the peripheral speed of the flywheel. Nothing like that has ever been found, and therefore the diameter of the driving wheels can have no influence on the indicated power of a locomotive. It is reflected, though, in the tractive-effort values.

The tractive effort of a locomotive is one of the two components of the locomotive horsepower. The cylinders and driving wheels permit resolving the horsepower into tractive effort and speed in accordance with Formula [5], namely, $P = T \times V/375$.

Thus the tractive-effort calculations can be simplified by determining first the locomotive horsepower as a function of either the rpm or the piston speed, depending upon which of the two influences on the efficiency of the locomotive is reflected in S_h, and then later resolving the horsepower into tractive effort and locomotive speed.

The foregoing, of course, refers to the boiler tractive-effort curve, which has a hyperbolic shape (Fig. 1). As to the horizontal portion of the tractive-effort curve, this is determined entirely by the rated tractive effort (Formula [2]). There is no connection between these two except only as far as the sizes of the cylinders and boiler in a well-proportioned locomotive are dependent upon each other.

Boiler Tractive Effort

Thus the tractive-effort curve depends in its major part upon the amount of steam generated in the boiler and the consumption of steam per horsepower-hour. The natural thing, therefore, is to establish the laws of the two variables. The analytical method can hardly lead us to the result sought for, and we have to rely entirely upon test figures.

Unfortunately, tests are not being conducted in such a way as to enable us to establish the two above-mentioned variables as completely as is desired. Even the most elaborate tests, which are supposed to give all data in which an investigator should be interested, attempt to find solutions for various problems not always with a view to establishing the tractive-effort curve. However, by analyzing available data, certain conclusions can be drawn, as will be seen below.

Strictly speaking, horsepower and tractive effort are not definite conceptions unless we specify certain conditions at which power and tractive effort are being considered. There can be the *maximum* tractive effort which the engine is capable of producing irrespective of the amount of coal burned and the cost of such a forced operation. There can be the *most economical* tractive effort, and this from the point of view of fuel only, when short cut-offs and long expansions are used, or from the point of view of

[10] "Das Eisenbahnmaschinenwesen der Gegenwart," by Blum, von Borries, and Barkhausen, I—Lokomotiven, Wiesbaden, 1912, p. 123.

[12] "The Steam Engine," by Sir J. Alfred Ewing, Cambridge, 1926, p. 208; also "Steam Power," by W. E. Dalby, p. 237.

total operation expenses. The latter is the more important, and it is safe to assume that under ordinary conditions the mode of operation of locomotives, established by long experience, is in the end the most economical. This can be called "performance tractive effort." Only in exceptional cases, when the locomotive is pulling a fast passenger train at top speeds and is forced to the limit of its power, is the maximum tractive effort, or what is called the "capacity tractive effort," developed.

The method of plotting the maximum and average performance curves is clear from Fig. 16. Both horsepower and tractive-effort test figures have been used and mutually checked by Formula [5].

Some European investigators, in order to introduce more definiteness into the terms, consider horsepower and tractive effort at a certain evaporation rate either normal or maximum. Professor Nordmann, who is in charge of the Locomotive Test Department of the Reichsbahn, has established a standard evaporation of a locomotive boiler equal to 57 kg of steam per square meter of inside (fire side) heating surface. This is equivalent to 11.7 lb per sq ft of inside (fire side) heating surface, or approximately 10.6 lb per sq ft of outside (evaporative) heating surface, as it is customary to figure in this country. For the purposes of the tests conducted by Professor Nordmann, such a method is perfectly justified, because the main object of his tests is to compare the power and efficiency of German standard-type locomotives. This standard evaporation figure makes it possible to reduce, for purposes of comparison, all locomotives to one basis.

However, such a method, which is also followed by other European railroads, only with different standard evaporation figures, would not enable us to plot the locomotive tractive effort as we understand it, because a locomotive working under actual operating conditions is not regulated in such a way as to generate a certain constant amount of steam per square foot of heating surface under varying conditions of work.

The amount of steam which is generated by a locomotive depends, primarily, upon the amount of coal burned in the firebox, and, secondly, upon the efficiency of the boiler under that condition. There is a limit to both the amount of coal that can be burned on a certain area of grate and to the amount of heat that can be transferred through the heating surface of a boiler into the water. In locomotives with small grate areas the first will be the ruling factor. In locomotives with excessive grate areas, the second may be the controlling factor. In well-designed locomotives the proportions are such that the two factors will more or less balance.

On the other hand, the amount of coal burned on the grate of a locomotive depends upon the draft in the smokebox, which in turn depends upon the amount of steam put through the exhaust nozzle.

Thus the evaporation depends upon the rate of firing, which in turn depends upon evaporation. This establishes a balanced condition in a locomotive boiler at certain rates of firing, permitting a lesser or greater forcing of the boiler. A locomotive can be operated very hard, at the limit of its capacity, burning as much as 200 lb or more of coal per square foot of grate area, but the efficiency of the boiler will then be very low and the total amount of steam may not be much more than at a lower firing rate. Experienced firemen and engineers know what the normal working conditions of a locomotive should be, and ordinarily they fire so as to develop a certain, reasonably economical, amount of steam. Road tests give a fairly good indication of these conditions. When an engineer takes over the road a full-load train, it may be expected that he operates the locomotive so as to develop a reasonable horsepower and tractive effort under the existing operating conditions. Certain horsepowers and tractive efforts are then developed which were referred to above as performance curves. As it will be shown later, they correspond to what we usually consider normal evaporation of the locomotive boiler.

However, a locomotive may be able to develop more than its performance curves would indicate. The limit of its capacity is normally higher. Therefore, on some roads, in addition to performance tests, special capacity tests are being made in order to establish the maximum output of the locomotive. These tests should be so conducted that both the maximum boiler pressure and the water level remain constant during the test. The fulfilment of these two conditions is absolutely necessary in order to obtain reliable figures for sustained capacity operation; when they are not adhered to, exaggerated results will follow.

The underlying idea of the European method of testing locomotives at constant evaporation of the boiler is that the evaporation does not depend upon the performance of the locomotive engine. The advocates of this theory claim that a locomotive boiler can generate any desirable amount of steam, up to its limit, independently of the speed of the locomotive. They assume that because more steam is generated and passed through the exhaust nozzle, the draft is accordingly increased, permitting in turn the generation of the increased amount of steam. It is also claimed that this amount is independent of the manner in which the steam is exhausted, whether intermittently or continuously; in other words, by a small number of heavy exhausts, or a large number of small puffs, creating in the latter case a practically uniform draft. Professor Goss was a believer in this theory,[13] and there are other authorities (for instance, L. H. Fry[14]) who share this view.

On the other hand, an opposite view is held by a large number of engineers. Von Borries, for instance, was of the opinion that uniformity of draft results in better boiler efficiency and higher evaporation rates, which, he thought, was proved by tests with cross-compound locomotives having only half the number of exhausts.[15] Further, in the author's opinion, the vibration of the locomotive on a railway track, which increases with the speed, must influence steam generation very favorably. The amount of air which is forced into the ashpan in larger quantities as the speed goes up should also affect the evaporation. In other words, as a result of all these causes, the boiler evaporation increases with the speed.

There are no direct tests which would indicate the correctness of either of these theories, because, to the best of the author's knowledge, no tests have ever been conducted with this purpose in view. Ordinary road tests do not give the information, because the speed during the test varies all the time. The amount of water which is measured at the beginning and at the end of the test cannot show the relation between total evaporation and variable speed.

It would seem that stationary tests should give the figures of maximum evaporation and speed, because each test is conducted at constant cut-off and constant speed, and the most severe combination of these two variables should be close to the limit of boiler capacity. With this in view, curves were plotted for five Pennsylvania locomotives (K4s, E6s, K2sa, L1s, and I1s), as shown in Fig. 2, for different numbers of revolutions of the driving wheels per minute. The data were taken from bulletins published by the Pennsylvania Railroad on locomotive tests at the Altoona testing plant. For better comparison, evaporation is given not in absolute figures but in percentages of evaporation

[13] "Locomotive Performance," by W. F. M. Goss, New York, 1907, p. 138.

[14] Trans. A.S.M.E., vol. 47 (1925), p. 1271.

[15] "Compound Lokomotiven," by von Borries, *Organ für die Fortschritte des Eisenbahnwesens*, 1883, pp. 190–192; also "Das Eisenbahnmaschinenwesen der Gegenwart," by Blum, von Borries, and Barkhausen, I—Lokomotiven, Wiesbaden, 1912, pp. 118–119.

for respective boilers in accordance with Cole constants (A. L. Co. Hand-Book, 1917, p. 59).

It will be seen that while the curves differ very widely, their shapes all have the same parabolic characteristic of increase with speed up to a certain limit, and subsequent drop for higher speeds. The peak points are from 12 to 28 per cent above the Cole figure. This must have been due to forcing the boilers to high evaporation rates. The peak point on curve 1 (locomotive K4s), for instance, corresponds to a rate of firing of 171 lb of coal per sq ft of grate area per hr. On curve 5 (locomotive I1s) the rate of firing is still higher, due to the small grate area of this locomotive. In Fig. 2 the rates of firing for peak points are inscribed in rectangles. The figures in circles represent the ratios of heating

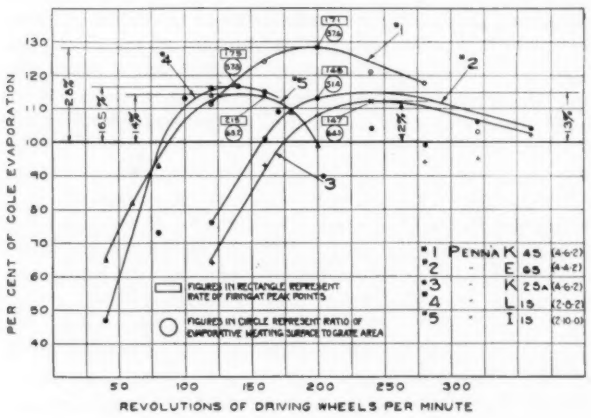

FIG. 2

surface to grate area for each of the five locomotives. In other cases they have also been very high, indicating that Cole's evaporation corresponds very closely to a rate of firing of 120 lb per sq ft of grate area per hr, as was assumed by him.

The shape of the curves evidently depends upon the ratios between the principal dimensions of the boilers. It can be assumed that the ratio between total heating surface and firebox heating surface, as well as the ratio between total heating surface and grate area, influenced the shape of the curves and the location of the peak points. The drafting arrangements and the size and type of the exhaust nozzle must have also been of great importance in this respect.

It is not possible to find a formula for the curves of evaporation as functions of these variables. They do not run consistently enough, and there are other variables that cannot be put in a formula, as, for instance, the quality of coal. More consistent results were obtained from plotting curves of road tests, as shown in Fig. 3. Three locomotives are considered here (New York Central J-1a and L-2, and Boston & Albany A-1), representing three different classes of service: high-speed passenger, high-speed freight, and moderate-speed freight.

As stated above, there are no test data which would permit plotting these curves directly. An indirect method was therefore evolved for this purpose. From road tests with locomotives the maximum-performance indicated horsepowers and corresponding speeds and cut-offs were chosen. From the Altoona tests, locomotives of similar engine size were selected, and the steam consumption per horsepower was found. It was corrected for difference in boiler pressures and superheats, and further, a certain percentage for auxiliaries was added from road-test data. Thus the probable specific consumption of road locomotives per indicated horsepower at various speeds was established. The product of horsepower and the established specific steam consumption furnished a means of finding the probable steam evaporation of the road locomotive for the maximum-performance power.

It will be seen that in this case the variation of the maximum evaporation of different locomotives is much less; it is between 2.7 and 6.7 per cent greater than the Cole figure. The variation in the location of the peak points in relation to speed is also less, and they all happen to be between 150 and 170 rpm. Nevertheless, even in this case it was not possible to tie up the shape of the curves with the principal dimensions[16] of the corresponding locomotives by a mathematical formula.

Other locomotives were also studied, and on the basis of the accumulated information it was found possible to draw a probable curve of evaporation, as shown in Fig. 4. It has a peak point 7 per cent above that of the Cole figure, and at about 200 rpm.

All locomotives shown in Fig. 3 were equipped with feedwater heaters, and it is very striking to find that the average maximum evaporation is about 7 per cent above the Cole figure. This is easily explained by the increase in efficiency due to feedwater heating. In other words, we may assume that the Cole evaporation figures still hold good for boilers on modern locomotives without feedwater heaters, but when locomotives are equipped

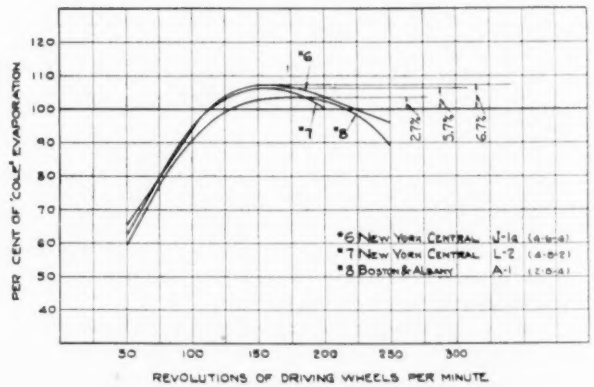

FIG. 3

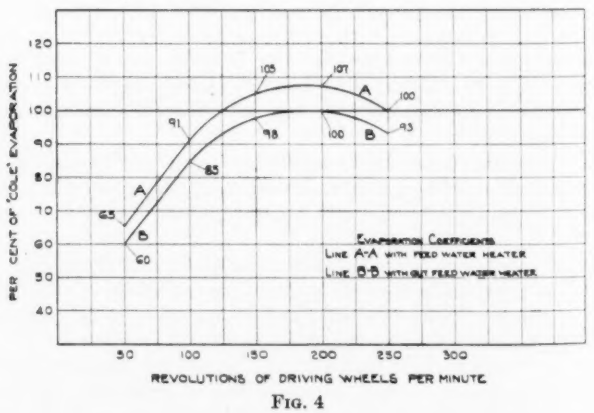

FIG. 4

with feedwater heaters, the boilers generate 7 per cent more steam.

It will be seen that the curve was plotted rather conservatively; at low speeds it follows the lowest portions of curves from road tests, while at high speeds it is slightly above the average for road tests—this for the reason that other locomotive data with feed-

[16] The principal dimensions of all locomotives represented in Figs. 2 and 3 are given in Appendix No. 1.

water heaters pointed in this direction. The plotting of this curve can be done by using the following formula:

$$E = \beta E_c \quad \ldots\ldots [7]$$

where E = boiler evaporation at a certain speed
E_c = Cole evaporation figure
β = evaporation coefficient in relation to the Cole evaporation figure.

The evaporation coefficients are shown in Fig. 4 and repeated in Table 2 in relation to the crank speed.

TABLE 2

Speed, rev per min	Evaporation coefficient — Locomotives without feed-water heater	Evaporation coefficient — Locomotives with feed-water heater
50	0.60	0.65
100	0.85	0.91
150	0.98	1.05
200	1.00	1.07
250	0.93	1.00

It may appear that the average curve was plotted rather arbitrarily, and that another curve could be chosen for the average evaporation with equal justification. It will be seen later that the ultimate recommendations for plotting horsepower and tractive-effort curves are based on test results and do not depend directly on the evaporation coefficients. They are independent of the evaporation curve plotted in Fig. 4, which is given here simply as an illustration of the principle of the method.

Recommended Method

When the boiler evaporation is determined, the indicated boiler horsepower can be found from the previously given Formula [6]:

$$P_i = \frac{E(1 - x)}{S_A} \quad \ldots\ldots [6]$$

where E = evaporation, lb per hr
x = ratio of steam used for auxiliaries
S_A = steam consumption per horsepower-hour, lb (steam rate)

provided S_A is known.

It was thought more advisable to study $S_E/(1 - x)$, which represents S_a, the steam consumption per horsepower-hour, including auxiliaries, rather than S_A and x separately. Various locomotives were analyzed and it was found that the average steam consumption per horsepower-hour, including auxiliaries, can be well represented by one of the two curves shown in Figs. 5 and 6, depending upon whether we refer them to the rpm or to the piston speeds.

It can be seen that the two curves differ very little; in other words, the piston speed has actually very little effect on steam consumption within the limits of strokes in modern locomotives, namely, 28 to 32 in. It is therefore practically of little importance for the computation of boiler horsepower whether the steam rate is taken as a function of crank speed or piston speed, at least for strokes between 28 in. and 32 in.

The method of figuring boiler horsepower can thus be reduced to the following:

On the basis of general boiler dimensions the Cole evaporation E_c is figured[17] and the various evaporations E for different crank speeds n (rpm) are calculated in accordance with Formula [7] and Table 2. The figures thus obtained for E are divided over the corresponding steam rates S_a of Fig. 5 and the quotients obtained are horsepowers P_i for the various speeds.

If it is desired to use Fig. 6, which gives steam rates with respect to piston speeds, then it is necessary that the evaporation figures estimated in accordance with Formula [7] and Table 2 be referred to piston speeds, which can be calculated for various crank speeds n by the formula

$$S_p = \frac{s \times n}{6} \quad \ldots\ldots [8]$$

where S_p = piston speed, ft per min
s = stroke, in.

In either case, whether the horsepower has been figured in relation to crank speed or piston speed, in order to find the tractive effort it is necessary to refer horsepower to locomotive speed, which can be done by using the formula

$$V = \frac{D \times n}{336.134} \quad \ldots\ldots [9]$$

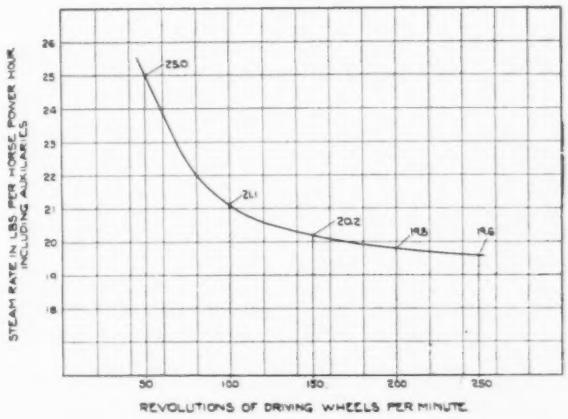

Fig. 5

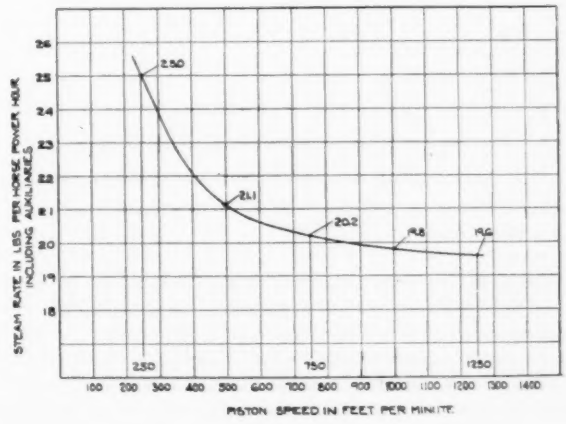

Fig. 6

The tractive effort is easily calculated by using Formula [5]. Tables for the conversion of crank speed into piston speed and locomotive speed for different strokes and diameters of wheels are very helpful in making these calculations.[18]

Thus the boiler tractive effort is determined and can be plotted on a chart. The rated tractive effort is then figured in accordance with Formula [1], plotted as a straight constant-effort line on the same chart, and extended until it intersects the boiler tractive effort. The point of intersection determines the speed at maximum tractive effort.

Regarding steam-rate curves (Figs. 5 and 6), the following is to be said:

The test data were not sufficient for plotting through the whole

[17] See Appendix No. 2.

[18] See Appendix No. 3.

range of speed. Only a portion of the curves, representing the most frequent average speeds of road tests, could be plotted. In order to cover the whole range of speed, an inverted method has been used; assuming that the coefficients of evaporation (β) as above given were correct, the total evaporations of several existing locomotives were calculated as functions of speed and divided over the corresponding horsepowers. The results for various curves are shown on Figs. 7 and 8 in reference to rpm and piston speed. Figs. 5 and 6 represent averages of the curves shown on Figs. 7 and 8.

It will be seen that the steam rates S_a give very consistent results at low speeds up to about 150–180 rpm, while above 200

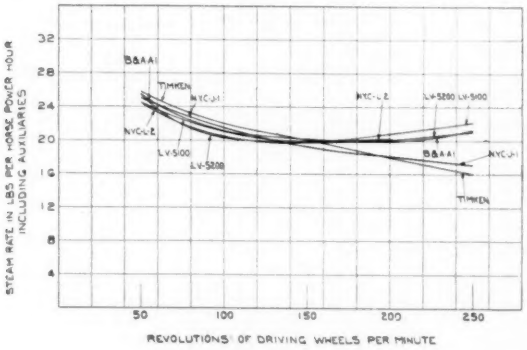

FIG. 7

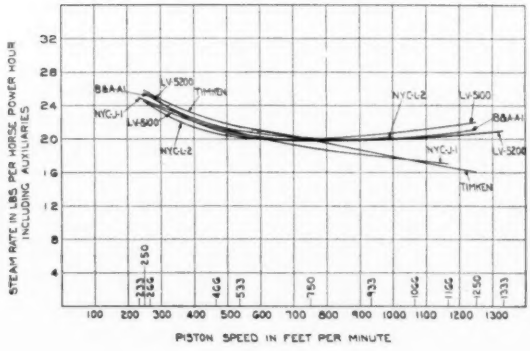

FIG. 8

rpm the steam rates vary rather widely. This cannot be due to the coefficient of evaporation β, because this is practically constant between 150 and 250 rpm. It is due to the usual discrepancy between locomotive-test results at high speeds, because the influence of such factors as quality of coal, size of nozzle, drafting arrangement, steam passages in the cylinders, and valve-motion design become more pronounced at higher speeds.

The average curves check fairly well with steam-consumption figures obtained from tests for the ranges of speed for which data are available. By correcting them back through the coefficient of evaporation and test results for horsepower, the influence of β is eliminated if the horsepower of an existing locomotive is calculated as suggested above, on the basis of β and of steam rate S_a corrected on the same basis. This will be made still clearer later, when the simplified method is described.

An example may better illustrate the method. Suppose that we wish to find the tractive-effort curve for a 4-6-4 locomotive with 25 × 28-in. cylinders, 225 lb per sq in. working pressure, 79-in. driving wheels, type "E" superheater, feedwater heater and a boiler of given dimensions (New York Central J-1a).

We determine first the Cole evaporation E_c in accordance with the A. L. Co. Handbook and table given in Appendix No. 2, or calculate the evaporation by some other means—for instance, assuming an average evaporation of 12.2 lb per sq ft of total evaporation heating surface. If we follow the A. L. Co. figures, we find that

$$E_c = 54{,}662 \text{ lb of steam per hour}^{19}$$

Suppose that we prefer to figure on the basis of steam rate in relation to piston speed rather than rpm. In this case draw up Table 3 on the basis of the curve, Fig. 6. Then plot the boiler tractive-effort curve DE (Fig. 9). Calculate the cylinder (starting) tractive effort in accordance with Formula [1], and plot a horizontal line AD corresponding to the cylinder tractive effort up to its intersection with the boiler tractive effort. The line ADE represents the indicated tractive effort of the locomotive calculated on the basis of piston speed.

If instead of Fig. 6, Fig. 5 were followed, i.e., with the steam rate referred to crank speed in rpm instead of piston speed, the procedure would be simpler, because no conversion to piston speed would be necessary, as can be seen from Table 4.

The results are plotted on Fig. 9 as curve BC, and ABC represents the indicated tractive effort of the locomotive calculated on

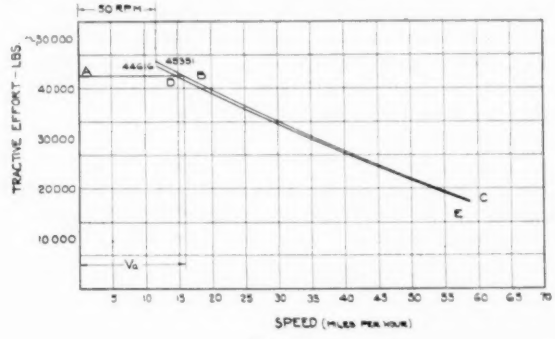

FIG. 9

the basis of crank speed. It can be seen that the difference between curves ABC and ADE is very slight.

SIMPLIFIED METHOD

It can be seen that if the above-described method is carried out on the basis of crank speed in rpm (Table 4), the calculation can be simplified by combining various constants into a single one, and obtaining the indicated-horsepower and tractive-effort figures directly. We already have the following relations:

$$P_i = \frac{E(1-x)}{S_h} = \frac{E}{S_a} \quad \ldots\ldots\ldots\ldots\ldots [6a]$$

$$E = \beta E_c \quad \ldots\ldots\ldots\ldots\ldots [7]$$

Indicated tractive effort, lb (T)	44,616	37,260	30,074	23,449	17,706

TABLE 4

Cole evaporation (E_c)	54,662 lb per hr				
Revolutions per minute (n)	50	100	150	200	250
Coefficient of evaporation (β)	0.65	0.91	1.05	1.07	1.00
Total evaporation (E)	35,530	49,742	57,395	58,488	54,662
Steam rate, lb per hp-hr (S_h)	25.0	21.1	20.2	19.8	19.6
Indicated horsepower (P_i)	1421	2357	2841	2954	2788
Speed, mph (V)	11.75	23.50	35.25	47.00	58.75
Indicated tractive effort, lb (T_i)	45,351	37,611	30,223	23,568	17,795

[19] Other evaporation figures are given in Appendix No. 1.

$$T_i = \frac{375P_i}{V} \quad [5_i]$$

$$V = \frac{Dn}{336.134} \quad [9]$$

Consequently

$$P_i = \frac{\beta}{S_a} E_c \quad [10]$$

and

$$T_i = \frac{375\beta \times 336.134}{S_a \times n} \frac{E_c}{D} = \frac{126{,}050 \times \beta}{S_a \times n} \frac{E_c}{D} \quad [11]$$

or denoting the factors preceding E_c in [10] by M_p, and preceding E_c/D in [11] by M_t, we may write

$$P_i = M_p \times E_c \quad [12]$$

$$T_i = M_t \times \frac{E_c}{D} \quad [13]$$

The values M_p and M_t may be called the "horsepower modulus" and "tractive-effort modulus," respectively, and they may be calculated from the above definitions, namely,

$$M_p = \frac{\beta}{S_a} \quad [14]$$

$$M_t = \frac{126{,}050 \times \beta}{S_a \times n} \quad [15]$$

Coefficient β and the steam rate S_a are functions of the crank speed n; therefore M_p and M_t are also functions of n and may be calculated on the basis of the previously stated values for these variables (Table 2 and Fig. 5). They are given in Table 5.

TABLE 5

Revolutions per minute (n)	50	100	150	200	250
Modulus $M_p \times 1000$[20]	26.00	43.13	51.98	54.04	51.02
Modulus M_t[19]	65.55	54.36	43.68	34.06	25.72

Thus the calculation of horsepower and tractive effort reduces to the operations indicated in Table 6, the results being practically identical with those of Table 4.

TABLE 6

Cole evaporation (E_c)	54,662 lb per hr				
Revolutions per minute (n)	50	100	150	200	250
$M_p \times 1000$	26.00	43.13	51.98	54.04	51.02
$P_i = M_p \times E_c$	1421	2357	2841	2954	2788
M_t	65.55	54.36	43.68	34.06	25.72
$T_i = M_t \times E_c/D$	45,354	37,611	30,222	23,566	17,795

If the tractive effort is the only curve which is desired and the horsepower values are not immediately wanted, the calculation can be still simplified by figuring only T_i and using the modulus M_t.

As an illustration of the simplified method, the previously mentioned locomotives, for which reliable road-test results are available (New York Central L-2, J-1a, Boston & Albany A-1, Timken roller-bearing locomotive, and Lehigh Valley locomotives Nos. 5100 and 5200[21]), have been checked and the results plotted on the charts of Figs. 10–15 in relation to crank speed and locomotive speed in miles per hour. The performance curves previously referred to are drawn on all these charts, and the corresponding simplified-method curves are marked "1932." The Cole curves are also given for comparison, and on two locomotives the capacity-test curves are also shown. It will be seen that the agreement is sufficient for practical purposes, and that the simplified method gives the maximum performance figures very closely. In the case of the New York Central J-1a and Timken locomotives, the discrepancy shown may have been due to the good quality of coal used in the tests.

The 1932 curves are drawn in solid lines up to 200 rpm. The agreement is very good, because the test results, as has already been pointed out, are very consistent up to that speed. For higher speeds there are not sufficient available data on which to base a precise method. For this purpose more than merely the principal dimensions would have to be taken into consideration, namely, some of the ratios already mentioned, such as total heating surface to firebox surface, heating surface to grate area, combustion-chamber surface to firebox surface, type, location and size of exhaust nozzle, valve-motion characteristics, areas of steam passages in cylinders, and quality of fuel expressed in a way suitable for a formula. For average conditions the curve will most probably have, at least for performance tests, a drooping characteristic, as shown for curves 1932, but it is not impossible that it might approach a horizontal line, shown by dots and dashes. More experimental data at high speeds will be necessary in order to impart more definiteness to that portion of the 1932 curve.

It has been pointed out earlier that the ultimate figures for horsepower and tractive effort do not depend upon the evaporation coefficient. This can be more clearly seen from Formulas [14] and [15], in which the ratio of S_a to β is what matters. The steam rates S_a as plotted in Fig. 7 are, as has been explained in the proper place, figured on the basis of the evaporation coefficients of Table 2, and therefore their ratio does not depend upon the numerical value of either of the two. In other words, if instead of variable β, a constant coefficient of evaporation of 100 per cent, as advocated by some investigators, had been taken, the values of S_a shown in Fig. 7 would be changed in the ratio of 1.00 to β. The moduli M_t and M_p would, in this case, remain unchanged because instead of variable β, 1.0 would be inserted in Formulas [14] and [15].

There is no doubt in the author's mind that for locomotive horsepower, the boiler evaporation is the controlling factor, at least for the proportions found in existing locomotives. However, if we imagine a boiler of very large proportions, one able to supply more steam than we usually get in the most modern locomotives, longer cut-offs would become possible, and at high speeds the mean effective pressures might drop below those that are obtained at present for corresponding cut-offs, on account of the steam resistances in passages (wire drawing). It is doubtful whether this would happen on locomotives of conventional proportions, but as a safeguard it may be advisable to set a limit for the possible increase in maximum horsepower compared with Cole's cylinder horsepower, which for superheated steam is expressed by 0.0229 times the area of one cylinder in square inches times the boiler pressure in pounds per square inch.[22]

In the author's opinion, that limit could be made not less than 24 per cent for engines with feedwater heaters, but as a conservative figure, 20 per cent should be recommended until further information can be gathered.

Of locomotives for which the charts of Figs. 10–15 show horsepower and tractive-effort curves, only one, the Lehigh Valley No. 5200, had a boiler sufficiently large to show an increase over the Cole formula of more than 20 per cent. Curve 1932 of Fig. 15 was therefore drawn in such a way as to have a peak point only 20 per cent above the Cole figure.

[20] These moduli apply to locomotives with feedwater heaters; for locomotives without feedwater heaters they should be reduced by 7/107 = 6.54 per cent.

[21] The principal dimensions of these locomotives are given in Appendix No. 1.

Conclusion

As was pointed out at the beginning, the object of this paper is to suggest a simple method for figuring horsepower and tractive effort for modern locomotives. To this class belong locomotives with type "E" superheaters, feedwater heaters, and valve motions with about $8^1/_2$ in. of valve travel. This presupposes that the superheater heating surface assures sufficient superheat, which in locomotives with the type "E" superheater is about 250 F. If locomotives have higher superheats, the power may increase, but it was not thought advisable to give constants for various superheats for the reason that before a locomotive is tested, its superheat is not known, and therefore these constants would not be helpful in calculating the horsepower of a locomotive beforehand. It would be logical to base such constants on the relation of the superheating surface to the evaporative heating surface, or to the amount of generated steam, but a comparison of these ratios with test results of various locomotives had not been conclusive.

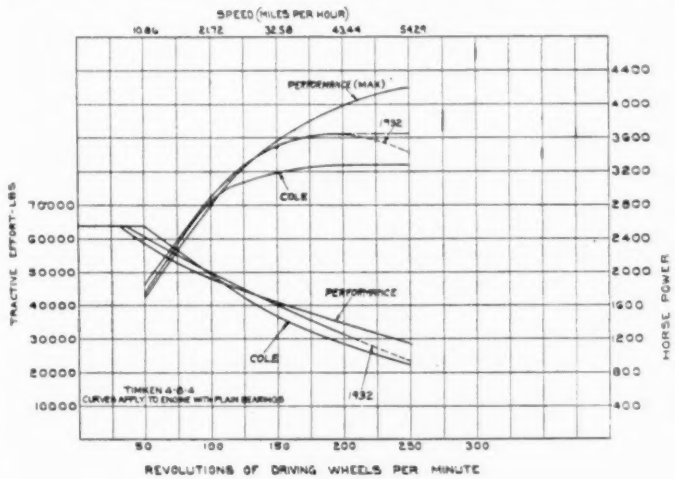

Fig. 13

For locomotives of older design, with type "A" superheaters, new constants could be worked out similar to those given in the paper, but it is suggested that for these latter locomotives the Cole formula should be used. While it would be possible to work out new constants on the basis of boiler horsepower instead of cylinder power, it is thought that until the new method has proved to be practical, the Cole formula should be used for locomotives with type "A" superheaters. This should not imply, however, that type "A" superheaters can never develop the horsepowers recommended by the new method. Locomotives are known that have given very high performance figures with type "A" superheaters on good coal.

A question may arise whether the suggested method can be used in designing locomotives. It is evident from the paper that this can be done very simply. If the desired maximum tractive effort is given, the cylinder dimensions are thus established. If, in addition, the desired speed is given, the horsepower is then established and from Formula [10] the evaporation can be figured. For instance, if a locomotive is desired with a certain tractive effort represented by the line AB, Fig. 9, necessary for pulling a given load on a certain grade, and if the speed V_a is desired on that grade, the horsepower P_i at point B is determined by Formula [5]. Formula [10] enables us then to find E_e because coefficient β and the steam rate S_a at speed V_a are known from Figs. 4 and 7. The boiler can be designed so as to generate E_e pounds of steam per hour.

If the speed for a certain train be given for a tractive effort other than maximum, for instance, on a level, the tractive efforts at this speed, and consequently the horsepower, can be determined as above. Formula [10] will also enable us to calculate the evaporation E_e and to design a boiler accordingly.

For practical purposes the moduli values given in Table 7 can be used.

Acknowledgments

Thanks are due to Mr. J. B. Ennis, vice-president of the American Locomotive Co., New York, N. Y., for encouragement and valuable advice given to the author during the preparation of the paper, and to Mr. C. W. Todd, assistant engineer, American Locomotive Co., Schenectady, N. Y., for his assistance in calculating tables and plotting curves.

Appendix No. 2

Evaporation figures for tubes and flues in pounds of steam per hour per square foot of outside heating surface are given in Table 28 of the A. L. Co. Handbook, p. 59. This table covers 2-in. and $2^1/_4$-in. open tubes and $5^3/_8$-in. and $5^1/_2$-in. flues (with superheater units). Tables 8 and 9 give similar values for $3^1/_2$-in. open tubes and $3^1/_2$-in. flues (with superheater units),

Discussion

G. F. STARBUCK.[23] The paper fills an important need in making possible the closer estimate of the indicated tractive effort of modern locomotives than could be made by the Cole method, although that has filled a very useful place for many years. The recounting of the research by which the author reached his method is of value in showing the impossibility of accurately expressing the tractive effort of all locomotives by any one method or formula. Besides differences in steam pressure, superheat, heating surface, grate area, firebox volume (with combustion chamber), draft appliances, and the efficiency of the feedwater heater, we have to consider the condition of the locomotive, quality of the coal, and the ability of the crew to get the most out of the engine. Heating surface will be variously divided into firebox, siphon, combustion chamber, and tube and flue and superheating surface, the tubes and flues being of varying lengths. So, when plotting the results of actual tests, we must expect considerable scattering of the plotted points, with a few of them near the computed line.

Since in formula [4] U is the swept volume of the piston, it seems that the cut-off does depend on the stroke. Moreover, it seems to be the practice to let the diameter of the cylinder, regardless of the stroke, determine the dimensions of the ports, distributing valves, and dry pipe. So it seems from these considerations more logical to consider the steam per indicated horsepower-hour as depending on piston speed.

It is believed that a discussion of the effects of limited and restricted cut-off would be of value. Since the diameter of the cylinder is made larger for short maximum cut-offs than for 85 per cent or longer, it seems that the ratio of the steam rate to the angular velocity would be different. Apparently at least some of the tests forming the basis of the factors of the method were made with a limited cut-off locomotive.

It is often desired to plot tractive-effort curves for locomotives having boosters, and it has been the custom to add the tractive effort of the booster to that of the main engine. That appears to be wrong, for, with the booster working, the cut-off must be shortened at less speed: that is, up to the speed at which the boiler can furnish steam for both the booster and the engine at full cut-off, the tractive effort is the sum of the two efforts; from that speed up to the speed for cutting out the booster, the tractive effort of the main engine is reduced on account of the necessary earlier cut-off or drop in steam-chest pressure.

It may be questioned whether valve travels in the region of 8½ in. are properly to be considered a necessary feature of modern locomotives. Long travel adds greatly to the cost of valve-gear maintenance and increases port openings by but a small amount. It appears better to secure free passage through the ports by the use of a valve of sufficient diameter, made as light as possible by well-known features.

H. B. OATLEY.[24] The paper is of more than ordinary value, as it is a carefully prepared study on a subject that is of prime importance in the design of steam locomotives.

The Cole ratios, which have been considered as a standard for more than a generation, were and still are of great value, and have had widespread use by both railroads and locomotive builders. The marked change in value of factors entering into the design of locomotives during this time has made it necessary that extensions to and modifications of the Cole ratios be made so that there could be comparisons between different types of locomotive and the effect of improvements be evaluated.

The paper offers methods and formulas which, while somewhat more complicated than have been used hitherto, are more easily applied and far less complex than methods used abroad. Any set of equations must of necessity be considered approximate within recognized limits. The interrelation between combustion, heat absorption, and conversion to external work is so intimate that the design of the various parts forming this "linked triangle of fire, water, and air," as well phrased by Mr. Lawford H. Fry, introduces a large number of variables that cannot be accurately determined. These conditions have been considered by the author.

While it is proposed to use rpm instead of piston speed, it appears to be of relatively small moment which is used, as in either case a conversion has to be made to "miles per hour of the locomotive"—which is of course the measure that is of interest in locomotive design.

GEORGE W. ARMSTRONG.[25] The author has fittingly brought out the interdependence of tractive power, a function of cylinders and boiler capacity or output. This was also stressed, to a lesser degree, by the late F. J. Cole in the preparation of his ratios.

[23] Technician, Mechanical Engineer's office, Boston & Maine Railroad, North Billerica, Mass. Mem. A.S.M.E.

[24] Vice-President in Charge of Engineering, Superheater Company, New York, N. Y. Mem. A.S.M.E.

[25] Consulting Mechanical Engineer, Ridgewood, N. J.

The boiler bears a vital part in the locomotive performance, and it is the uncertainty attendant upon such boiler performance in advance of test data affording knowledge of actual capacity that makes the prediction of engine output the uncertain and variable element pointed out by the author. Front-end design, together with grate design, plays a major part in determining boiler output, boiler design remaining the same. An article in the June, 1932, issue of *Railway Mechanical Engineer* clearly demonstrates this fact.

Regarding the aspect of draft under continuous or intermittent steam flow, it might be added that experiments made with different locomotives using continuous flow on standing tests compared with subsequent observations at similiar back pressures under road operation, where intermittent flow is found, confirm the conclusions cited as reached by Messrs. Goss and Fry. Except at low speeds, where a definite interval exists between exhausts, a close agreement was recorded. Some of these experiments are reported in the Front End Committee report of the International Fuel Association of 1930.

The Pennsylvania test-plant experience for the engines used by the author represents boiler output at the time deemed capacity, with front-end design generally superior to most in use at that time. Subsequent and recent improvements in front-end design have given much greater maximum capacity output; 72,000 lb actual evaporation per hour for the K-4s as contrasted with a former maximum of 55,000 lb; 96,000 lb for the M-1 (4-8-2) as compared with 66,000 lb. This naturally affects the engine or tractive-power output of the locomotive, and developments for improvement in draft conditions and back-pressure reduction have in more than one instance resulted in 200 to 250 hp increased output, due to greater boiler capacity. The great value of front-end improvement lies in the ability to support more efficiently high combustion rates, with consequent increase in available steam for engine output. In meeting the demands for modern operation this phase is important, as it results in higher sustained tractive power at speed.

Evaporations as high as 10 lb of water per square foot of equivalent heating surface have been attained in road operation. On such a basis the New York Central J-1, cited by the author, should be capable of delivering around 78,000 lb of steam per hour, instead of the 54,600 lb which would very materially influence tractive power and horsepower output. Experience with improved draft appliances on locomotives with boiler characteristics similar to this engine indicates that this expectation is not unreasonable. The author has recognized this phase to some degree by placing "the peak point only 20 per cent above the Cole figure."

It might be pertinent, with respect to the feedwater-heater factor, to inquire whether this is predicated upon observations with the same type of heater, inasmuch as the engines cited are predominatingly equipped with one type. However, the factor given corresponds closely with average results, under varying road operation.

In the final analysis, the utility of any method such as Messrs. Cole and Lipetz have devised lies in the comparability that it affords as to a reasonable locomotive performance, a logical standard of measure; and while actual results may be obtained in excess, the standard here proposed admirably serves as a comparometer of equitable value. Serving a useful purpose of pointing out what should be expected, it tends to improve performance or work for its improvement should it fall below this reasonable expectation.

R. Eksergian.[26] This paper is a very illuminating and valuable contribution on locomotive performance. The author has pointed out the many difficulties in accurately predicting locomotive tractive effort and horsepower characteristics, such as on the cylinder side of estimating and allowing for cylinder condensation and wiredrawing against speed, and on the boiler side the difficulties of estimating evaporation and likewise its variation with speed. His recommended method for the calculation of horsepower and tractive force against speed is unquestionably rational and probably the best approximation in a preliminary analysis. For estimating the evaporation, the Cole method has been retained, with a correction coefficient as a function of the speed. The data on steam consumption per horsepower-hour are found to concur with similar data that the writer had occasion to study a few years ago while at the Baldwin Locomotive Works.

However, in the application of the author's method we are immediately confronted with allowances that must be made for variations in boiler proportions and for different types of locomotives. These variations become sufficient to question the need of the Cole evaporation figure. This does not mean that the data supplied by the late F. J. Cole, on evaporative yields for firebox and particularly for tubes of different lengths, are not of extreme value in aiding in the calculation of the correct evaporation of a boiler, but such data become modified, with large grates, combustion chambers, etc., so that the data are perhaps antiquated except for a guide in a first approximation to modern power. The author himself has seen the necessity of this in his correction coefficient β.

The author has pointed out that the analytical method of estimating performance becomes extremely involved due to allowance for cylinder cooling, wiredrawing, etc., and on the boiler side due to proper heat-transfer calculations, combustion and draft considerations, and the effect of grate, firebox, and other proportions on the evaporative yield. However, even crude approximations along the analytical line give surprising results, and such calculations should be encouraged, as in them lies the possibility of improvements in basic proportions.

In other lines of engineering a great degree of success has been obtained by similarity methods; thus in hydraulics the introduction of functions of non-dimensional parameters, such as the Reynolds modulus, has made it possible to bring about an orderly interpretation of otherwise chaotic test data on pipe-line friction losses. The same method has been extended to interpretation of heat-transfer data. For this reason the writer feels that horsepower and tractive-force data could be put in the form of dimensional equations with parameters including important variables in design, and then the variation of the functions of these moduli could be studied from all available statistical data.

A few years ago the writer attempted a preliminary analysis of performance in a paper in *Mechanical Engineering*.[27] The horsepower and tractive-force curve were plotted against rpm and piston speed, and the adhesion range was limited to approximately 50 rpm and the power range beyond 50 rpm. While admitting a small drop in cylinder tractive effort in the adhesion range, the tractive force may be considered in this range to depend essentially on the adhesion limits, where

$$Z_i = \frac{A}{\alpha} = \frac{cW}{\alpha} \text{ (initial tractive force)}$$

A = adhesion weight on drivers

α = factor of adhesion

c = coupling ratio = $\dfrac{\text{weight on drivers}}{\text{total weight of locomotive}} = \dfrac{A}{W}$

[26] Engineering Department, E. I. du Pont de Nemours, Inc., Wilmington, Del. Mem. A.S.M.E.

[27] "Preliminary Power Rating and Tractive Force of Modern Locomotives," vol. 48, 1926, p. 1095.

The limit of the adhesion range was considered at a speed

$$N_a = \frac{9.16\, V_s\, q_a\, H}{d^2 S}$$

where

d = diameter of cylinder (in.)
S = stroke (in.)
N_a = rpm at end of adhesion range
H = heating surface (sq ft)
q_a = unit evaporation at low speed (lb/sq ft)
V_s = estimated specific volume at cut-off (cu ft/lb).

In the subsequent power range, the horsepower was estimated from the relation

$$hp = H\frac{q}{h} = H\frac{q}{f(\epsilon, N)}$$

ϵ = per cent cut-off
N = rpm

The unit or rated horsepower of the locomotive was selected at that corresponding to 200 rpm, and if q_o and h_o are the mean evaporation yield per square foot of total evaporative heating surface and h_o is the corresponding steam consumption at an economical cut-off at 200 rpm, then

$$(\text{hp})_{\text{rated}} = H\frac{q_o}{h_o}$$

and the horsepower at any other speed could be written

$$\text{hp} = H\frac{\beta q_o}{r h_o} = \frac{\beta}{r}(\text{hp})_{\text{rated}}$$

where β corresponds to the author's β, and $rh_o = h$ is obtained from the author's curves 5 and 6.

Now,

$$Z_i = \frac{p_i d^2}{D/S} = \frac{cW}{\alpha} \text{ (starting tractive force)}$$

at speed, $Z = xZ_i$ (or $p_m = xp_i$) and

$$\frac{xZ_iV}{375} = \text{hp}, \quad N = \frac{V}{D} \times 336$$

so that

$$x = \frac{126{,}000}{N}\,\frac{\alpha}{cD}\left(\frac{H}{W}\right)\left(\frac{\text{hp}}{H}\right)$$

Now $\dfrac{\text{hp}}{H} = \dfrac{\beta}{r}(\text{hp})_{\text{rated}}$

The per cent of initial tractive force x, therefore, is

$$x = \frac{126{,}000}{N}\,\frac{\alpha}{cD}\left(\frac{H}{W}\right)\left(\frac{\beta}{r}\right)\left(\frac{\text{hp}}{H}\right)_{\text{rated}}$$

This equation shows the effect on the percentage of the initial tractive force of certain basic proportions in the design of a locomotive. Thus a locomotive with a low factor of adhesion falls off quicker in mean effective pressures against speed than does a locomotive with a high factor of adhesion—that is, an under-cylindered locomotive.

Since the heating surface per pound of weight of locomotive does not vary greatly (i.e., H/W = const.), the falling off of tractive force depends principally on the coupling ratio. A Santa Fe type will fall off quicker than a Mikado, while an Atlantic type, with a low coupling ratio, will sustain a high operating-at-speed tractive force relative to its initial value.

There may be considerable objection of referring the evaporation on the basis of the total evaporative heating surface. This would be true for stationary practice where we find considerable variation in heating surface and grate proportions, with resulting good boiler efficiencies, but with the locomotive, due to construction limitations, the component elements bear a relatively constant proportion of the total heating surface. For this reason the evaporative heating surface appears a satisfactory dimensional unit for characterizing the evaporation of a locomotive boiler. In estimating the mean yield per square foot, however, we must resort to a similar coefficient as the author's β. This would be a function of the proportions of the boiler, a function of the speed, and a function of the rate of firing.

Following the pioneer work of L. E. Fry, assuming the boiler efficiency to fall off at a rate linearly with the rate of firing, it can be shown that the unit of evaporation can be expressed by the relation

$$q = \left[\frac{\text{Btu}_c}{(HA_v)\Phi}\right]\left[\frac{K_x - mx^2}{100}\right]$$

where

Btu_c = heat value of the coal
Φ = total heat of steam, including that for superheating
x = coal rate per hour per square foot of grate
H = evaporative heating surface
K = 75 to 85
m = 0.2 to 0.3.

It would appear from this relation that increasing the grate would increase the evaporative yield. This is true provided satisfactory firebox volume can be maintained. But the essential feature of the foregoing relation is that it gives the characteristics of firing rate and evaporation.

In conclusion, it is felt that the steam consumption per horsepower can be estimated much more accurately than the evaporative yield, and for this reason further study is necessary to evaluate such a coefficient as the author's β for different boiler proportions as a function of speed, rate of firing, etc., whether the yield is expressed in terms of the Cole unit or a unit yield per square foot of heating surface of the boiler.

THOS. C. MCBRIDE.[28] The system of locomotive ratios proposed by the author considers the feedwater heater and its effect in increasing the maximum evaporation obtainable from the boiler. The statement of this increase introduces a new and important ratio. A large amount of information that has been collected over a number of years on locomotives without heaters is made available in the consideration of present-day locomotives with heaters by the application of this new ratio. Careful consideration and accurate statement of this new ratio are therefore important.

The author reaches the conclusion that the Cole evaporation figures still hold good for boilers on modern locomotives without feedwater heaters, but when locomotives are equipped with feedwater heaters, the boilers generate 7 per cent more steam. In contrast with this conclusion, feedwater temperatures obtained from feedwater heaters on locomotives operating at the maximum rates of the Cole ratios indicate an average of approximately 15 per cent additional heat to the boiler through the heater, and this additional heat can get out of the boiler only through a like increase in evaporation. The difference between these two figures is too great to neglect, especially in developing a system of locomotive ratios.

The author has taken great pains to collect and carefully apply

[28] Consulting Engineer, Railroad Department, Worthington Pump & Machy. Co., Philadelphia, Pa. Mem. A.S.M.E.

a mass of data obtained partly from road trials of locomotives, but road trials necessarily involve large "probable errors." A few temperature readings taken simultaneously while the locomotive is known to be working at the desired maximum make it possible to calculate the extra heat going to the boiler through the heater with a probable error of but a few per cent. It is necessary only to read the temperatures of the water entering and leaving the heater and the steam pressure and superheat at the moment the indicator card or other check is made on the capacity of the locomotive. The process can be repeated every few minutes and more exact information gathered in an hour than could be obtained from a month of road trials.

The writer has shown that (assuming 200 lb boiler pressure, 150 F superheat, and 215 F feedwater temperature obtained, with alternate assumptions of water at 40 F from the tender to represent winter and 70 F to represent summer conditions) the additional heat supplied to the boiler through the heater is 13.6 and 11.1 per cent, respectively. That is, presuming exactly the same amount of fuel burned and exactly the same amount of heat transmitted to the water and steam in the boiler, with the consequent same efficiency of the boiler, the feedwater heater increases the heat to the boiler and consequently the evaporation from the boiler by 13.6 and 11.1 per cent, respectively, under the conditions assumed.[29]

These assumed conditions were considered representative of usual road operation in 1920. When locomotives are operated at the maximum contemplated in the ratios, much higher feedwater temperatures are obtained, generally 240 F and frequently 250 F.

If the conditions assumed in the paper of 1920 are again used for the sake of comparison, but with a feedwater temperature of 240 F, each pound of water will carry into the boiler from the heater 240 — 40, or 200 Btu, and will require 1284.6 + 32 — 240, or 1076.6 Btu from the fire for generation into steam. The heater increases the heat from the fire by 200/1076.6, or 18.6 per cent. But of the total of 118.6, 2 per cent, or 2.4, is required to operate the feed pump, leaving 118.6 — 2.4, or 16.2 per cent net increase in heat because of the heater. Similarly, with the alternate assumption of water at 70 F from the tender, each pound of water carries into the boiler 240 — 70 or 170 Btu, and requires from the fire the same 1076.6 Btu. The addition to the heat from the fire by the heater is 170/1076.6, or 15.8 per cent. Of the total of 115.8, the feed pump requires 2 per cent, or 2.3, for its operation, leaving 113.5, or a net of 13.5 per cent additional heat to the boiler through the heater.

The average of 16.2 and 13.5 is 14.8, or practically 15 per cent. It is thought that this figure, or some figure close it, depending on the conditions assumed to represent average present-day locomotive-operating conditions, should be adopted for the ratios instead of the 7 per cent obtained from road trials.

In constructing the system of locomotive ratios, the author rightly starts at the boiler. It is desired to determine the maximum evaporation that can be obtained from the boilers of locomotives on the road. The use that can be or is made of the steam is not considered until later. The limitation of the maximum boiler capacity obtainable is the amount of fuel that can be burned under the existing conditions of fire and fuel and the existing condition of the boiler, or both. Tests to determine the increase in maximum boiler capacity obtainable on the road from heaters should be made with the same locomotive without the heater and with the heater, the heater necessarily of sufficient capacity to supply the entire maximum capacity requirement of the boiler, and with fuel burned at exactly the same rate. Could such tests be made and all errors eliminated, there is no doubt that they would show the same increase in maximum boiler capacity because of the heater as is indicated by the temperatures.

The condition of the fire is a factor controlling the maximum evaporation obtainable from boilers of locomotives to an extent seemingly worthy of consideration. At one time it was thought that 12 lb of water per square foot of evaporative heating surface was the maximum that could be depended upon from boilers with an old (or older) fire, but that 15 lb could be obtained with a new fire. If this is true, the condition of the fire, not considered in the ratios, introduces a variable greater in extent than change in rpm at usual speeds or even the feedwater heater. Neglect of the ratios to consider condition of the fire brings about a condition in which the locomotive builder must furnish a boiler big enough to meet expected performance at the 12-lb rate, but appliances like the feed pump might be expected to be of sufficient capacity for the 15-lb rate, even though this 15-lb rate of the combination of maximum power requirement and fresh fire were called for but very occasionally. Feed pumps would then on the average have to be 25 per cent too big for anything but the very occasional requirement. This situation may be difficult to handle in the ratios, at least until much more road test data are available, but some recognition of it and its consequences seems important.

In summing up, the writer believes we are bound to recognize the differential of 15 per cent or thereabout increased evaporation in favor of the boiler with heater, in view of the direct and accurate evidence of the temperatures obtained. It will then be necessary to modify Fig. 4 and Table 2, spreading the "evaporation coefficient" to a differential of 15 per cent at high and medium rpm. But over all this looms the condition of the fire, new or old, demanding at least recognition.

The use of feedwater heaters on locomotives naturally tends to reduce the superheat, because more steam is generated for the same amount of fuel burned. At the same time there is a reduction in back pressure because of the exhaust steam taken by the heater. For a number of years as a result of tests these two effects were considered as counterbalancing with no change in steam consumption per indicated horsepower because of the heater. In that case the 15 per cent increase in maximum heat obtained through the heater resulted in 15 per cent increase in maximum indicated horsepower obtainable. Locomotives intended for operation with heaters are now provided with extra superheating surface; the intended superheat is obtained and the steam consumption per indicated horsepower is decreased because of the reduced back pressure obtained with the heater. The 15 per cent additional heat to the boiler therefore results in more than 15 per cent increase in maximum indicated horsepower obtainable from the same maximum fuel burned. Since the machine friction of the locomotive is not changed by the application of the heater, there will be a still greater increase in tractive effort, and since the locomotive resistances are also not changed by the heater, there is a still greater increase in maximum drawbar pull at speed because of the heater. These further increases in the maximum power obtainable on the road are substantial in amount, but vary with individual cases. They will appear as the method of calculation recommended by the author of this paper is pursued.

HARRY S. VINCENT.[30] The author has adopted the convention that the low-speed end of a tractive-effort graph can be represented by a horizontal line. The writer also accepted this convention, until his attention was called to the fact that all locomotive tests made at low speed prove that the tractive effort can

[29] "Locomotive Feedwater Heating," by Thomas C. McBride, Trans. A.S.M.E., 1920, vol. 42, p. 307.

[30] Retired. Late Chief Consulting Engineer, Franklin Railway Supply Company, New York, N. Y. Mem. A.S.M.E.

be most accurately represented by a slanting line. Those who have ridden the footboard of a freight locomotive know very well that a heavy train can be urged over the "sticking point" at a speed of 2 mph, when 8 or 10 mph would be impossible.

In establishing the rated tractive effort of a locomotive, it is the custom to select some point on the speed-effort curve, calling this the nominal effort of the locomotive. At this rating speed, the locomotive is assumed to develop in the cylinders a mean effective pressure of 85 per cent of boiler pressure. From this is developed the well-known tractive-effort formula:

$$TE = \frac{d^2 s 0.85\,P}{D} \qquad [16]$$

in which

TE = nominal or rated tractive effort, lb
d = diameter of cylinder, in.
s = stroke of cylinder, in.
P = boiler pressure, lb per sq in.
D = diameter of driving wheels, in.

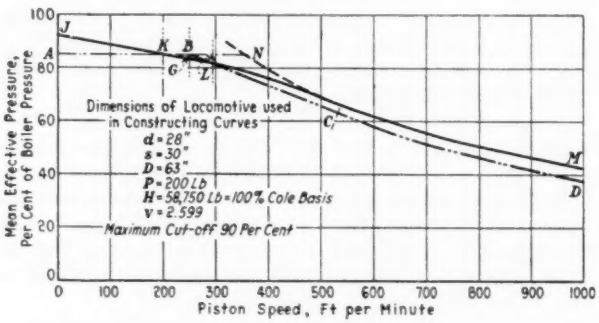

FIG. 17

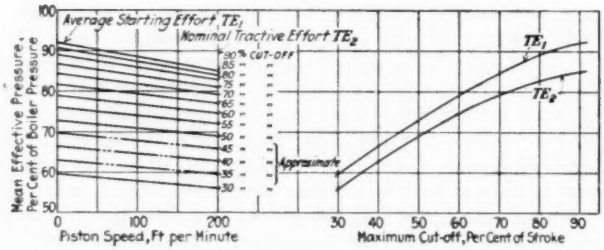

FIG. 18

The broken lines in Fig. 17 indicate by $ABCD$ a graph based on the speed factors shown in Table 14 of "Locomotive Handbook," American Locomotive Company, 1917, p. 24, generally known as the Cole factors. The horizontal scale represents piston speed in fpm and the vertical scale percentage of boiler pressure. It is characteristic of these tables that the graph constructed from them is composed of a horizontal straight line A-B, a slanting straight line B-C, and a hyperbola C-D. In making tractive-effort curves from these factors, it has always been the custom to join the two straight lines by a curve, indicated by the dotted curve G, this curve terminating at a piston speed of approximately 200 fpm. The writer's experience of many years has convinced him that the tractive effort of a locomotive at low speed cannot be indicated by a horizontal line, such as A-B. It can be shown more accurately by the slanting line J-K, in which K represents the nominal or rated effort and J the average effort at starting, or zero speed. The examples of actual road tests, shown by Figs. 19 and 26, would seem to substantiate the writer's contention.

The vertical position and slope of the line J-K depend entirely on the maximum cut-off for which the locomotive is designed. It is evident, that as the maximum cut-off is reduced, the nominal or rated effort, for any given engine constant, must be represented by a lower percentage of the boiler pressure. For instance, a locomotive having a maximum cut-off of 90 per cent, has a rated effort, based on $0.85\,P$, whereas one having a maximum cut-off of 60 per cent, will be rated at $0.745\,P$.

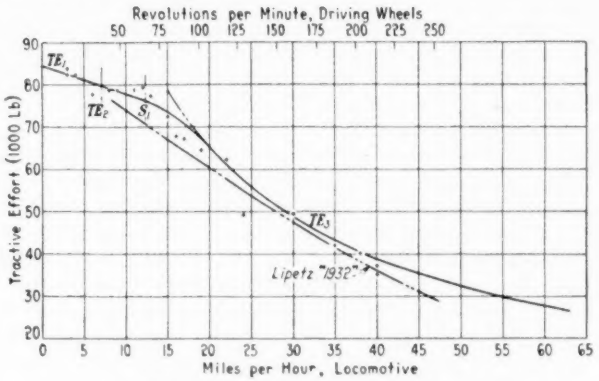

FIG. 19 TEXAS & PACIFIC 2-10-4

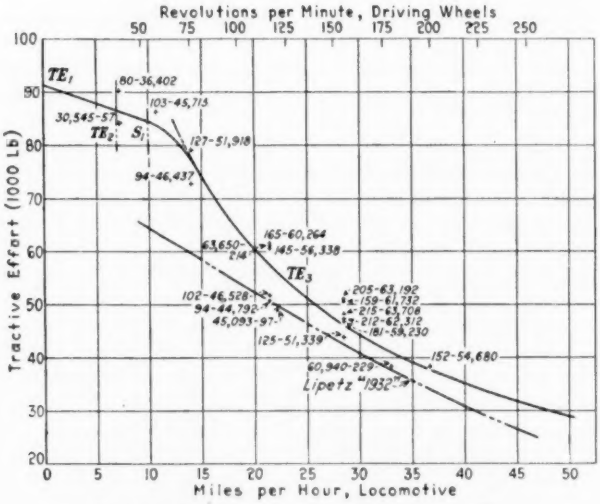

FIG. 20 PENNSYLVANIA RAILROAD CLASS I1s

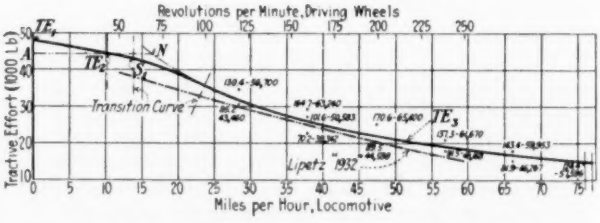

FIG. 21 PENNSYLVANIA RAILROAD CLASS K4s

Fig. 18 gives the position and slope of the line J-K, for maximum cut-off, varying by 5 per cent, from 30 to 90 per cent. These data have been used very successfully by the writer for several years, in representing the tractive effort of modern locomotives. One very important result of adopting the slanting line J-K in place of the horizontal line A-B, to represent tractive effort at low speed, and of making the point K the rating point, is that it establishes a norm by which all locomotives can be measured and compared. The adoption of the straight line A-B would permit any locomotive builder to claim, with reason,

a higher rated power for a locomotive than is justified, if a test shows that its tractive effort comes anywhere on the lines *A-B*, although it is self-evident that of two competing locomotives that one is most powerful which gives its rating nearer *B* than *A*.

The author's recommended method of expressing the tractive effort of a locomotive is dependent entirely upon the validity of the values shown in his Figs. 4 and 5. Like any other power plant, the locomotive is designed to deliver its rated effort at a predetermined efficiency. Like other power plants, it is often pushed to a rating far beyond the normal, involving a decrease in thermal efficiency, although perhaps increasing its operating efficiency as a transportation unit. This is well illustrated by the author's Fig. 2, in which the five Pennsylvania locomotives

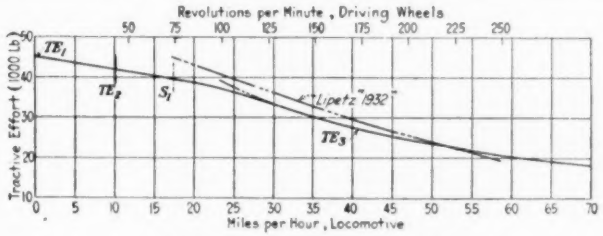

FIG. 22 NEW YORK CENTRAL 4-6-4

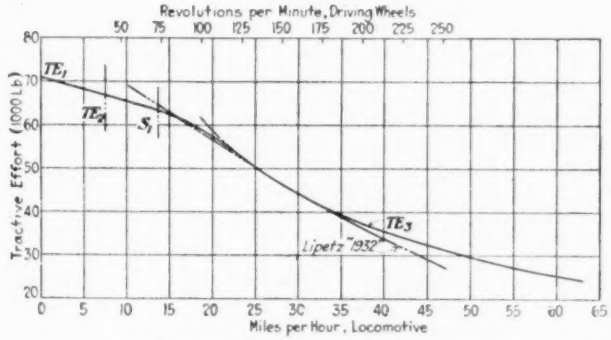

FIG. 23 BOSTON & ALBANY 2-8-4

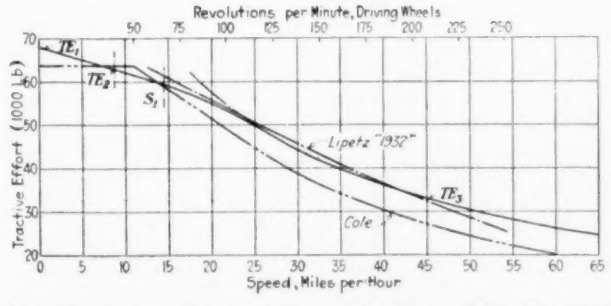

FIG. 24 TIMKEN ROLLER BEARING COMPANY 4-8-4 NO. 1111

shown were pushed to their limit on the test plant, in one instance developing an evaporation as high as 28 per cent above the mean for which it was designed. This sort of operation cannot be used as a basis for developing a tractive-effort formula. Such a formula should be based on the normal operation of a locomotive designed in accordance with the most approved engineering practice known.

In the writer's opinion the best available practice does not justify the drop in the evaporation curve beyond 200 rpm as shown in the author's Fig. 4. There is no apparent reason why a locomotive boiler, after it has reached its normal evaporation, should not continue indefinitely at the same rate, provided (*a*) it is properly proportioned, (*b*) the fuel burned does not exceed the normal hourly rate per square foot of grate surface, (*c*) it has a well-designed drafting arrangement, and (*d*) the steam-using apparatus (the cylinders, valves, and valve gear) are so designed and constructed that they will supply to the drafting apparatus

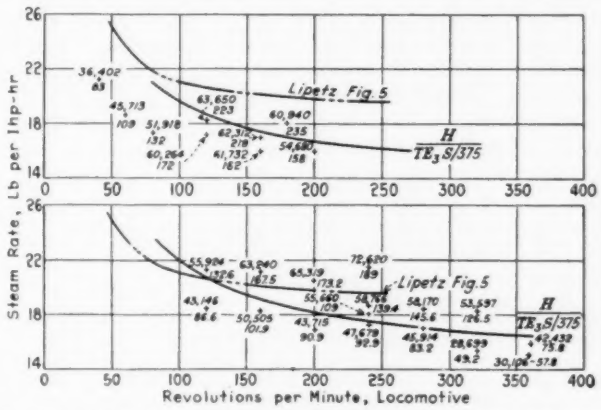

FIG. 25 (Above) PENNSYLVANIA RAILROAD I1s, FROM BULLETIN NO. 32. (Below) PENNSYLVANIA RAILROAD K4s, FROM BULLETIN NO. 29 AND LATER TESTS

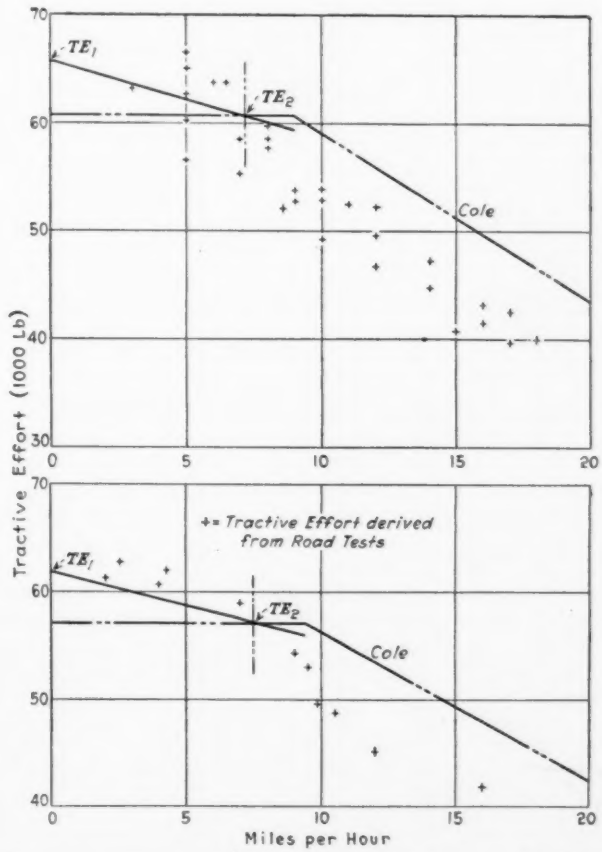

FIG. 26 (Above) FREIGHT LOCOMOTIVE 2-8-2, 29 × 28, 56-IN. DRIVING WHEEL. (Below) FREIGHT LOCOMOTIVE 2-8-2, 28 × 30, 63-IN. DRIVING WHEEL

equal weights of steam per unit of time. It is the requirement (*d*) that usually fails, causing the evaporation curve to assume the droop shown by Fig. 4.

The author's tractive effort modulus *Mt* is predicated on a

steam rate which is assumed to be constant for any given rpm or piston speed, illustrated in his Fig. 5. In discussing this curve, the author states that "only a portion of the curves, representing the most frequent average speeds of road tests, could be plotted"; for the remainder of the curves he uses an "inverted method" based on several assumptions. It has been the writer's experience that there are very few road tests of a locomotive which can be used for establishing a normal horsepower or tractive-effort curve, for the reason that the results obtained in such tests are average results; that is, the horsepower, the water and fuel consumption, the speed, etc. are given as the average over a run. It is only in those exceptional cases, where a test is made under constant conditions of grade and speed, that the results may be used in establishing a rating curve. Road tests are of course invaluable to a railroad, as they give information which can be used by the transportation department in fixing and adjusting tonnage.

The results obtained from operation of a locomotive on a test plant, when intelligently analyzed, give, in the opinion of the writer, far more useful information for the construction of rating curves than can be secured from road tests. In test-plant operation the uniform conditions under which each test is conducted can be continued as long as necessary to secure the desired result; this is impossible in a road test. The apparatus for recording the data can be operated more efficiently and accurately than is possible on a moving locomotive or car, and the test is conducted by a staff, each of which is thoroughly familiar with his duty.

In adopting the water rates given in his Fig. 5, the author makes no allowance for differences in maximum cut-off. Such differences materially affect water and fuel rates, especially at the lower speeds. They have an appreciable effect at all speeds. This will be discussed later.

There are six major factors involved in the calculation of the tractive effort of a locomotive; these are:

(*a*) The engine constant
(*b*) The normal evaporation of the boiler, lb of steam per hour
(*c*) the working pressure, lb per sq in.
(*d*) the maximum cut-off
(*e*) the average steam temperature in the cylinders
(*f*) the speed of the locomotive.

In the writer's opinion, the most practicable formula for combining these elements in one equation to form the basis for a correct speed-effort curve was devised by W. F. Kiesel, Jr., mechanical engineer of the Pennsylvania Railroad, and first published in "Locomotive Operation and Train Control," by A. J. Wood, 1915, p. 27. The formula has been successfully used by Mr. Kiesel for many years, being derived from results obtained on the Altoona test plant and modified to apply to road conditions. This formula, as slightly altered and transposed by the writer, is:

$$TE_3 = \frac{1.95\,P_1M}{1 + (36.66\,MS)/(Hv)} \quad \ldots\ldots\ldots [17]$$

in which

TE_3 = indicated tractive effort, lb
P_1 = average initial pressure in cylinder = boiler pressure less 10 lb
M = the engine constant = d^2s/D
S = linear speed of locomotive, mph
H = the normal evaporation of the boiler, in lb steam per hr
v = specific volume of steam at P_1 pressure, and 100 deg superheat, assumed to be the cylinder average.

The writer has availed himself of an article, "The Kiesel Train-Resistance Formulas," by A. J. Wood, *Railway Mechanical Engineer*, December, 1916, giving the complete derivation of the Kiesel formula. In addition to the notations given elsewhere, let

E = the expansion ratio
mep = mean effective pressure in cylinder
n = revolutions per minute of driving wheels.

Then

$$\frac{H}{60} = \text{lb of steam per min}$$

$$\frac{H}{60 \times 4 \times n} = \frac{H}{240\,n} = \text{steam per stroke}$$

$$\frac{\pi d^2 s}{1728 \times 4 \times v} = \text{weight of one cylinder full of steam}$$

$$E = \frac{\pi d^2 s}{1728 \times 4 \times v} \times \frac{240\,n}{H} = \text{expansion ratio}$$

But $n = \dfrac{1056\,S}{\pi D}$

therefore $E = \dfrac{\pi d^2 s \times 240 \times 1056\,S}{1728 \times 4 \times H \times \pi D \times v} = \dfrac{d^2 s \times 36.66 \times S}{H \times D \times v}$,

But $\dfrac{d^2 s}{D} = M$

therefore $E = \dfrac{36.66\,MS}{Hv}$

$$\text{mep} = \frac{1.95\,P_1}{1 + E} = \frac{1.95\,P_1}{1 + (36.66\,MS)/Hv}$$

since $TE_3 = \text{mep}\,\dfrac{d^2 s}{D}$

$$TE_3 = \frac{1.95\,P_1M}{1 + (36.66\,MS)/Hv} \quad \ldots\ldots\ldots [17]$$

The term E, called by the late Professor Wood the expansion ratio, is not what is usually known by that term, but is a ratio found by dividing the weight of a cylinderful of steam at the initial pressure by the weight of steam actually passed through a cylinder at each stroke. In terms of volume, this expansion ratio is found by dividing the cylinder volume by the volume which the steam passed through in one stroke would have at the initial pressure. The writer acknowledges his indebtedness to Mr. Lawford H. Fry for this definition of the term E.

A comparison of the tractive-effort curves derived from the author's recommended constants with those resulting from the formulas proposed by the writer is given in Figs. 19 to 24, inclusive. The specific dimensions of the locomotives used in making curves Figs. 20 to 24, inclusive, are given in the author's Appendix No. 1. The dimensions of the locomotive for Fig. 19 are appended.

In Fig. 19 the crosses represent the tractive effort derived from indicator cards taken at various speeds in a road test of the locomotive. The curves TE_1, TE_2, and TE_3 are constructed by the method described herein. It is evident that the curves closely approximate the actual tractive effort developed. Particular attention is directed to the low-speed portion TE_1, TE_2, and S_1, which represent the actual test much closer than would a horizontal line drawn through the rating point TE_2.

The moduli of the author, as given in his Table 7, were used

to construct the curves marked "Lipetz 1932." The curve is fairly consistent with the test results for speeds above 25 mph, but falls below the indicated effort at the lower speeds. This locomotive has a maximum cut-off of 60 per cent of the stroke; consequently, the steam consumption per ihp-hr is lower than contemplated in the author's Fig. 5. Therefore the tractive effort based on evaporation is correspondingly higher.

The test data, as given in the writer's Figs. 20 and 21, are taken from Pennsylvania Railroad Bulletin No. 29, record of test of class K4s, passenger locomotive, and No. 32, record of test of class I1s, heavy freight locomotive. The crosses represent the tractive effort as derived from the indicated horsepower developed at various speeds. The figures shown adjacent the crosses give the fuel consumption per square foot of grate surface and the evaporation rate of the boiler at the time of making the tests. The tractive effort curves TE_1, TE_2, and TE_3 are constructed by the method described herein. It is evident that they closely approximate the test results. The boiler of the I1s has a rated hourly evaporation of 61,718 lb, but due to the relatively small grate this rating was developed only at high unit fuel consumption.

The K4s locomotive has a boiler rating of 51,100 lb steam per hr, and has ample grate area to deliver this evaporation at a normal fuel rate. The curve TE_3 for this locomotive approximates a position consistent with the rated evaporation.

The curves marked "Lipetz 1932," as shown in the writer's Figs. 20 and 21, are derived from the author's constants. They approximate the test results at the higher speeds, but are evidently too low at the lower speeds. The I1s locomotive has a maximum cut-off of 55 per cent, therefore giving steam rates much below those shown in the author's Fig. 5. The K4s locomotive has a 90 per cent maximum cut-off, to which the author's moduli should apply. It is evident, however, that they are not suitable for the lower speed range in this locomotive.

Figs. 22 to 24 represent the same locomotives as do the author's Figs. 11 to 13. Tractive effort curves TE_1, TE_2, and TE_3 are drawn in conformity with the writer's method. The curves marked "Lipetz 1932" are constructed by the formula of the author from the constants given in his Table 7 for locomotives with feedwater heaters. It will be observed that they are not the same as the "1932" curves, shown in the author's Figs. 11 to 13. He has evidently used constants for locomotives without feedwater heaters, although the records indicate that heaters were used.

In the writer's Fig. 24 a curve is shown marked "Cole"; this is constructed in accordance with the Cole factors, in which, at the nominal effort, mep equals 0.85 P. The Timken locomotive has a maximum cut-off of 85 per cent; the nominal mep is therefore 0.84 P. For this reason the rated tractive effort TE_2 falls slightly below the Cole curve.

The author has given no data for locating the horizontal portion of his curves except his Formula [2]. It is evident from his curves Figs. 12 to 13 that he does not use 0.85 P for limited cut-off locomotives.

Referring to the writer's Fig. 21, the sloping line $TE_1 - TE_2$ is extended to S_1. At the latter point the straight line becomes tangent to the transition curve, connecting the straight portion of the curve with the hyperbola. The locus of S_1 is a function of the boiler capacity. Its location may be determined graphically by drawing a horizontal line through TE_2 intersecting the hyperbola at N. S_1, then, equals 0.84 AN. The position N is the point on the hyperbola where the cylinders would utilize the normal boiler capacity at maximum cut-off if the tractive effort remained constant from A to N. Stated as an equation,

$$S_1 = \frac{(1.95\ P_1 M) - TE_2}{(36.66\ MTE_2)/(0.84\ Hv)}$$

The transition curve between the straight portion of the graph $TE_1 - S_1$ and the hyperbola TE_3 is empirical. No error of any consequence is possible by this process.

The writer has shown in his Fig. 25 the steam rate as related to rpm of the driving wheels, developed in tests of the Pennsylvania Railroad locomotives, class I1s and K4s. The crosses represent the steam rates at the evaporation and unit fuel consumption shown by the figures adjacent them. The full-line curve is the steam rate obtained by dividing the rated evaporation of the boiler by the indicated horsepower corresponding to the tractive effort curves TE_3 of the writer's Figs. 20 to 21. These curves fit in with the test results, much better than do the curves in broken lines, which are constructed in accordance with the author's Fig. 5. This is especially true of the I1s locomotive, constructed with 55 per cent maximum cut-off.

The formula for constructing the hyperbola TE_3 involves somewhat more work than does the author's moduli. Usually all such calculations are made with a slide rule, so that the additional labor is negligible. In the writer's practice, a simplified form of calculation is used, giving the same results. An example of this is given in Table 11, using the dimensions of the Timken locomotive, as the basis of calculation. The tractive-effort curves resulting are given in Fig. 24.

TABLE 11 SIMPLIFIED METHOD FOR CALCULATING THE HYPERBOLA TE_3, FIG. 24

(Based on dimensions of Timken locomotive No. 1111.)

d = 27 in.	H = 72,540 lb	Constants	Maximum cut-off
s = 30 in.	r = 2.111	1.95	85 %
D = 73 in.	P_1 = 240 lb	36.66	

$$\frac{72{,}540 \times 2.111}{36.66} = 4175 \qquad \frac{27^2 \times 30}{73} = 299.5$$

$$1.95 \times 240 \times 4175 = 1{,}953{,}000 \qquad 4175/299.5 = 13.95$$

Mph		Hyperbola TE_3
10	1,953,000/23.95	81,600
15	28.95	67,500
20	33.95	57,550
25	38.95	50,200
30	43.95	44,450
35	48.95	39,900
40	53.95	36,200
45	58.95	33,150
50	63.95	30,550
55	68.95	28,350
60	73.95	26,400
65	78.95	24,750

$$TE_1 = \frac{27^2 \times 30 \times .908 \times 250}{73} = 68{,}000 \text{ lb}$$

$$TE_2 = \frac{27^2 \times 30 \times 0.84 \times 250}{73} = 62{,}900 \text{ lb}$$

$$S_1 = \frac{(1.95 \times 240 \times 299.5) - 62{,}900}{\dfrac{36.66 \times 299.5 \times 62{,}900}{0.84 \times 72{,}540 \times 2.111}} = 14.4 \text{ mph}$$

TABLE 12 PRINCIPAL DIMENSIONS OF LOCOMOTIVE FOR FIG. 19

(Texas & Pacific Railroad.)

Class	I-1
Wheel arrangement	2-10-4
Cylinder diameter, in.	29
Cylinder stroke, in.	32
Wheel diameter, in.	63
Boiler working pressure, lb per sq in.	250
Weights in working order, lb:	
On drivers	300,000
Total locomotive	448,000
Heating surfaces, sq ft:	
Firebox	473
Tubes and flues	4640
Total evaporative surfaces	5113
Superheating surfaces, sq ft	2100
Superheater type	E
Grate area, sq ft	100
Feedwater heater	Elesco

The writer's tractive-effort formulas, as given here, have been in successful use for a number of years. They are applicable in principle to all simple multi-cylinder locomotives. From examples shown, it is evident that they are more general in their application than those submitted by the author; therefore it

would appear that there is no good reason for the adoption of a new method.

W. A. POWNALL.[31] The author has given something of much value in trying to arrive at a method of determining the horsepower and tractive effort of the modern steam locomotive. The writer has done considerable work on the rating of locomotives for fast freight trains, using a new method of dividing the resistance per ton on a so-called "equivalent grade" for each district into the theoretical drawbar tractive power at the desired speeds. In actual service the modern engine made a better performance than what had been predetermined by calculation, bringing out the fact that the tractive-power curve determined by Cole's method needed raising somewhat for modern engines, just as pointed out by the author. The revised methods proposed should produce approximately correct horsepower and tractive-power curves for the modern locomotive of conventional design with type-"E" superheater, feedwater heater, etc. However, there seems to be a way to materially increase the horsepower and tractive power at high speeds through increased evaporative capacity and lower steam rate through reduced back pressure. This can be done with a different design of exhaust nozzle, front-end appliances, and a larger stack. Recent experience with such designs has shown that a considerable increase in evaporative capacity of the boiler can be obtained, and although this of course means an increase in the rate of coal burned per square foot of grate area, and which is attended by a falling off in boiler efficiency, the general result is a considerable increase in locomotive capacity.

Fig. 13 shows the Timken engine with a performance curve much higher than the Cole or the proposed method. The author states that this may be due to a good quality of coal, but it is believed that this exceptional performance at high speeds is due to the type of front end used on the Timken locomotive. The exhaust nozzle is a six-ported star-shaped design, of larger area than the customary round nozzle tip, but which at the same time produces a steam jet with greater entraining power due to its greater periphery. The usual draft plates and deflector plates in the front end are dispensed with, and in their place is an inside stack with flare, the lower edge of which is about 12 in. above the bottom of the smoke arch, and the netting consists of a straight cylinder extending from the lower edge of the stack to the bottom of the smoke arch. The stack itself is somewhat larger than the conventional stack. This arrangement produces very strong draft, and with less back pressure on the cylinders, and because of the strong draft, grates with reduced air opening have to be used.

The Wabash has equipped a 4-8-2 type locomotive with similar front-end arrangement, and has obtained as high as 4900 ihp at a speed of 55 mph. The maximum cylinder horsepower by the Cole method would be 3215, and by the Lipetz method 3237. This engine in actual service evaporated at times water at the rate of about 80,000 lb per hr, whereas the maximum evaporation from the Cole method would be 63,764. The evaporation based on the Cole method is figured with coal burned at the rate of 120 lb per sq ft of grate area per hour, whereas this rate was very much exceeded during the actual performance of the engine in question. Tests of Pennsylvania Railroad engines equipped with this front-end arrangement (this design of front end was developed on the Pennsylvania) have shown similar high evaporative rates and increased horsepower. The high horsepower developed is undoubtedly contributed to by a lower water rate due to reduced back pressure, and the writer would point out this low water rate on the Timken engine as indicated in Figs. 7 and 8 of the paper.

[31] Wabash Railway Company, Decatur, Ill.

At the present time the majority of the fast-freight business in the country is being handled by locomotives of modern design, and the method developed by the author will be very helpful in establishing fast-freight tonnage ratings for these locomotives. However, in view of the increased capacity that the experience given above indicates, the writer believes we will in the future obtain still higher tractive-power and horsepower curves for moderately high locomotive speeds.

JOHN E. MUHLFELD.[32] The author's reference to Cole's ratios recalls the writer's association with Mr. F. J. Cole, on many occasions, in connection with the designing of different steam locomotives, including the adaptation of the Mallet articulated type to American practice, for various railroads in the United States and Canada. The writer is heartily in accord with respect to the usefulness of the Cole formulas and that they still hold good in many cases.

Concerning the author's proposed modernization of the Cole ratios for the purpose of meeting present-day requirements of steam locomotive design and operation, the writer, while agreeing that there is a need for this, questions the differentiation based on the so-called types "E" and "A" superheaters. In his conclusion, the author states: "the object of this paper is to suggest a simple method for figuring horsepower and tractive effort for modern locomotives. To this class belong locomotives with type 'E' superheaters, feedwater heaters, and valve motions with about $8\frac{1}{2}$ in. of valve travel. This presupposes that the superheater heating surface assures sufficient superheat, which in locomotives with the type 'E' superheater is about 250 F. . . . For locomotives of older design, with type 'A' superheaters, new constants could be worked out similar to those given in the paper, but it is suggested that for these latter locomotives the Cole formula should be used."

Any number of modern steam locomotives equipped with type "E" superheaters, with from 200 to 250 lb boiler pressure, are not averaging superheated steam of over 600 F, or much over 200 deg of superheat, when working steam. This performance can be duplicated by many of the older locomotives, originally constructed without superheaters, but which since have been equipped with type "A" superheaters and, with 200 lb boiler pressure, can raise total steam temperatures of from 700 to 750 deg, and average from 600 to 650 F, thereby producing as high as 350 deg superheat as a maximum and from 200 to 250 F as an average.

For example, during 1914 some Consolidation freight locomotives, built in 1906, were equipped with the conventional type "A" superheaters, piston-valve steam chests, brick arches, and automatic fire doors. These locomotives have the following characteristics:

Tractive power, lb	44,880
Weight on drivers, loaded, lb	186,000
Size of cylinders, in	22 × 30
Diameter of driving wheels, in	55
Boiler pressure, lb	200
Grate area, sq ft	33.5
Firebox heating surface, sq ft	231
Tube and flue-heating surface, sq ft	2080
Superheater heating surface, sq ft	520
Valves	Piston
Valve motion	Stephenson
Valve travel, in	$5\frac{1}{4}$
Boiler feed	Live-steam injectors

On test runs made with these locomotives over 1.0 per cent ruling grades, which were accompanied by representatives of the railroad, superheater, and arch-brick companies, the superheated-steam temperatures ranged from 612 F to 632 F, with a maximum range of from 700 F to 740 F. When operating over 1.0 per cent grades, both injectors were used to supply the

[32] Consulting Engineer, New York, N. Y. Mem. A.S.M.E.

boiler, the water level in the boiler was increased 3 in., the maximum steam pressure was maintained, and the total temperature of the superheated steam ranged from 670 F to 740 F. Indicator diagrams were taken during this performance. During this trip the center row of arch brick melted away while the 740 F temperature of the steam obtained, indicating approximately 350 deg of superheat. This was an unusual performance for a coal-burning locomotive, but is cited to demonstrate what can be accomplished with a locomotive equipped with a type "A" superheater of the description as given, and that superheated steam temperatures obtainable with type "E" superheaters can be readily duplicated with type "A" superheaters.

The particular feature of the type "E" superheater has been its increased superheating surface, which reflects favorably on the boiler capacity, and, in combination with the higher velocity draft, has been set up as the principal advantage over the type "A." However, as compared with the type "A," the type "E" has many operating disadvantages, due to the overheating, swelling, and burning out of the torpedo type of forged return bend; the more restricted gas area through the superheater flues; the stopping up with cinders, ash, soot, and other foreign matter of superheater flues resulting in stuck units; the increased gas velocities through the superheater flues tending to cut out crown-sheet staybolt heads and the beads on the firebox end of the flues; and to a more rapid cutting action of the cinders against the return bends and the element necks, necessitating application of innumerable shields to these parts to prevent such action. All of these conditions mean increased maintenance troubles and expense and of operating inefficiencies and failures, which do not obtain with the type "A" superheaters.

Summing the locomotive superheater situation, it is the writer's opinion that the author's method of calculating tractive power should be used on locomotives having 100 per cent or larger boilers, modern long-travel valve gear, and a sufficient degree of superheat, whether equipped with a type "E" or a type "A" superheater.

The author emphasizes the type "E" superheater as the most outstanding improvement for increasing the power of the steam locomotive, on the basis that it will produce about 250 F or higher superheat. He also considers that boiler evaporation is the controlling factor for locomotive horsepower and that to determine the tractive power it is necessary to refer horsepower to locomotive speed. In the writer's opinion, boiler pressure, grate area, firebox volume, firebox evaporation surface, factor of adhesion, cylinder back pressure, cylinder clearance space, and various other major details are all most important in the development of the modern steam locomotive hauling capacity, or drawbar pull, or drawbar horsepower, and its efficiency and economy in operation.

(1) Gage pressure, lb	(2) Superheat, deg F
200	200
350	200
500	200

Gage pressure, lb per sq in.	Superheat, deg F	Total temp., deg F
200	310	698
400	250	698

The tractive "power" or "force" or "effort" of a steam locomotive is the pressure exerted by the action of the steam against the pistons in the cylinders, through the medium of connecting mechanism, to turn the driving wheels and cause the locomotive to advance. It is measured at the tread of the driving wheels, the internal friction or resistance of the engine being neglected. It is closely related to "hauling capacity," and in practice both are influenced by such factors as weight on and diameter of driving wheels, arrangement of leading and trailing truck wheels, factor of adhesion, steam-generating and superheating capacity, steam pressure and temperature, diameter and stroke of cylinders, mean effective pressure, and uniformity of crank effort, or torque.

The hauling capacity or drawbar pull or drawbar horsepower of a locomotive, which is the real measure of its ability to start and accelerate a train and move tonnage at sustained speed, can only be determined when its tractive power, and the locomotive, grade, and uncompensated curvature resistances which tend to prevent the movement of the locomotive, are known, provided the locomotive has sufficient adhesion to develop this power, without excessive slipping.

With respect to high superheat temperatures, it is questionable as to the practical advantage or economy in superheating steam to higher temperatures than what is required for minimum cylinder condensation, in view of the useful heat that will be exhausted to the atmosphere. To produce 70,000 lb tractive power in a single expansion-cylinder locomotive, carrying 200 lb pressure, with 63-in. driving wheels, would require the admission of live steam into two $28^1/_2$ in. in diameter by 32 in. stroke high-pressure cylinders. At 250 lb pressure the diameter of the cylinders would be about $25^1/_2$ in., at 275 lb pressure about $24^1/_2$ in., and at 300 lb pressure about $23^1/_4$ in. If 500 lb pressure is used, in combination with single-expansion cylinders, it would only be necessary to put live steam into two 18 in. in diameter by 32 in. cylinders, with 63 in. in diameter driving wheels, in order to develop 70,000 lb tractive power, and in which case, with the conventional amount of superheat, from 75 to 100 deg of superheat would be wasted in the exhaust steam.

By increasing the conventional 200 to 250 lb boiler pressure, assuming 200 F superheat as a constant, regardless of the pressure, Table 13 shows what can be accomplished and that only 28.5 additional Btu are required to produce steam at 500 lb as compared with 200 lb.

The ideal condition of the Rankine cycle, as illustrated in Table 14, is also illuminating.

It will be noticed that the 400 lb pressure, 250 deg superheated steam will do about 25 per cent more work per pound of steam than the 200 lb pressure, 310 deg superheated steam. This would result in the use of about 20 per cent less fuel per horsepower hour. The 200 lb pressure, 310 deg superheated steam will still have about 30 deg superheat when exhausted, while the 400 lb pressure, 250 deg superheated steam will be of about 96 per cent quality, saturated, when exhausted.

If locomotive designers and builders in the United States are right in limiting modern locomotive superheated-steam pressures at from 200 to 250 lb, in combination with stayed crown and side sheet fireboxes of relatively small evaporative capacity, then all of the modern central power station and marine boilers, as well as the German State Railway and other European locomotive designers, who are making use of from 350 to 1500 lb and higher superheated-steam pressures, must be wrong.

TABLE 13

(3) Total Btu in steam, per lb	(4) Total Btu in steam rejected from cylinders in exhaust at atmospheric pressure	(5) Btu transformed into useful work in cylinders (3 — 4)	(6) Theoretical efficiency as per Rankine cycle (5 ÷ 3)
1309.7	1083	226.7	17.3%
1325.5	1058	267.5	20.2%
1338.2	1042	296.2	22.1%

TABLE 14

Entropy increase in unavailable energy	Total Btu in steam, per lb	Total Btu in steam rejected in exhaust at 20 lb gage cylinder back pressure	Total Btu transformed into useful work	Efficiency Rankine cycle
1.7066	1364.0	1182.0	182.0	13.3%
1.6318	1365.1	1130.0	225.1	16.6%

The thermal efficiency of the conventional steam locomotive, carrying from 200 to 250 lb boiler pressure, when operated in road service, averages from 4 to 6 per cent at the tender drawbar, in terms of the heat value of the coal as fired. Road service tests of the D. & H. No. 1400 locomotive, which uses 350 lb pressure, show it to have a thermal efficiency at the tender drawbar of 8.75 per cent; the D. & H. No. 1401, with 400 lb pressure, develops 9.3 per cent, and the D. & H. No. 1402, with 500 lb pressure, develops 10.4 per cent. The last locomotive therefore has about double the thermal efficiency of the average conventional steam locomotive, and in the hope of substantially increasing this percentage, the Delaware and Hudson Railroad now has another locomotive under construction at the Schenectady shop of the American Locomotive Company, D. & H. No. 1403, which will carry 500 lb boiler pressure and will be the first triple-expansion type of steam locomotive that has ever been built.

The author has contributed interesting and valuable information concerning calculations for the designing of the modern steam locomotive which will be of great benefit for the guidance of railway and builder's engineers. At the same time we should not overlook the practical operating and maintenance factors, which can only be determined upon by dynamometer-car tests, for the purpose of obtaining actual information relating to indicated horsepower, sustained drawbar pull and drawbar horsepower, fuel and water consumption, boiler and superheater capacity and efficiency, and mechanical and thermal efficiency of the locomotive as a whole—these data to be scientifically utilized to develop empirical formulas.

W. F. Kiesel, Jr.[33] The stated object of the paper is to establish a method of figures for calculation of indicated tractive effort as a function of speed. Throughout the paper references are made to the difficulties of establishing accurate formulas applicable to various types and variations of locomotives, and detail equipment, establishing the need of adopting empirical data.

The author points out that Cole's ratios are no longer applicable to modern locomotives and submits his method of corrections necessary to make the Cole formulas more closely conform to modern power results. Tests of Pennsylvania Railroad locomotives, classes K4s, E6s, K2sa, and L1s, made in 1914 and 1915, and I1s made in 1919, used as examples by the author, are rather too old, as much improvement in locomotive design has been developed since then.

The Cole ratios have been of use in establishing comparisons between locomotives of different design, and it is agreed that they are obsolete. There seems to be no good reason to attempt to resurrect them at this late date, in view of the fact that closer comparisons can be made by other methods of calculation, equally or more simple.

The question of first importance is, "How much steam can any given locomotive make, available for use in the cylinders?" The author is rather vague on this point. He calls attention to boiler tractive effort, as distinguished from rated tractive effort. The latter is dependent on boiler pressure and proportions of cylinders and drivers, and its calculation has been standardized by a simple formula. The designer is mainly interested in maximum boiler tractive effort, which is dependent on maximum evaporation possibilities of the boiler. Conventional fire-tube boilers, with staybolted firebox, vary very little in important proportions.

From various tests and writings, published in the past, it is not far wrong if we assume that the evaporation per square foot of the combustion-space heating surface, compared with that of the flues and superheater (with flue sheets spaced about 20 ft apart) is 6 to 1.

Assuming that equivalent heating surface is the sum of superheater, flue, and six times the combustion-space heating surfaces (steam and water side), it has been developed from tests that the evaporation limit to date is closely $11^1/_2$ lb per hr per sq ft of equivalent heating surface, which permits the empirical assumption that the steam available for use in cylinders may be as high as 10 lb per hr, for each square foot of equivalent heating surface, for the whole range of boiler tractive effort. When test results of a locomotive fall materially short of this, it is advisable to make an investigation to determine reasons for the shortage.

The second phase of this problem is to determine the results in cylinder tractive effort of the use of various amounts of steam in the cylinders up to the available limit. The author determines drawbar horsepower, but it would seem preferable to find the cylinder tractive effort and subtract engine and tender resistance, the result being drawbar pull at rear of tender. Piston speed, or crank speed, suggested in the paper, can be used, but the writer prefers to use speed (V) in miles per hour, because that value is more generally used. He also prefers to determine cylinder tractive effort (T), which can readily be transformed to indicate horsepower, if that figure is desired.

Assume:

Initial pressure, P = 10 lb less than boiler pressure
Engine constant, $C = d^2S/D$
Steam constant, $M = 3W/110w$

d = cylinder diameter, in.
S = piston stroke, in.
D = driver diameter, in.
W = amount of steam used, per hr
w = average weight of steam per cu ft at 100 deg superheat and pressure P.

Since modern locomotives, with few exceptions, use boiler pressure between 200 and 300 lb per sq in., the steam constant M may be written $M = xW$, the values of x being

Boiler pressure	200	225	250	275	300
Coefficient x	0.0716	0.0643	0.0571	0.0532	0.0493

Having determined P, C, and M, the formula for tractive effort becomes

$$T = \frac{2PM}{(M/C) + V}$$

The writer submits that this formula, in use for the last 20 years, though to a certain extent empirical, is based on a rational theory, gives fairly close results, and permits deriving more information, to determine preferential locomotive designs, with less effort than by the use of modified Cole ratios.

For more explicit information as to the theory on which the foregoing is based and for locomotive and tender resistances, see "Principles of Locomotive Operation," by Arthur Julius Wood, McGraw-Hill Book Company.

G. T. Wilson.[34] The writer thoroughly appreciates the fact that the results as obtained are subject to a factor of correction where the performance of the locomotive to which it is applied varies to an appreciable extent from the average results upon which the method of calculation is based.

The application of this boiler-performance calculating method to two of the most modern types of New York Central Lines locomotives, the J-1 4-6-4 and L-2 4-8-2 indicates that the results

[33] Mechanical Engineer, Pennsylvania Railroad, Philadelphia, Pa. Mem. A.S.M.E.

[34] General Equipment Inspector (Motive Power), New York Central Lines, New York, N. Y.

as shown for tractive effort and indicated horsepower in respect to speed are not representative of capacity rating for these locomotives as shown from dynamometer road tests.

It is the practice of the New York Central Lines to rate a locomotive on capacity test results represented by the drawbar pull-speed curve for the respective locomotive or class. The capacity test results represent the maximum sustained drawbar pull and horsepower for all speeds for the respective class of locomotive as governed by the existing boiler ratios, drafting arrangement, valve setting, and cylinder characteristics.

For the last 20 years the capacity results have been used for tonnage rating with success. In the last few years we have made it possible by means of a device applied to the locomotive to provide the engineman with a visible indication of cut-off correlated to speed, so that with full-open throttle the engineman may select a cut-off to produce maximum drawbar pull for that incidental speed. The cut-off indication of this device is based upon the capacity test results for that class of locomotive to which it is applied. The incidental cut-off in terms of speed corresponds to the cut-off used when maximum sustained capacity was developed during dynamometer road tests.

Experience has proved that we may duplicate in every-day performance the actual capacity test results by selection of the same incidental cut-off as used to develop the drawbar pull-speed curve.

Application of the performance test results for boiler evaporation and steam consumption per indicated horsepower in calculating the tractive effort, as proposed in this paper, results in a reduced rating of $2^1/_2$ per cent at driver speed of 50 rpm to 42 per cent at 300 rpm for the J-1 4-6-4 type and $7^1/_2$ per cent at 50 rpm and 17 per cent at 225 rpm for the L-2 4-8-2 type of locomotives.

The pronounced effect of the personal element in operation, drafting arrangement, and wide differences in track profile and operating demands causes a wide variation in both the boiler evaporation and cylinder performance when based upon the results of performance tests.

It is regretted that boiler and cylinder performance are not observed when capacity tests are made, so that more definite results would be available in a study of this kind. For the older designs of locomotives the grate area was the controlling factor in boiler performance. For the performance tests of the J-1 4-6-4 and L-2 4-8-2, the average coal fired per square foot of grate area per hour was 62 and 66 lb, respectively.

For operation of our J-1 class 4-6-4 type locomotives in regular revenue service where maximum capacity has been required for the major portion of continuous service over two divisions, the estimated coal consumption indicated a firing rate of 125 lb of coal per square foot of grate per hour. Our locomotives are not normally worked to maximum capacity in every-day operation except during acceleration and on grades, but conditions often require maximum sustained capacity.

From stationary locomotive boiler evaporation tests we have found that for a boiler of somewhat earlier design and proportionally smaller grate area the evaporation rate was reasonably efficient up to a firing rate of 180 lb of coal per square foot of grate per hour.

Based upon our observations from dynamometer tests and average every-day operation we do not believe that the results for tractive effort and horsepower for a modern design of locomotive may be consistently based upon average performance tests as representative for the tractive effort and power of the locomotive. We contend that the capacity performance of a locomotive is representative of the true characteristics of the boiler and engine because such results eliminate the human variable, common in performance results, and show the true performance as governed by the design of the boiler, feedwater heater, superheater, drafting arrangement, and steam distribution to cylinders.

A. Giesl-Gieslingen.[35] The writer would like to take up Mr. Wilson's remarks dealing with locomotive "capacity" versus "maximum performance." Certainly a railroad is interested in the utmost limit of capacity of a locomotive, since it is of importance on frequent occasions. However, this limit is subject to many influences, the most imponderable of which is probably the boiler capacity, as it is governed by the accidental quality of the coal and the ability of the fireman. These latter influences are of course always felt, whether the engine is working light or hard; but for every locomotive there is a reasonable maximum of performance which can safely be developed whoever may handle it and whatever conditions may be, and this is what the author primarily determines. The boiler is then called upon to work only at a conservative rate.

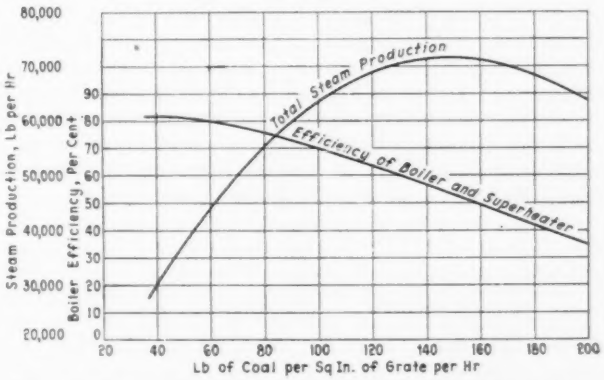

Fig. 27 Boiler Performance of Hudson Type Locomotive

A good idea of what happens when this "safe maximum performance" is being exceeded and the engine is being forced to capacity may be obtained by studying combustion rate and steam production. The writer had an opportunity of observing road tests with the Hudson type locomotives of the New York Central, during which, at times, the capacity limit was being reached. A carefully developed diagram (see Fig. 27) shows the total steam production of the boiler plotted against combustion rate, obtained under the specific conditions of these tests, with a very good fireman and high-grade coal. These engines have a rather large grate area, and therefore a combustion rate of 90 lb produced 60,000 lb of steam, which is about the limit used by the author in his calculation of "maximum performance." The utmost limit of evaporative capacity lay close to 72,000 lb, or about 20 per cent higher, but in order to produce the 20 per cent more steam about 65 per cent more coal had to be fired, bringing the combustion rate up to 150. An interesting point is that a further increase in the firing rate resulted in a diminished output of steam. This is easy to understand if it is considered that, as an extreme example, choking the firebox with coal would kill the steam production altogether; there must be a limit somewhere, but this limit is often being reached at lower rates of combustion than one would assume.

In the neighborhood of the boiler limit, the curve of steam production plotted against combustion rate becomes nearly horizontal, as shown in the diagram, meaning that about the same amount of steam is being generated by widely varying amounts of coal. With the forced operation of present days, this condition is quite often being reached and accounts for much

[35] New York, N. Y.

of the seemingly strange fluctuations in boiler efficiency. The writer has observed cases where the fireman, in an attempt to quickly meet the increasing steam demand during speeding up, unknowingly exceeded that firing rate where the steam generation reaches a maximum; thus instead of producing, say, 66,000 lb of steam with a combustion rate of 123 lb, he did the same job firing 173 lb, or 40 per cent more.

If it is further kept in mind that the absolute value of steaming capacity and the corresponding combustion rate are widely influenced by local conditions, it is apparent that the maximum capacity of a locomotive is something beyond calculation and should be obtained from special capacity tests to suit the specific requirements of the railroad. On the other hand, what the author calls maximum performance, as determined by his interesting and simple method, is a function of locomotive dimensions and can be used efficiently to calculate safe performance figures and to compare various engines with each other.

Finally, a word about train resistance: Like the locomotive formulas, those for the running resistance of cars should be revised to meet modern conditions. The writer has found that the resistance values obtained by the University of Illinois at the beginning of this century are at least 30 per cent and sometimes 50 and 60 per cent too high for our modern freight trains. Here is a very important field for cooperative study, and now that the author has shown how to obtain the tractive power of our locomotives, it would be desirable to determine with equal accuracy what we can do with this tractive power.

W. G. KNIGHT.[36] It is our experience, from carefully observed tests using our dynamometer car, that some changes are necessary in the Cole formula with respect to cylinder horsepower, especially on engines of the super-power type. We have noticed particularly at ranges of speed from 30 to 35 mph that the superpower type of engine produces a higher cylinder horsepower than that provided for in the Cole ratios.

F. E. RUSSELL.[37] The author's analysis of horsepower and tractive effort of steam locomotives is very interesting and enlightening, in view of the fact that he attacks this problem from a different angle, and confirms the accuracy of Cole's evaporating capacity of locomotive boilers. The writer has used Cole's evaporating figures for a number of years and finds them to give very accurate results. The author has endeavored to determine a simplified method for figuring horsepower and tractive effort of modern locomotives. In his endeavor to do so he has introduced "revolutions per minute" in preference to piston speed as the basis of his calculations, and justifies this method by stating that there is not a wide range in crank radius or stroke in modern locomotives, which range from 28 in. to 32 in. stroke.

Prior to 1921, when the Southern Pacific Company introduced a 30 in. stroke in passenger service, the common practice was to use strokes of from 24 in. up to 28 in. Since 1921 long strokes have been adopted for both freight and passenger service in use with superheated locomotives, and some have been placed in service with 34 in. stroke. It must also be borne in mind that there is a wide range in diameter of drivers from 51 in. up to 81 or 84 in. Therefore we should not adopt an average or approximate method, but stick to fundamentals and use piston speed which can be as easily converted into miles per hour as can revolutions per minute, besides being more accurate. The final result is generally desired at a specified speed in miles per hour.

To arrive at the most correct results we must consider the two primary elements separately—the boiler, the unit that generates the steam, and the engine, the unit that converts the heat units in the steam into tractive power and horsepower, either of which can be converted into the other by taking into consideration the time or rate of doing work. Therefore, for most accurate results, we should determine the efficiency and capacity of the boiler to supply the engine, and then consider the capacity and efficiency of the engine itself. In other words, by determining the capacity of the boiler and by using the correct mean effective pressure and pounds of steam per horsepower hour dependent upon the quality and temperature of steam supplied, the maximum horsepower or tractive power can be easily calculated for any speed in miles per hour.

At the time Cole established his ratios and adopted 27 lb. of saturated steam per horsepower-hour and 20.8 lb of superheated steam per horsepower-hour, locomotive superheaters might be considered in their infancy in this country and were mostly of the type "A" construction, developing low superheat as compared to temperatures developed in modern type "A" and "E" superheaters, with the result that steam consumption per horsepower-hour has decreased from 20.8 lb to 19 lb or less per horsepower-hour with type "E" superheaters. Also, both the mean effective pressure and the amount of heat in the steam will vary on different roads and in different territories on the same road, due to character of operation, such as high speed in comparatively level territory or slow speed on heavy grades in mountain territory.

Certain devices applied to locomotives, such as superheaters and feedwater heaters, materially affect the capacity of the locomotive as a whole as well as its efficiency. The superheater, by increasing the temperature of steam, not only has an effect equivalent to increasing boiler capacity, but also increases the mean effective pressure on account of reduction in back pressure; hence it increases both the capacity of the boiler and the engine

The feedwater heater, when of proper capacity, increases the evaporating capacity of the boiler about 10 per cent and also further affects the horsepower or tractive effort by increasing the mean effective pressure due to the reduction of back pressure. Back pressure is also materially affected by the area and shape of exhaust passages and the size of the exhaust nozzles.

Apparently some engineers have spent so much time to prevent wiredrawing of steam on its way to the cylinders that they have paid little attention to the even more important feature of easy curves and large areas for passage of steam from the cylinders to the atmosphere.

It is simpler to determine horsepower and tractive power by means of mean effective pressure based on piston speed, which takes into consideration both stroke and wheel diameter.

L. K. SILLCOX.[38] The various formulas which have been submitted from time to time to assist in the approximate predetermination of locomotive operating characteristics prior to construction have as a rule produced remarkably similar results. These equations assume a variety of forms, depending upon the method of approach to the problem, and each involves certain assumptions with respect to prospective ability. The Cole analysis and the tractive-effort equation have been widely adopted by reason of the simplicity of application, the apparent logical arrangement of factors, and the close agreement which has been observed between road test results and the calculated performance. No marked deviation from the Cole results were ever witnessed so long as locomotives were constructed in general accordance with the proportions upon which the Cole ratios were based. For a number of years, locomotives have been designed

[36] Mechanical Superintendent, Bangor & Aroostook Railroad Company, Derby, Maine.

[38] Vice-President, New York Air Brake Company, Watertown, N. Y. Mem. A.S.M.E.

for highly specialized services; the former standardized ratios have been disregarded, and various improvements, involving both internal modifications and the addition of auxiliaries of proved merit, have been incorporated in the construction to produce higher efficiencies and to adapt modern steam motive power to its required functions.

High speeds, sustained high speeds, sustained high speeds produced economically—these three factors, or the evolution of a single factor, have been largely responsible for the obsolescence of past practices in locomotive design, and when we add to speed the elements of high capacity and the required degree of availability, we observe a locomotive which quickly illustrates the advance which has been made in locomotive building since the Cole ratios were derived. The basis of the Cole locomotive ratios is the cylinder horsepower of the locomotive at or near its maximum power, using this to proportion the firebox area and tube heating surface. Assuming that 120 lb of coal of good quality is about the maximum burned per square foot of grate area per hour, the proportions of the grate can be computed. The grate area being determined, the firebox volume within certain limitations cannot be altered, since it is determined largely by the length of the grate and the diameter of the boiler. The basic factor in boiler efficiency is heat production, and this depends on the fuel fired per cubic foot of firebox volume per unit of time, together with the ratio of firebox surface to firebox volume—in other words, to the cooling influence of the water jacket. In a large firebox the surface/volume ratio is low. The cooling of the flame depends on the water-cooled surface exposed to radiation and convection, and this is less in proportion to the volume and weight of burning gases and solids as the linear dimensions of the firebox are increased. Consequently, in a large firebox, the flame loses less of its heat to the walls, and combustion is more rapid and therefore more complete than in a smaller firebox at the same rate of firing per square foot of grate or per cubic foot of volume. Hence, the usually accepted ratios of grate area to the various heating surfaces are really of little value unless the firebox volume also be known. The boiler can hardly be made too large provided the firebox is also increased. Locomotives with large boilers have a reserve of power and capacity, and are thereby enabled to get over difficult sections of the road or give high sustained capacity without seriously reducing the boiler pressure.

The important function of the locomotive cylinders in converting the heat energy in the steam into mechanical work, and the many modifying influences due to variable conditions under which the work must be performed, together with the limits imposed by the loading gage, are some of the more important points which must have consideration in determining the most efficient arrangement of cylinders when designing a modern high-power locomotive. Since it is governed almost entirely by the steam-producing power of the boiler, the wheel diameter, the speed at which a given load must be hauled over the ruling gradient, and the working steam pressure, cylinder capacity, per se, is generally determined beforehand. The work to be performed therefore becomes a problem involving the weight of the steam available and the efficiency with which the steam can be employed in the locomotive cylinders, the maximum tractive effort accordingly being determined by these and other less important governing factors.

Since the term maximum tractive effort is only an expression involving cylinder volume, wheel diameter, and boiler pressure, it is quite useless as an index of the normal horsepower of a locomotive or the load that a locomotive can haul at any speed above a very low rate. Tractive effort depends solely upon the size of the cylinders and the mean effective pressure, whereas horsepower depends upon both the mean effective pressure and the speed. The so-called maximum tractive effort can only be exerted at exceedingly low speed with nearly full-stroke admission, and in many cases with the feedwater supply shut off in order that the boiler may produce an abnormal amount of steam, which conditions of course cannot be continuously maintained for any serviceable period of time. The utilization of the greatest possible percentage of the heat energy in the steam delivered by the boiler can only be obtained by using the steam expansively, and since there are definite limits to the steaming capacity of the boiler, it will be obvious that the term "maximum tractive effort" may be very misleading indeed. The volume/surface ratio of a locomotive cylinder is equally as important as in the case of the firebox. If the volume in proportion to the metallic surface exposed to the steam is great, the percentage of cylinder condensation and of surface radiation are minimized, although probably the latter is of relatively small moment. For any particular ratio of diameter to length of a hollow cylinder, the volume increases more rapidly than the surface as its linear dimensions are increased, and for any particular cylinder volume the surface is at a minimum and the volume/surface ratio at a maximum when the diameter and length are equal. Such a cylinder is the most efficient from the thermodynamic point of view, and the larger such a cylinder is made the more efficient thermodynamically it becomes.

The author, in arriving at a basis upon which to construct his suggested method of calculation, acknowledges the importance of speed which introduces the time element into all calculations. He would abandon the elements of cylinder size and piston speed as subordinate to boiler evaporation and crank speed. In the first case, he replaces a fixed dimension with a rate of transforming energy. In the second case, both factors involve a time interval, and he defines his reasons for preferring to base his calculations upon crank speed, stating that either method is equally applicable, but since the majority of factors involved bear a fixed relation to and are normally expressed in their relation to crank speed, his final equations are to that extent simplified.

At low rates of firing it has been found that 5 to 10 per cent of the fuel (bituminous coal) and 25 per cent of the oxygen which enters the firebox through the grates are lost through the stack due to imperfect combustion. The principles of complete combustion are simple, although not always easy to carry out, especially in the case of bituminous coal. Combustion comprises the introducing of the coal into the firebox, raising its temperature to the burning point and supplying sufficient air for the combustion of the gases which are given off during this process. It is also necessary that the air be thoroughly mixed with the combustible gases and that these be maintained at a high temperature during the process. With bituminous coal, in some cases, 50 per cent or more of its weight constitutes volatile matter which is driven off when heated. When fresh coal is fired on top of the fuel bed, the gases are expelled at a point where the air supply does not easily reach them, and the result is that a large proportion of them are apt to be carried out of the stack unburned. The introduction of fresh coal tends to shut off the air supply when it is most needed, and, in addition to this, it must be remembered that all coal contains more or less moisture, which in the process of evaporation cools the firebox and thus further interferes with combustion. The next consideration has regard to the production of water gas by the water in the steam uniting with the carbon to form carbon monoxide and hydrogen. This absorbs still more heat from the firebox, which, however, would be given back if sufficient air at a high temperature could be supplied above the fuel bed to burn the gases. It is not possible to do this where the air admitted is too cold; hence a large proportion of these gases passes off unconsumed. After the

moisture has been driven off, distillation of the hydrocarbons begins; part of these are burned, while the remainder, owing to lack of air and low temperature, are wasted. This entire cycle results in the formation of smoke and the waste of combustible gases.

We may inquire into the wisdom of constructing locomotives which will at times be required to operate under conditions of maximum rates of combustion—that is, with an area of evaporating surfaces which taxes the capacity of the grates in order that the heating surfaces may be fully utilized. Under such conditions we know the boiler efficiency is very low. However, if we consider a district made up, for the most part, of a uniform grade, with a maximum grade of short duration, a relatively small grate area is justified and an excess amount of coal is fired with a known loss in utilization for a short interval, and the net efficiency over the entire run may yet be very high. Locomotives are designed with the conditions under which they are to operate fully analyzed, and thus the variation in relative proportions is explained. Such variation limits the application of a single equation which has been employed heretofore in the calculation of expected performance results. Merely cylinder diameter and stroke are of but little service for guidance as to the actual amount of steam a locomotive will require, under different conditions of operation, and such ratios as cylinder volume to grate area, cylinder volume to heating surface, and the like have no meaning whatever in this respect. Further, the futility of such refinements as varying the cylinder diameter by $^1/_4$ in. in order to meet an assumed greater or lesser capacity of a boiler by reason of a few square feet more or less of tube heating surface, will be obvious. The more important features that really do matter, when considering locomotive proportions, may be listed as follows:

(*a*) The speed at which the locomotive will be required to perform the major portion of its work should be retained, if possible, somewhere between these prescribed limits:

Diameter of driver	Revolutions per mile	Revolutions per minute	Speed, miles per hour
63 in.	320.1	120–180	23–57
70 in.	288.1	120–180	42–63
73 in.	276.2	120–180	44–65
79 in.	255.3	120–180	49–71
85 in.	237.3	120–180	51–76

(*b*) The cylinder volume should be sufficient to enable the locomotive to perform its work at an actual cut-off of from 30 to 35 per cent of the stroke, with full boiler pressure in the steam chest, or as near thereto as liberal steam-pipe and throttle area will allow.

(*c*) The provision of ample area in the steam and exhaust ports, with a valve travel as long as possible, in order to avoid wiredrawing, both at admission and exhaust.

(*d*) Smokebox, smokestack, and blast-pipe arrangements to be so designed that a maximum draft efficiency and facility of free release of the exhaust steam is obtained. This is of vital importance at high speeds, when the indicator diagram is necessarily restricted, under which conditions back pressure has a far greater detrimental effect than when the diagram is large at lower speeds.

Much may be said in explanation of the manner in which the mean effective pressure and steam consumption of a locomotive may be expected to vary with changes of speed and cut-off. Unfortunately, the results of such explanations are not amenable to representation in the form of a compact formula; and, indeed, except as a rough guide, curves obtained from the performance of one particular locomotive cannot be relied upon for reliable indicatives relative to the probable performance of another locomotive.

The variation of speed factors with the piston speed for superheated locomotives are shown in Table 15, as derived by Cole in March, 1910, at which time it was found that the average maximum horsepower was reached at 1000 ft piston speed per minute and remained constant at higher speeds. Recent tests with locomotives indicate a distinct rise in percentage of about 10 per cent beyond the figures shown from 1000 ft piston speed and up, and herein lies the advantage which is observed in the locomotive constructed in 1933 compared with 1910, when sustained capacity at speed is to be judged.

TABLE 15

Piston speed, ft per min	Speed factor	Modified speed factor—1910 locomotive (Cole) mod. factor = 0.85	Modified speed factor—1933 locomotive (test) mod. factor = 0.93
0–250	1.000	0.85	0.930
300	0.955	0.812	0.888
500	0.770	0.655	0.716
700	0.605	0.514	0.562
1000	0.445	0.378	0.414
1200	0.371	0.315	0.345
1400	0.318	0.270	0.296
1600	0.278	0.236	0.258

One can readily subscribe to the accuracy of the author's method of approach to the problem of predetermining locomotive characteristics. So long as authentic data are available for guidance in estimating the probable relation between the expected and Cole evaporation, no marked discrepancies should be introduced in the results. Much of the familiar Cole formula is retained. In fact, the effect of the addition of a superheater might be similarly expressed by constructing a curve to indicate the relative performance of a locomotive so equipped with respect to one employing saturated steam. Conversely, the Cole constants may be extended to include factors which take into account the benefits derived by the preheating of feedwater, by the partial elimination of throttling losses effected by long-travel valve gears, and by any improvement which serves to increase the availability of the energy contained in the fuel fired. In like manner, the Cole speed factors may, by the application of proper modifications, be rendered applicable to any change in the relation between boiler and cylinder capacity, anticipating probable change in the shape of the horsepower curve.

Whether the author's method is adopted or the Cole analysis modernized, the results should bear marked similarity. Locomotives must be grouped, in either case, on a basis of relative proportions and the extent to which the latest refinements are incorporated in their design. Both are dependent upon the accumulation of adequate test data for the degree of accuracy experienced. While simplification of calculation is claimed for the author's analysis, familiarity, confidence, and universal acceptance recommend retaining the Cole method in principle. The many tests already catalogued in their agreement with calculated performance using the Cole equations suggest the desirability of continuing the practice so well established in order that a common basis of comparison of the old and new may be preserved. The introduction of any method which represents a departure from an accepted standard will likely be strenuously opposed so long as the familiar process can be revised to produce dependable results.

Ching Pong Pei.[39] It is correctly stated in the paper that no one formula can express the tractive effort of all locomotives. It is equally difficult to express all the factors affecting the development of the tractive effort of the locomotive under the varying operating conditions in any single, simple formula or equation. In other words, a single, simple equation for the calculation of locomotive tractive effort cannot be all-inclusive, and any all-inclusive expression for the locomotive tractive effort cannot be simple in nature or in its application. Such being the

[39] Champaign, Ill. Mem. A.S.M.E.

case, in the formulation of any one simple equation for the tractive effort of all locomotives, one is forced to make a choice in the selection of the more important items and the elimination of the lesser ones.

The author, in arriving at a basis upon which his suggested method of calculation is constructed, used the most direct method of first determining the horsepower output of the locomotive and then obtaining the tractive effort from the well-known equation $P = (T \times V)/375$ or $T = (P \times 375)/V$.

The horsepower output of the locomotive is to be determined by the direct method of dividing the total boiler evaporation by the steam consumption of the locomotive cylinders and the auxiliary devices. The relation between the horsepower and the tractive effort of the locomotive as defined by the latter equation is mathematically exact. Hence the whole problem is reduced to the determination of horsepower, which entails only two factors —the total boiler evaporation and the total steam consumption.

In the determination of the boiler evaporation, the author proposed the equation $E = \beta E_c$. The evaporation coefficient β is made a function of the rotative speed of the locomotive. Strictly speaking, there cannot exist any relation between the speed of the locomotive and the capacity or the output of the locomotive boiler. It is undoubtedly true that the demand on the boiler is necessarily and primarily a function of the rotative speed of the locomotive. However, the boiler output of the locomotive may be more or less than the required amount of steam at the corresponding rotative speeds, for the locomotive boiler and the locomotive engines are, after all, two separate units.

The amount of steam generated by a locomotive boiler depends primarily upon the amount of fuel fired in the firebox and upon the efficiency of the boiler. Due to the falling off of the boiler efficiency with the increase in the firing rate, a point may be reached at which the boiler evaporation is actually diminished in the face of increased firing rate. Such a point is seldom reached if ever at all, in locomotive road performance. The amount of fuel that can be efficiently burned in the firebox depends upon the draft in the front end, which, in turn, is a function of the steam passing through the exhaust nozzle. It is in this respect that the performance of the locomotive boiler is interlocked with the performance of the locomotive engine, and the connecting link between the two is the performance of the locomotive front end.

The justification of correlating the boiler evaporation with the rotative speed of the locomotive, as expressed by the formula $E = \beta E_c$ is, as the writer sees it, premised on these assumptions:

1 The Cole evaporation figures E, as derived from the performance of the locomotives of the pre-war period, still hold good on modern locomotives.

2 The draft efficiency is uniform on all locomotives, being only a function of the amount of steam passing through the exhaust nozzle, which implies that the same amount of steam is exhausted from the cylinders at a certain rotative speed of all locomotives.

3 The firing rate in the firebox and the boiler efficiency are each only a function of the draft produced in the front end.

There is no way to prove or disprove the validity of the first assumption, since no mention has ever been made about the firing rate in connection with the Cole evaporation figures. Likewise, the author avoided specifically stating the firing rate or the boiler efficiency at which the evaporation figures were derived. There is no doubt that at some firing rate an evaporation figure as shown by the Cole figure can be obtained. It is equally true, at some other firing rates, that the evaporation rate can be either higher or lower than the Cole figures. In other words, the original Cole evaporation figures are indefinite and ambiguous, and the question naturally arises as to the propriety of using those figures as the basis for the estimate of boiler evaporation. In the derivation of boiler-evaporation figures, the author stated that the Cole evaporation figures still hold good on modern locomotives. Whatever significance may be attached to the Cole evaporation figures, it is clear from the foregoing statement, according to the author, that there has been no material improvement in the locomotive boiler performance, with the exception of the increase in boiler capacity made possible by the addition of feedwater heater, during the last 15 or 20 years. Does this not offer a challenge to the railroad mechanical department in general and the locomotive designer in particular?

It is rather difficult to subscribe to the second assumption in that the same amount of steam is always exhausted from the cylinders at a certain rotative speed of the locomotive. This would be true only when the locomotive is operated with a definite and exacting relationship between the cut-off and the rotative speed. In a general way, the locomotive is operated with longer cut offs at low speeds and with shorter cut-offs at high speeds, and this is as far as the relation between the cut-off and the rotative speed goes. Hence, this assumption cannot hold true for any one locomotive, let alone for all locomotives.

Whether or not the intermittent character of the locomotive exhausts has any effect on the draft produced in the front end, there must exist a certain definite relationship between the amount of steam passing through the exhaust nozzle and the amount of air admitted into the firebox. We may choose any arbitrary ratio, such as the pounds of exhaust steam per pound of air admitted into the firebox, as the draft efficiency. In this case, it can be readily seen that the design of the front end as well as the design of the ashpan, grates, firebox, and the boiler itself exert a large influence on the draft efficiency. In spite of the similarity of the modern locomotives, we know from experience that the draft efficiency is not uniform on all locomotives, even if it were possible to always exhaust the same amount of steam from the cylinders of all locomotives at the corresponding rotative speeds.

From the test results of locomotives, both in road service and on testing plants, we find that neither the firing rate nor the boiler efficiency is a function of the draft in the front end only. In locomotive road operation, it is perfectly clear there is no such thing as a constant firing rate, as the amount of fuel burned in the firebox will have to depend upon the load and the speed of the train and the profile of the road. Within the operating range of a locomotive, it may be generally stated that the tractive effort of the locomotive increases with the increase in the amount of fuel burned, though not necessarily in the direct proportion. There is no denying the fact that one of the major factors, if not the major factor, affecting the boiler evaporation of the locomotive is the firing rate. It is exceedingly difficult to follow the logic of any estimate of the boiler evaporation without due regard to the amount of fuel burned.

The steam consumption of the locomotive cylinders is naturally mainly a function of the percentage of cut-off at which the engine is operated. It is also a function of the pressure and the temperature of the steam, both at the steam chest and at the point of cut-off. Test results of locomotives on testing plants seem to indicate that there is always a narrow range of cut-offs to be operated with a certain rotative speed, the combination of which results in the minimum steam consumption, other conditions remaining unchanged. On the other hand, if we were interested only in the maximum capacity of the locomotive, it may be operated with a much longer cut-off than that at which the minimum steam consumption is obtained, limited only by the capacity of the boiler to supply steam. At any stated boiler capacity, which is mainly a function of the amount of fuel burned, the locomotive can be operated with a number of different cut-offs at one rotative speed, in which case the locomotive would develop

different values of tractive effort, according to the cut-off, at the same rotative speed. It is therefore not sufficient to merely correlate the tractive effort and speed, as represented by the ordinary tractive-effort-speed curves, without specifying the manner in which the particular tractive effort figure is obtained.

As previously pointed out, it is not possible to express the tractive effort of locomotive by any single, simple formula, however desirable it may be, and it is also almost meaningless to merely state that the locomotive would develop so many pounds of tractive effort at a certain speed without specific qualifications. In view of these difficulties, would it not be more logical to present the locomotive tractive-effort data in the form of a series of tractive effort-speed curves, each one representing a certain firing rate and each point on a curve representing the tractive effort obtained with the most suitable cut-off at the corresponding rotative speed? It thus presents a complete picture of the locomotive tractive effort to the railroad operating department, enabling them to determine in which way the locomotive can be most efficiently operated to meet the individual need of the road, whether in the obtainment of the maximum capacity of the locomotive at the expense of economy or in the selection of a most economical performance with some sacrifice in the locomotive capacity.

S. S. Riegel.[40] We worked out the horsepower and tractive-effort curves for our most recently acquired fast-freight locomotives by both Mr. Lipetz's simplified and the Cole method, and in our dynamometer tests, when the engines were first received, we developed horsepower and tractive-effort curves in harmony with the results secured by the Lipetz formula. We naturally are satisfied with the correctness of the deductions as stated in the paper.

Author's Closure

It is very gratifying to see that a paper on locomotive ratios evoked so much discussion, not only on the subject to which the paper was directly devoted, but also on other related subjects. The majority of these latter comments does not call for a reply, as no criticism was voiced by these discussions with respect to the proposed method of figuring horsepower and tractive effort of steam locomotives. I shall therefore restrict myself principally to discussions on the method itself, and later, in the conclusion, I will briefly reply to all other remarks. A brief recapitulation of the paper would be of use, as this may in part answer some questions of the discussers. At the beginning of the paper it was pointed out that there are two possible methods of evaluating the horsepower and tractive effort of a locomotive. The power of the locomotive is derived from steam through the means of the cylinders. In the first method, by using mathematical analysis, it would be quite possible to follow through the various processes taking place in the cylinders for a certain amount of steam of known quality (pressure and temperature). This analysis would be very intricate, as a great number of complex factors has to be taken into consideration. Furthermore, as such an analysis would represent a consecutive chain of premises and sequences, the final result would depend upon the validity of each individual premise; and there would be no assurance that the method would lead to reliable results.

In order to eliminate all these difficulties and offer a practical quick method for evaluating the horsepower of a locomotive, it was suggested in the paper to apply an empirical method, by which the power is figured on the basis of the total evaporation of the locomotive boiler and the approximate steam rate per horsepower-hour at various speeds. Thus only two variable factors are introduced in the calculation instead of a multitude of factors, and in addition both factors are such that they can be figured fairly accurately. The evaporation of a locomotive boiler is more or less known. It has been measured and evaluated hundreds of times, and the Cole figures seem to represent very closely the amount of steam which can be generated by a locomotive under normal conditions without excessively forcing the boiler. As to the steam rate, it is also known that a well-proportioned and properly designed locomotive has fairly definite limits for steam consumption per horsepower-hour for various conditions of work. It would seem, therefore, that a method by which these two variables are tied together should give more accurate results than complex formulas.

Second, it must be borne in mind that the objective of the method is not to predict with accuracy the power-and-tractive-effort curve of any locomotive of any design. As Mr. G. W. Armstrong puts it rightly, the object is to provide a "comparometer" for evaluating locomotives of known designs. One or another locomotive having an unusually large superheater, or firebox, or combustion chamber, or cylinders, or a special draft arrangement, or some other novelties which are being tried out from time to time, can not be evaluated by the suggested method. Only the average well-proportioned and properly designed locomotive can be served by this method with a reasonable degree of accuracy, and the locomotive with the enumerated or other improvements has to be evaluated by comparing its performance with the predictions of the formula.

Third, as it has been already pointed out in the paper, there are great many kinds of tractive effort which are of interest and are being considered in different cases. It is therefore always possible to find fault with one or the other method of figuring tractive efforts and to point out that some tests show higher or lower figures than those obtained by the method. Tractive effort is not a definite thing, and it is not the *maximum* tractive effort which is being sought. It has been explained in the paper that the method permits to determine the *performance* curve which is usually obtained under normal conditions of work; and I should like to add here—and with a reasonable degree of efficiency. This will be explained later.

As regards the paper itself (not the method), it should be remembered that the theories and various statements made in the paper which may be open to criticism have no influence on the method in the final recommended form. Neither the theory of the variation of evaporation with speed, nor the evaluation of coefficient β, nor the actual steam rate as obtained from tests, has any bearing on the final results. These theories and statements had been brought out in order to make clearer the way by which the method was developed. After formulas [12] and [13] and Table 7 have been established, they were checked for all modern locomotives for which test data were available, and the results were shown in Figs. 10 to 15 of the paper. The preliminary theories and statements were thus no more than stepping stones, which can be removed after the final formulas and empirical constants had been established and verified, and the criticism of these theories, by purely theoretical considerations, cannot undermine the method itself. The author will not try to defend them as such, unless it is shown that they affect the method.

As a whole, all discussers agreed that cylinder dimensions alone cannot serve as a basis for figuring tractive efforts. No one disputes the fact that the tractive effort, especially for higher speeds, is determined by the boiler capacity. Dr. R. Eksergian, using more or less the same premises as the author's, tries, however, to point out the way by which an analytical method may lead to final results. I do not dispute his way of reasoning, but whether a practicable method can be worked out by following his lines, remains to be seen. Only Messrs. Kiesel and Vincent

[40] Mechanical Engineer, Delaware, Lackawanna & Western Railroad Company, Scranton, Pa.

dispute the correctness of figuring boiler tractive-effort curves on the basis of the boiler only, and devise formulas in which both the cylinders and boiler evaporation are included.[41] Mr. Kiesel made several general remarks and offered his well-known formula to which I will return later, but Mr. Vincent presented a very complete theory of an analytical method which is very interesting, and tried to prove by charts that the method recommended in the paper does not give in application to locomotives, even those which were considered in the paper, as good results as his method. In the case of the locomotives cited in the paper, Mr. Vincent made errors in calculating tractive efforts in accordance with the method submitted in the paper. In other cases, especially in his statements, he made several mistakes, which the author will try to correct. He will therefore start his replies with Mr. Vincent's criticism.

Formula [17], which is based on Mr. Kiesel's theory and is a modification of his formula, is actually a simplified form of Professor Strahl's method explained on the third page of the paper. Mr. Vincent neglects a great many things as compared with Strahl. He pays no attention to the cylinder clearance volume, to the release and compression volumes, to the exhaust pressure, to the distortion of indicator cards on account of speed, to the heat exchange between steam and cylinders, and to many other things. He further assumes constant evaporation through the whole range of boiler tractive effort. The only variable which he takes into account is the variation of cut-off with speed and the resulting change in expansion.

As it is clear from the derivation of formula [17], it has a meaning only if the second member in the denominator of the right-hand side, designated by E, is actually the expansion ratio, and $1.95P_1/1 + E$ is the mean effective pressure in the cylinders (mean indicated pressure), equivalent to p_i of formula [1] of the paper. Prof. A. J. Wood called E the "expansion ratio" and figured it by dividing the weight of a cylinderful of steam to steam per stroke, exactly as Mr. Vincent defines E. Further, Professor Wood assumed that the mean effective pressure is approximately equal to $2P_1/1 + E$,[42] very close to $1.95P_1/1 + E$ as Mr. Vincent assumes. Thus E for all intents and purposes is the expansion ratio, differing from the real expansion ratio only by the neglect of clearance and release volumes and the effect of cylinder cooling; in other words, it is the expansion ratio approximately estimated. Likewise, the mean effective pressure is roughly expressed by a simple formula $1.95P_1/1 + E$, as the real formula is much more complicated even if the distortion of indicator cards due to speed is not taken into consideration.

Because of this distortion effect, no formula can express the mean indicated pressure. Tests with the I1s locomotive on the Altoona testing plant (Pennsylvania Bulletin No. 32) give results (for representative indicator cards with full throttle) which are compared in Table 16 with values according to the foregoing formula.

[41] Mr. L. K. Sillcox, while not disputing the correctness of the author's method, prefers for practical considerations the Cole method. The author presents his reply to Mr. Sillcox at the end of his closure.

[42] *Railway Mechanical Engineer*, Dec., 1916, p. 627.

Thus the discrepancy between the actual and estimated mean effective pressure, fourth and sixth columns, especially at higher speeds, is enormous; the actual at 160 rpm is 36.7 per cent lower than the estimated, while at 40 rpm the actual is 12 per cent higher than according to the formula. It is true that E is not exactly the inverse of the cut-off, but whatever method is chosen for figuring the E, it will not make the foregoing comparison much better, as for the same cut-offs the mean effective pressures vary considerably with the speed.

It is inconceivable why v in formula [17] should correspond to the average pressure during *admission* with only 100 F of superheat as an average for the whole cylinder (including expansion ?), unless it is an empirical correction of errors caused by making the other assumptions. Nor is it easily understood why such an important factor as cylinder back pressure is not taken into account at all, and why auxiliaries, which on a road locomotive absorb in some cases as much as 10 per cent of the total steam, are disregarded altogether. In view of all these approximations, which affect the ultimate result in opposite directions, the formula may accidentally give sometimes fairly good tractive-effort figures for certain ranges of speed and boiler forcing.

Considering now more specifically Mr. Vincent's curves, which should prove that the recommended method is not applicable to some of the locomotives cited by me as examples, I will take up first his contention that at low speeds the cylinder tractive effort (TE_1) should not be represented by a straight horizontal line, but by an inclined line. In Fig. 1 of the paper, I have shown cylinder tractive efforts at different cut-offs. They actually represent curves obtained from tests with the New York Central 4–8–2 locomotive. The curves have a sloping shape, and up to a certain speed can be assumed to be straight inclined lines. The rated tractive effort of this locomotive, which has 85 per cent maximum cut-off, is, with 0.85 mean indicated pressure factor, 60,620 lb. It can be seen from Fig. 1 that the top curve for 85 per cent cut-off lies above the rated tractive effort up to a speed of about 12 mph, which is slightly more than the speed of the intersection point of "1932" curve with the horizontal rated tractive effort line on Fig. 10 of the paper. We can thus afford to draw the rated tractive effort with 0.85 factor as a horizontal line, but we could also draw an inclined line, starting it from a higher point, as long as this point is below R on Fig. 1 and the inclination is properly chosen. It seems to be simpler to draw the rated tractive effort as a horizontal line and extend it to the intersection with the boiler tractive effort, as this will be less, by a certain margin, than all cylinder tractive points at low speeds obtained at 85 per cent cut-off. In other words, if we estimate the rated tractive effort with the usual factor 0.85, which leaves a certain margin for the peak tractive-effort points, the line can be horizontal, but if, as it is sometimes being done, a factor of 0.90, or even 0.92 to 0.93, is assumed, it is necessary to draw an inclined line.

The foregoing figures are true for long cut-off locomotives. It would be appropriate to state here what the conditions would be for locomotives with limited cut-offs. In this case the factor in formula [1] should be taken in accordance with the limitation of the cut-off as shown in Table 17.

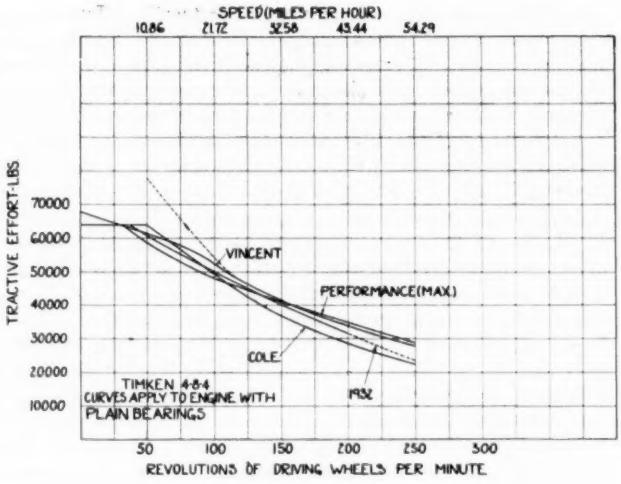

FIG. 13-A

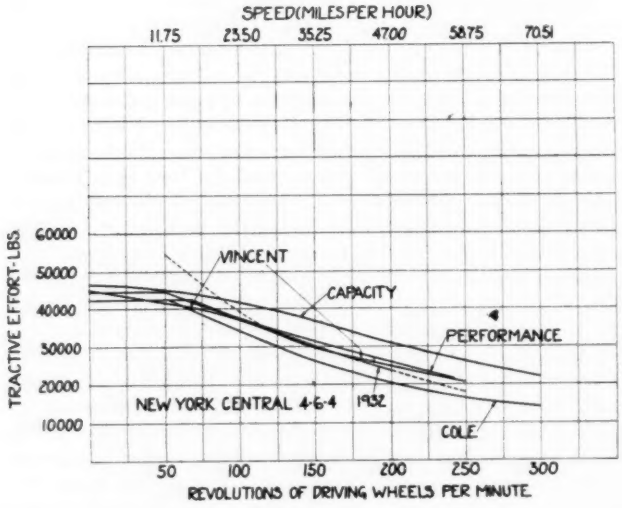

FIG. 11-A

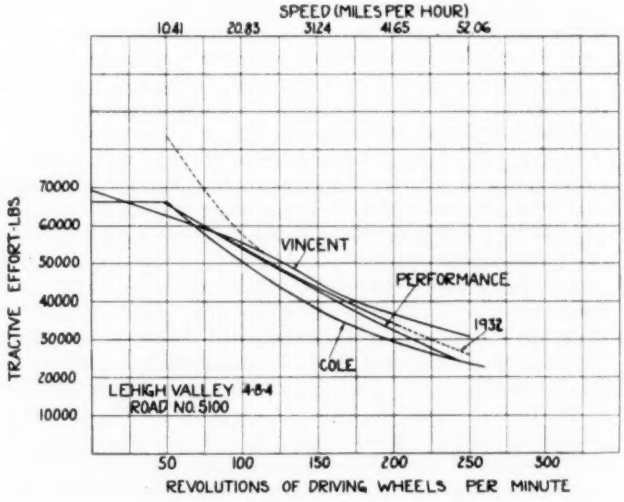

FIG. 14-A

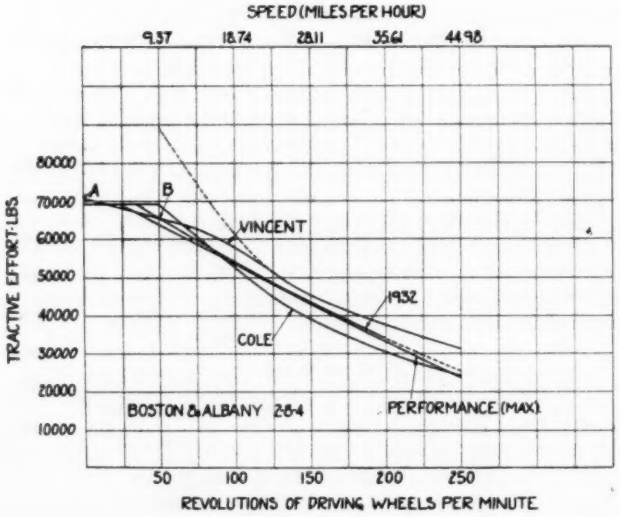

FIG. 12-A

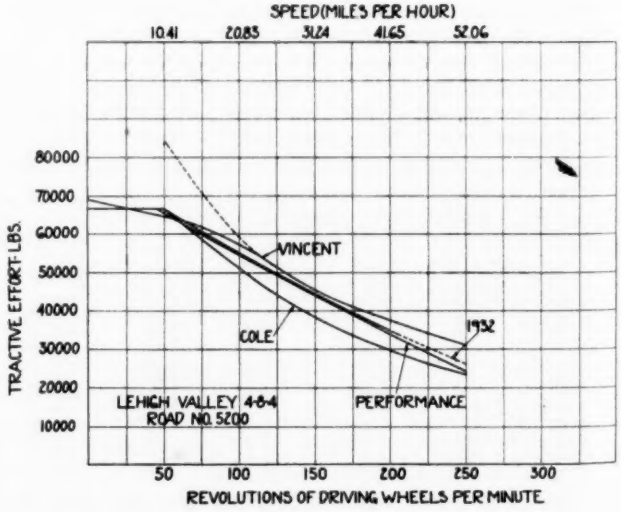

FIG. 15-A

These figures represent more closely the actual maximum values for the mean indicated pressure ratios, and therefore it would seem that there is more justification in this case for plotting the rated tractive effort as an inclined line. However, as every limited cut-off locomotive has either auxiliary ports, or some other arrangements for starting, the straight line may still be applied because these ports will permit an additional margin above the real mean indicated pressure. So, for instance, in Fig. 12 the rated tractive effort is represented by a straight horizontal line drawn at a height of 69,600 lb, corresponding to a factor of 0.78. The Boston & Albany locomotive has a 60 per cent limited cut-off. This is a reply to one of Mr. Vincent's remarks.

Moreover, in a well-proportioned locomotive, either long or limited cut-off, the rated tractive effort corresponds to the limit of adhesion, and the straight line represents not only the rated tractive effort, but also the adhesion limit. It is for this reason that I prefer to put it as a straight horizontal line. When Mr. Vincent uses the inclined line, beginning at 92 per cent mean indicated pressure ratio, part of his cylinder tractive-effort line may very often be above the adhesion line, as can be seen from the examples of the locomotives which are shown later with Mr. Vincent's curves.

Leaving now for a moment Mr. Vincent's transition curve (TE_2) and going over to his main curve (TE_3), it can be seen from Figs. 10-A to 15-A, which represent Figs. 10 to 15 of the paper with Mr. Vincent's tractive-effort curves added and horsepower curves eliminated, that his curves are, in all cases except one, higher than the "1932" curves and do not, when applied to these locomotives, represent the test results any better. This also applies to Fig. 12-A, which shows the Boston & Albany limited cut-off locomotive, as to all other examples which are long cut-off locomotives, except New York Central 4–6–4 (Fig. 11-A), for which it is slightly lower for speeds below 25 mph.

The reason for the author's replotting these curves is that Mr. Vincent made an error in figuring the "1932" values for his Figs. 22, 23, and 24, which are supposed to show the same curves as Figs. 11-A, 12-A, and 13-A. Although an example was given in the paper showing how the "1932" method should be applied, and the tractive efforts for the New York Central 4–6–4 locomotive in that example were calculated, Mr. Vincent made the error of giving credit for the feedwater heater twice: first, by adding 7 per cent to the Cole evaporation figure (E_c), and second, by using from Table 7 those factors which are supposed to be used for locomotives with feedwater heaters and the Cole evaporation figure (E_c) without any additions. However, this led Mr. Vincent to state, referring to his replotted curves for the three locomotives, Figs. 22 to 24, including the New York Central 4–6–4: "It will be observed that they are not the same as the '1932' curves, shown in the author's Figs. 11 to 13. He has evidently used constants for locomotives without feedwater heaters, although the records indicate that heaters were used." The discrepancy is due to Mr. Vincent's use of 1.07 E_c instead of E_c, together with factors for feedwater heaters shown in the second and third lines of Table 7. The right procedure calls for the use of E_c in all cases—this in accordance with formula [13]—and for different factors for locomotives with or without feedwater heaters, as the case may be, in accordance with Table 7. The curves of Figs. 11 to 13 were found to be correct, and therefore they have been replotted on Figs. 11-A to 13-A. Mr. Vincent's curves have been recalculated and added to the charts. In addition, new charts have been also made for the remainder of the locomotives cited in the paper, Figs. 10-A and 14-A to 15-A, which show Mr. Vincent's curves and the "1932" curves correctly.

Mr. Vincent's curves, although practically in all cases higher than those of the author, follow the same trend as the "1932" curves for speeds above 20 to 25 miles, below which Mr. Vincent's curves have to be replaced by an arbitrary transition curve. If his curves were to follow his formula below these speeds, they would be as shown by the broken line on Figs. 10-A to 15-A, and much above either the "1932" curve or test results. It is only because they are cut off and replaced by an arbitrary curve, which is made to bend down so as to meet the low-speed line (TE_1), that Mr. Vincent's curves represent the results more or less correctly; in other words, although his formula [17] depends both on cylinders (machine part of the locomotive) and evaporation, with a predominating influence of cylinders for low speeds and evaporation for high speeds, his formula is actually recommended by him only for high speeds, at which the boiler and not the cylinders are of importance. Thus, at speeds from 0 to about 10 mph, Mr. Vincent uses a chart of inclined straight lines, depending upon the size of the machine part only—this is at least logical in principle. From 10 to about 20 to 25 mph, he makes use of his transition curves, with no formula, which is rather arbitrary, and only for speeds higher than 20 to 25 mph he offers a formula, depending on sizes of both machinery and boiler, whereas in this case only the boiler is of importance. This is not logical even in principle. Moreover, the rational, mathematically derived formula turns out to have a limited application. It could not be otherwise, since so many essential factors have been neglected without even attempting to compensate for them, except by introducing various unjustified approximations.

The reason that Mr. Vincent's figures, nevertheless, come so close to those of the author at speeds above 20 to 25 mph, and therefore represent more or less correctly test results, is that at those speeds the formula is actually of the same form as formula [13] of the paper, as can be easily shown by following mathematical manipulations. Mr. Vincent's formula [17] is:

$$TE_3 = \frac{1.95\ P_1 M}{1 + 36.66\ MV/Ev} \qquad \text{[17-A]}$$

if the paper's notation for speed (V) and evaporation (E) are used. For locomotives with feedwater heaters, Mr. Vincent assumes $E = 1.07\ E_c$. Consequently,

$$TE_3 = \frac{1.95\ P_1}{1/M + 36.66\ V/1.07\ E_c v} = \frac{1.95\ P_1 E_c v}{E_c v/M + 34.25\ V}$$

If steam were a perfect gas, P_1v would be constant at constant temperature, in accordance with the law of Boyle. For superheated steam varying between narrow limits of pressures and temperatures, P_1v is approximately constant; namely, for boiler pressures 215 to 265 lb (gage) per sq in. and 100 deg superheat, the figures are as given in Table 18, and the product P_1v varies

TABLE 18

P_1 in lb per sq in. (gage)	T_1 in deg F	In cu ft per lb	P_1v
215	493.7	2.328	500.5
240	502.7	2.111	506.6
265	511.1	1.931	511.7
Average			506.3

very little. Substituting in the formula the average figure 506.3 for P_1v in the numerator, and the value of V from formula [3] of the paper for V in the denominator, we obtain:

$$TE_3 = \frac{1.95 \times 506.3\ E_c \times 336.134}{E_c v\ 336.134/M + 34.25 \times nD} = \frac{1.95 \times 506.3 \times 336.134/34.25}{336.134\ E_c v/34.25\ M + nD} E_c,$$

or, carrying out the arithmetical calculations,

$$TE_3 = \frac{9689.3}{9.814\ E_c v/M + nD} \times E_c \ldots\ldots [17\text{-B}]$$

Formula [17-B], in view of its derivation as given above, is thus identical with Mr. Vincent's formula [17]. Comparing it with formula [13] of the paper and neglecting the difference in constants, it will be seen that the structure of the formulas in both cases is very similar: the tractive effort varies directly with evaporation E_c and inversely with diameter D, with this difference, however, that instead of M_t/D of formula [13], a more complicated factor for E_c must be used in order to make their product equal the tractive effort, namely:

$$\frac{M_t'}{D} = \frac{9689.3}{9.814\ E_c v/M + nD} \ldots\ldots [19]$$

In this expression M_t' has been introduced as a modulus similar to modulus M_t of formula [15]. Comparing it with [15], it will be seen that both M_t and M_t' vary inversely with speed n, although the law of variation is different in view of the presence of the first member of the denominator in formula [19], which member is missing in the denominator of formula [15]. The first member introduces the influence of the machinery in the modulus, and as at low speeds its value is proportionately larger than that of the second member of the denominator, dependence of tractive effort on the evaporation is not so direct as in the method proposed in the paper. The effect of this member is reflected in the broken portions of the Vincent curves on Figs. 10-A to 15-A. The effect of the cylinders (M) is too great. At high speeds, on the other hand, the second member of the denominator gains in value, and the influence of the machinery on the results of formula [17-B] diminishes, while that of the boiler increases. Therefore, the Vincent formula comes closer at high speeds to the formula of the author than at low speeds.

As to Vincent's transition curve, the reason for its existence is not clear. If a locomotive had an unlimited boiler supply, there would be no boiler tractive effort, and the limitation would be by the maximum cylinder tractive effort, which would be the only one to consider. If, on the other hand, the boiler capacity would be limited, but the cylinder dimensions were so large that the decrease of the cut-off would have to begin almost from the start, the boiler tractive effort would be the only one to consider practically through the whole range of speeds. If, as it actually happens in real locomotives, both the cylinder dimensions and boiler capacity are limited, the tractive effort must consist of two intersecting curves, as it can be only either one or the other. Therefore, there should be no justification for a transition curve, although I can see a reason for a transition curve in the case of the Vincent formula, because at intermediate speeds it gives exaggerated results for all locomotives (broken lines on all previous figures) which have to be corrected by a curve of some sort interposed between two other curves (TE_1 and TE_3), which are approximately correct—one for the reason that it corresponds to the limitation of the cylinders, which is more or less simple and definite, and the other for the reason that it comes close to the method suggested by the author.

In addition to the curves which have been discussed, Mr. Vincent also shows in Figs. 19 to 21 the application of his and the author's methods to three other locomotives. Fig. 20 refers to the Pennsylvania I1s, which is a locomotive with a very limited cut-off (maximum 55 per cent).[44] Mr. Vincent shows that at low speeds test figures are above the boiler tractive-effort curve based on "1932" factors. He explains it by the fact that the author's formulas have been derived from data of full cut-off locomotives, which at low speeds, when long cut-offs are used, show higher steam consumption than locomotives with shorter cut-offs. In his opinion, for this reason higher powers and tractive efforts can be obtained from the I1s locomotive than the author's formulas would indicate. In substance it should be so for very limited cut-off locomotives, but Mr. Vincent's explanation does not prove the point in so far as the application of the method to locomotives, or even to limited cut-off locomotives, is concerned.

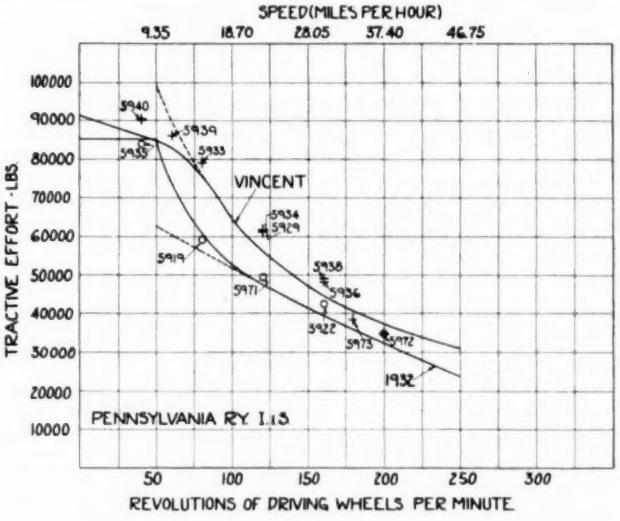

FIG. 28

In order to make a better comparison, the author replotted the "1932" curve of Fig. 20, as Mr. Vincent's plotting was not quite accurate. It is shown on Fig. 28 with Mr. Vincent's curve. He also repeated the most representative test points shown on Fig. 20 by crosses. The numbers which accompany the crosses are test numbers as they appear in the Pennsylvania Bulletin No. 32, in which the test results of the I1s locomotive were published. Particulars about these tests are given in Table 19.

TABLE 19

Test No.	Rev. per min	Indicated tract. eff., lb	Dry coal per sq ft per hr, lb	Steam per ihp-hr, lb	Boiler eff., per cent	Overall locomotive eff., per cent
	Bulletin's column No.					
	14	49B	33D	46	41	52
5940.....	40	90,257	79.9	21.2	56	4.7
5939.....	60	86,072	103.0	18.6	55	5.1
5933.....	80	79,135	127.1	17.3	54	5.6
5929.....	120	61,219	214.0	18.3	42	4.0
5938.....	160	48,978	204.8	17.0	41	3.6
5936.....	160	48,121	214.7	17.4	39	3.8
5973.....	180	38,417	228.5	18.0	35	3.1
5972.....	200	34,827	158.0	16.0	49	4.4

It is doubtful that on account of the lower steam consumption of the locomotive the test figures are higher than what the "1932" curve would indicate. By analyzing the figures from the table, it can be seen that all the tests (except one, No. 5935, discussed below), which, according to Mr. Vincent, gave tractive efforts much above those recommended by the author, especially those at speeds below 120 rpm, have been obtained at steam consumptions from 17.3 to 21.2 lb per ihp. If steam consumed by auxiliaries on a road locomotive, which are not included in the Pennsylvania test results, are added, fairly high steam consumptions (up to 23 lb per hp-hr) will be obtained for these speeds, which are

[44] Maximum tractive effort corresponding to this cut-off is 90,024 lb, factor 0.75. On Fig. 28 rated tractive effort of 85,222 lb, corresponding to a usually cited cut-off of 50 per cent, is shown (factor 0.71). The higher figure is correct.

not far from those assumed by the author in his Figs. 5 and 6. The same applies to other speeds with the exception of test No. 5972, but this test point is below Mr. Vincent's curve. In the opinion of the author, the real reason for the test points lying above his curve is that all these points have been obtained by excessively forcing the boiler. In order to get 86,072 lb tractive effort at 60 rpm (test No. 5939), it was necessary to burn 103 lb of coal per sq ft of grate area per hour, which, at this low speed, is rather high. Likewise, in order to get the results of tests Nos. 5936 and 5938 at 160 rpm, it was necessary to burn 214.7 lb of coal per sq ft per hr, which is enormous even if the fact of the small grate of the locomotive is considered—after all, the ratio of the outside evaporative heating surface to grate area is only 68.4.

A good indication of forcing a boiler and a locomotive are the boiler and overall efficiencies shown in the last two columns of Table 19. They are very low—the latter varies from 3.1 to 5.6 per cent, and more often it is closer to the lower limit than to the upper. In order to make this point clearer, test points with results which come closer to "1932" curves are shown as circles on Fig. 28. Table 20 gives some data of these tests.

TABLE 20

Test No.	Rev. per min	Indicated tract. eff., lb	Dry coal per sq ft per hr, lb	Steam per ihp-hr, lb	Boiler eff., per cent	Overall locomotive eff., per cent
	Bulletin's colomn No.					
	14	49B	33D	46	41	52
5935.....	40	83,980	56.7	19.2	67	6.4
5919.....	80	59,188	70	15.9	65	7.3
5971.....	120	49,290	101	15.6	59	7.1
5922.....	160	42,261	132	15.4	54	6.2
5972.....	200	34,827	158	16.0	49	4.4

It will be seen from this table that the boiler was forced considerably less than in tests of Table 19, with the result that the efficiency was much higher—6.2 to 7.3 per cent, except only one case when it was 4.4 per cent.

Point 5935 is very interesting and is put on Fig. 28 on purpose—it is removed far from the boiler tractive-effort curve "1932," and at the same time the forcing of the boiler does not seem to have been excessive. This (probably incidental) point would bear out Mr. Vincent's contention, if there were at least one more point like it in this, or a similar point in another, limited cut-off locomotive. Then it would be necessary to revise the new moduli for the speed of 50 rpm for the 55 per cent limited cut-off locomotives. It would be premature to do it now, but when this is done, the method itself will not be affected, if for locomotives with 55 per cent cut-off a new modulus for $n = 50$ is established. The boiler tractive-effort curve would be drawn in that case as shown in Fig. 28 in full line marked "1932."

Commenting on his Fig. 21, which represents the Pennsylvania K4s long cut-off locomotive, Mr. Vincent states that "it is evident that they (the author's moduli) are not suitable for the lower range in this locomotive." This is far from being evident. An analysis similar to that made for the I1s locomotive proves just the opposite. Table 21 gives results of tests with locomotive K4s, marked by crosses in Mr. Vincent's Fig. 21. The locomotive has a ratio of outside evaporative heating surface to grate area of 58.3. The data have been taken from Pennsylvania Bulletin No. 29.

TABLE 21

4048.....	280	15,870	81.9	17.0	73.0	7.5

The first five lines represent higher points; the last six lines refer to the lower points, which are close to the "1932" curve. It can be seen that for the same speeds the tractive efforts differ sometimes very little, but the difference in the amount of burned coal and in efficiencies is very considerable. The overall locomotive efficiencies vary for the first group from 4.5 to 5.0 per cent, but for points which lie close to the "1932" curve they vary from 6.2 to 7.5 per cent. As it has been stated in the paper and repeated in the foregoing, the formulas recommended by the author have the objective to give average figures for *normal* operation, and therefore do not include cases where the locomotive is excessively forced. The recommended method gives curves with overall locomotive efficiencies of 6 to 7 per cent.

Fig. 19 shows the Texas & Pacific 2–10–4 locomotive, which is a locomotive with cut-off limited to 60 per cent. The author's curve is shown to be very close to Mr. Vincent's for higher speeds, and agrees with the test results given on the chart, in the transition curve region (speeds between 12 and 20 mph), even if the author's curve is lowered as it ought to be. The test results have not been published, and it is therefore impossible for the author to analyze the crosses given by Mr. Vincent, as it was done with the I1s and K4s locomotives. If those tests were available, the author is confident that the differences could be explained.

It is true that the "1932" factors were established mainly on the basis of tests with full cut-off locomotives. They seem, nevertheless, to be applicable to limited cut-off locomotives with moderate size cylinders. As it can be seen from Fig. 12-A, they correspond better to the test results than the Vincent formula. The Texas & Pacific tests show a fairly good agreement. The only locomotive which shows decidedly higher figures than the "1932" curve, and this only in the low-speed region, is the I1s locomotive, which has very large cylinders. It is possible that when more information on the performance of limited cut-off locomotives is available, the moduli for the ultra-limited cut-off locomotives may have to be revised, most probably for one speed only, 50 rpm, as the influence of limited cut-off at speeds where short cut-offs are used anyway, will hardly be noticeable. The method itself will not suffer from such a modification—just the opposite; this will only prove the flexibility of the method. As soon as for locomotives of a certain new type the steam rate, S_a, shown on Figs. 5 and 6, requires revision, it can be easily done, provided sufficient reliable experimental information is available, and new moduli can be established in accordance with formulas [14] and [15]. I do not see how Mr. Vincent can improve his mathematically derived formula on the basis of new experience.

If transition curves should be tolerated, the author's method could be easily adjusted for the time, until the new moduli are established. For ultra-limited cut-off locomotives, for instance, the following procedure may be suggested:

In cases when the boiler tractive-effort curve, based on the "1932" moduli, lies so low that it cannot be intersected with the rated, or maximum, cylinder tractive effort (Fig. 28), draw an arbitrary transition line from the intersection point of rated tractive effort with the 50 rpm ordinate, so as to merge with the "1932" curve.

The necessity for plotting the transition lines will be very infrequent; it may happen only in cases where the locomotive is decidedly over-cylindered. In cases where limited cut-off locomotives are built with moderate cylinder sizes, such a case will hardly happen, as can be seen from the example given of the

Boston & Albany 2–8–4 locomotive, as shown in Fig. 12-A.

There are several other remarks made by Mr. Vincent which are not correct and which call for a reply. In discussing the author's method, Mr. Vincent states that "the author's recommended method of expressing the tractive effort of a locomotive is dependent entirely upon the validity of the values shown in Figs. 4 and 5." Mr. Vincent further states, referring to the possibility of pushing locomotive evaporation to the limit: "This sort of operation cannot be used as a basis for developing a tractive-effort formula. Such a formula should be based on the normal operation of a locomotive designed in accordance with the most approved engineering practice known."

But this is exactly what the author did. As it was shown in comparing Mr. Vincent's curves with the author's in application to the Pennsylvania I1s and K4s locomotives, the Vincent curves, not the author's, were near the limit of boiler capacity with the lowest boiler and overall locomotive efficiency. And it was further shown that the author's curves agree very well with normal road-test results, while the Vincent curves were practically in all cases higher.

Reverting to the first statement regarding Figs. 4 and 5, it has been explained in the foregoing that by checking formula [6] with road test results, Figs. 5 and 6 were established as averages of Figs. 7 and 8. This was done on the basis of Fig. 4, and therefore its accuracy, so to speak, is included in Figs. 5 and 6; in other words, if values of β were taken erroneously smaller or larger than what they ought to be, the error is correspondingly reflected in values S_a, and the moduli figured on the basis of both β and S_a will be correct, because in their ratio the error will be eliminated. This was explained in the paper.

Likewise, as to the discrepancy in steam rates as shown in Fig. 25, the same thing should be remembered—namely, that the ultimate recommendations of the paper, as given in formulas [12] and [13] and Table 7, do not depend upon Figs. 4, or 5 and 6 separately. They are interconnected, and therefore should be used together or not at all. Table 7 should be considered jointly with formula [12] for power, or [13] for tractive effort. If the Cole evaporation figure E_c should differ from the actual figures, curves 5 and 6 will correspondingly differ. In such a case, moduli of Table 7 will deviate in the same sense, but the ultimate results (P_i and T_i) will be, nevertheless, correct, because the moduli are established by checking of test results on the basis of *calculated* figures E_c. That the actual steam rates do not differ much from S_a is an indication that, even taken separately, the various rates and coefficients used in the method are more or less correct.

Furthermore, it should be remembered that the steam rates which are shown on Fig. 25 are taken from the Pennsylvania test results, and, as Mr. Vincent says himself, they do not include auxiliaries, whereas curve 5, as it is plainly shown in the designation of the abscissas, represents steam rates including auxiliaries.

Mr. Vincent is of the opinion that the drop in the evaporation curve for speeds above 200 rpm, as shown in the author's Fig. 4, is not justified. He says that there is no apparent reason why a locomotive boiler, after it has reached its normal evaporation, should not continue indefinitely at the same rate. If Mr. Vincent had in mind "indefinitely" in relation to time, then he would be right, but he refers to speed above 200 rpm, and in this case the author's opinion is borne out by the Pennsylvania tests shown in Fig. 2. Unfortunately, road tests as they are usually performed in this country cannot prove the point, but as far as the conclusions of the paper go, it is immaterial whether or not the author's statement can be strictly proved with respect to evaporation, because as regards horsepower this is unquestionably correct in the majority of cases.

All performance curves given in the paper, except those for the Timken locomotive and the capacity test for the New York Central 4–6–4 locomotive, show for the horsepower a tendency to drop after a certain speed. The same applies to all modern German locomotives very thoroughly tested by Professor Nordmann, to whom reference was made on the fifth page of the paper.[45]

The Pennsylvania tests also show such a maximum point for locomotives; so, for instance, the I1s maximum horsepower (3863 ihp) had been reached at 160 rpm, and for the K4s, the maximum powers (3150.0 and 3155.3 ihp) had been obtained at speeds of 240 and 280 rpm, respectively, after which the powers dropped. It is true that conditions (*c*) and (*d*) of those enumerated by Mr. Vincent are the most important in extending the maximum horsepower beyond the highest speed, but so far, the conventional drafting arrangements and valve motions have not proved to give the desired effect in all cases. The high evaporation capacity of the Timken locomotive, as Mr. Pownall pointed out, may be due to the star-shaped nozzle and the very efficient drafting arrangement of the locomotive. It is further possible that improved valves of the poppet type and other improvements will also contribute to the rising of the power curve at high speeds, but neither of these improvements has been universally adopted. When these improvements will become regular features of locomotives and test data will be available, the moduli for 250 rpm will be revised, and new moduli will be established for higher speeds, but for the present there is no justification for increasing them beyond the author's recommendation.

Further, Mr. Vincent states that the construction of his curve TE_3 involves somewhat more work than does the author's moduli, but thinks that the additional labor is negligible. He probably overlooked that the moduli, which have been already prepared and are given in the paper, apply to all types of locomotives, and that there is no need of figuring them at all. Formulas [14] and [15] are given simply in order to permit the reader to check Table 7, or to establish moduli for intermediate speeds, if he wishes. Consequently, there can be no question that Mr. Vincent's method calls for more work than that of the author.

Thus, in conclusion and in addition to what has just been said about the amount of work, it would seem that Mr. Vincent's method gives approximately correct figures for a short portion of the speed range, gives exaggerated values for speeds below that range, and therefore requires in all cases plotting of arbitrary transition curves, whereas the author's method recommended in the paper makes use of a clearly defined curve and a straight line, and their intersection, without the necessity of resorting to transition curves. This is true for locomotives of all types, including limited cut-off engines, except when the limit of the cut-off is very low, in which case a transition curve might be of use until the new moduli for 50 rpm are established.

Everything that was said in the foregoing in relation to the principle of the Vincent boiler tractive-effort curve (TE_3) also applies to the method of Mr. W. F. Kiesel, Jr., of which method Mr. Vincent's formula is only a slight modification. At the end of his discussion Mr. Kiesel refers to Professor Wood's book, "Principles of Locomotive Operation." In Fig. 13 of this book, 1915 edition, Mr. Kiesel's curve is plotted in application to Pennsylvania E6s locomotive. It has exactly the same tendency of giving too high values at low speeds as the Vincent method. This portion of the curve between 23 and 18 mph is shown by Professor Wood with an upturn (broken line), similar to what has been found in Figs. 10-A to 15-A with the Vincent curves. If Mr. Kiesel's formula should be extended for speeds below 18 miles, the curve would go up still higher and the values would be exaggerated. It is evident that some transition curve has to be

[45] Theorie der Dampflokomotive auf Versuchsmässiger Grundlage, by Prof. H. Nordmann, Organ für die Forstchritte des Eisenbahnwesens, May 15, 1930, pp. 267–269.

used in this method too, in application to all locomotives, and such a curve is actually shown by Professor Wood.

There is a difference, however, between Mr. Kiesel and Mr. Vincent in figuring the boiler evaporation. While Mr. Vincent accepts the Cole evaporation figure E_c as equivalent to H in his formula [17], Mr. Kiesel does not think it necessary to figure the evaporation of a locomotive separately for various parts of the boiler as established by Mr. Cole. He recommends to figure the evaporation on the basis of *equivalent* heating surface, assuming the equivalent heating surface equal to the sum of superheater, flue, and six times the combustion-space heating surfaces, and the average evaporation equal to $11^1/_2$ lb per hr per sq ft of so-defined equivalent heating surface. The firebox heating surface seems to be a part of the combustion-space heating surface. This designation for the equivalent heating surface is based on an empirical law found by Mr. Kiesel—namely, that the evaporation of a combustion-space heating surface is six times as high as that of the flues and superheater, if the length of the flues is about 20 ft. Mr. Kiesel further assumes that 10 lb per sq ft of equivalent heating surface represents steam available for use in cylinders.

I do not think that such a rough method of calculating the evaporation would satisfy us, with all the knowledge that we have now, especially the inclusion of superheating surface into the total surface for figuring evaporation. This can be considered only as a necessary correction for the increase of power due to superheating, although one correction for the effect of superheating is already included in the Kiesel formula by referring w to pressure P with 100 deg superheat. Moreover, such a method offers no advantages over the more accurate Cole formula, which has been proved to be satisfactory by many years of use, and to hold good even now for modern locomotives, as it has been shown in the paper and corroborated by many discussers. A simple calculation of evaporation for any of the locomotives cited in the paper, for which we have data, will show that Mr. Kiesel's empirical rule gives highly exaggerated figures. They are not evaporation figures any more, but simply values of W to be substituted in Mr. Kiesel's formula, which thus becomes a purely empirical formula. Mr. Kiesel concedes this, but is of the opinion that the formula is based on a rational theory. This may be true, but the rationality of it is more than offset by the omission of a great number of important factors which cannot be expressed by mathematical formulas, and therefore must be compensated by such figures as evaporation of a superheating surface and others, analyzed in the author's discussion of Mr. Vincent's formula.

Mr. Kiesel did not show any examples of the application of his method to those locomotives for which he says that his formula proved satisfactory for over 20 years of experience, and therefore the author could not check his method, as he did it in discussing the Vincent method, but there can be no doubt that if applied to locomotives cited in the paper, his formula will not agree with the known test results because the structure of Mr. Kiesel's formula is the same as that of the Vincent formula. It may, though, agree with the results of the Pennsylvania I1s locomotive, for the same reasons that were stated in discussing the Vincent method, and, most probably, for low speeds only.

There are several things in Mr. Kiesel's comments which call for a reply. He states that "tests of Pennsylvania Railroad locomotives classes K4s, E6s, K2sa, and L1s made in 1914 and 1915, and the I1s made in 1919, used as examples by the author, are rather too old, as much improvement in locomotive design has been developed since then." The test figures of the enumerated locomotives have been used only in connection with boiler evaporation figures, and as far as the evaporation of the boiler is concerned, very few changes in the conventional design of the boiler have been made. Furthermore, the results of these tests have not been used directly in the examples given by the author, by which he tried to prove the correctness of his method, and still further, they have no bearing on the method, as finally recommended, for reasons advanced in the paper and in this closure.

Neither can the author agree with the statement that he is vague on the point of how much steam can any given locomotive make available for use in the cylinders. There is a definite formula in the paper for the amount of steam available for the cylinders—namely, $E(1 - x)$, just preceding formula [6]. This is made use of in formulas [6] and [6-A]; evaporation E is explained and figured in the paper, x is included in Figs. 5 and 6. Mr. Kiesel's statement that the author "determines drawbar horsepower" while he prefers "the cylinder tractive effort" is evidently a misunderstanding, as the paper is about the indicated horsepower and tractive effort, with hardly mentioning the drawbar horsepower at all.

The question of *maximum* versus *performance* tractive effort was discussed by Messrs. G. T. Wilson and A. Giesl-Gieslingen The latter's discussion may be considered as a reply to Mr. Wilson, which makes a further reply unnecessary. The author will only add that he stated in the paper his reasons for working out a method by which the performance, and not the maximum horsepower and tractive-effort curves, would be plotted. It would not be desirable to develop a method by which only capacity curves, such as shown on Figs. 10 and 11, would be obtained. These two locomotives, both of the New York Central Railroad, and tested under similar conditions, give maximum capacity figures, which, according to Mr. Wilson, differ from those obtained by the author by 17 per cent in one case and 42 per cent in the other. Similar relation of discrepancy would be obtained if the Cole, or the Vincent, or the Kiesel formula were applied, although the figures might be different. No method would satisfy both capacity curves, and therefore these high power figures must be partly ascribed to local conditions, such as quality of fuel and method of operation, which may be different on different roads, and partly to the design of the different parts, which cannot be expressed by a formula. It would not be advisable to have a yardstick formula for comparison based on the capacity of the 4–6–4 J1 locomotive. These capacity curves every railroad has to find out for itself.

As to the value of capacity tests, it has been also pointed out in the paper that unless there is complete assurance that the capacity tests have been made without exceeding the sustained evaporation of the boiler, the capacity figures are likely to be exaggerated and cannot be taken as basis of locomotive performance.

Mr. Ching Pong Pei raises several interesting points. He seems to be somewhat puzzled that no reference has been made in the paper to the rate of firing. He refers to Mr. Cole's evaporation figures as "indefinite and ambiguous" because they are not tied up with a certain rate of firing.

As far as Mr. Cole's figures are concerned, the author is to blame for not having stated definitely that Mr. Cole was considering the rate of firing of 120 lb per sq ft per hr. As the author made reference to Mr. Cole's publications and the Alco Handbook, he did not think it necessary to repeat Mr. Cole's firing rate. Personally, he does not attach much significance to the rate of firing in the case of modern locomotives. When Mr. Cole devised his figures, the grate areas were comparatively small. Modern locomotives have much larger grate areas, and as stated in the paper on the fifth page, "in well-designed locomotives the proportions are such that the two factors more or less balance," the two factors being the limitation of the amount of coal which can be burned on a certain grate and the amount of heat which can be absorbed by a certain heating surface. In modern locomotives the second is more often than the first the ruling limitation, and it is therefore permissible to consider the evapora-

tion as determined by the heating surface, rather than by the grate area.

In view of the foregoing, smaller firing rates than what Mr. Cole figured on are now actually being used. Mr. Wilson states that for the performance test of the J-1 and L-2 locomotives the average[46] firing rate was 62 to 66 lb, and during their capacity tests, 125 lb of coal per sq ft of grate area per hour was to be the limit, without stating, though, how this was determined. Dr. Giesl-Gieslingen believes that in some tests on the New York Central, when the boiler was forced to the limit, the firing rate was 150 lb. In his paper the author was not interested in firing rates in view of the indefiniteness of the figures and also for the reason that they fluctuate too much. Moreover, they cannot serve as indications of forced or normal operation of a locomotive, as this depends upon the relative size of the grate. Therefore, the author would not be in favor of Mr. Ching Pong Pei's suggestion to plot a series of tractive-effort curves for various rates of firing. This would be a very indefinite basis for comparison, although it may be an interesting method of scientific investigation of locomotives of certain types.

The author already pointed out in the paper that, strictly speaking, tractive effort becomes a definite conception only when the conditions at which the tractive effort is produced are specified, as for instance the maximum tractive effort, the most economical tractive effort, the constant-evaporation tractive effort. Mr. Ching Pong Pei's suggestion is along these lines—he would have constant-firing-rate tractive efforts. Much more reliable conclusions can be drawn if these curves are plotted for different constant-evaporation rates. Professor Lomonossoff was the first to develop this method, and he used it in all his tests, giving curves for different evaporation rates expressed per unity of heating surface per hour.[47] Professor Nordmann, as it has been mentioned in the paper, refers his test results to one constant evaporation rate, which is 57 kg of steam per square meter of fireside heating surface. A still better way of comparing locomotives, at least for some purposes, would probably be on the basis of equal overall efficiencies.

However, the difficulty with all these methods, in which a system of curves is considered, is that during actual operation the locomotive is not burning a constant amount of coal per unity of grate area per hour, nor is it generating a constant amount of steam per unity of heating surface per hour, nor does it work at a constant efficiency. These factors are varying all the time, and in the opinion of the author, the higher rates of firing and evaporation are obtained at higher speeds. If anything, the locomotive is more likely to work at constant efficiency at certain modes of operation—performance, maximum performance, capacity. If a tractive-effort curve obtained from test performance, or capacity, be plotted over a chart consisting of a series of curves for different constant rates of firing or evaporation, probably it will be found that the actual tractive effort intersects all the other curves. If, therefore, a chart as suggested by Mr. Ching Pong Pei is presented to a railroad operator, as he recommends, it would be necessary to give him a table, or chart, indicating the speeds at which the different rates are actually materialized. This would enable him to determine points, one on each of the curves, and plot the actual tractive-effort curve.

The author preferred, therefore, not to be bound by such purely theoretical considerations and to consider the curves which from actual tests are known to be obtainable in every day's service. These, called *performance curves*, can be plotted as shown in Fig. 16 of the paper for the New York Central 4–6–4 locomotive. These curves correspond to reasonable overall efficiencies (about 6 to 7 per cent), as has been shown in the discussion of Mr. Vincent's method, and to firing rates for modern locomotives up to 90 to 110 lb per sq ft of grate area per hour, as can be figured out from the total evaporation (E_c), average evaporation of coal (7 lb of water per 1 lb of coal), and grate area of any of the foregoing examples.

The author is not in agreement with the second and third premises, quoted by Mr. Ching Pong Pei, as those on which the correlation between boiler evaporation and rotative speed of the locomotive is based. Neither of the two premises has ever been mentioned by the author; as a matter of fact, the meaning of the second is not clear to him. The correlation referred to is for him a matter of observation of innumerable locomotive tests and conclusions drawn from stationary tests. As it has been stated elsewhere, the ultimate recommendations of the method do not depend upon the correctness of the assumed correlation.

Mr. J. E. Muhlfeld takes issue with the author in considering the type "E" superheater as a part of the "modern locomotive," asserting that type "A" superheaters are able to give just as high superheats as the type "E." In this latter respect Mr. Muhlfeld is quite right. In his conclusion, which was partly cited by Mr. Muhlfeld, the author stated also that "this [the use of the Cole method for all locomotives with type 'A' superheaters] should not imply, however, that type 'A' superheaters can never develop the horsepower recommended by the new method. Locomotives are known that have given very high performance figures with type 'A' superheater on good coal."

It is obvious that the locomotive power depends upon the proper superheat, and that if type "A" superheater is so dimensioned that it can insure as high a temperature as type "E" superheater, the performance of a locomotive equipped with this type of superheater should be just as good as that with the type "E." It has also been stated by the author that it would be better to refer the performances not to the type of the superheater, but to the temperature of superheat. However, it was pointed out that "it was not thought advisable to give constants for various superheats for the reason that before a locomotive is tested, its superheat is not known, and therefore these constants would not be helpful in calculating the horsepower of a locomotive beforehand." It was also mentioned that it would be more logical to base such constants on the relation of the superheating surface to the evaporative heating surface. The author tried to find a law for such a dependence, but so far such comparisons did not give conclusive results.

There is one important thing which justifies considering the type "E" superheater a feature of the "modern locomotive," especially American; namely, it is difficult, even impossible, to build a type "A" superheater with a sufficiently large heating surface in a large locomotive boiler, while the type "E" superheater permits doing it. The ratio of the superheating surface to the evaporative heating surface in the largest type "A" superheater is only about 0.32, whereas it is possible to design a type "E" superheater with a ratio of 0.45. The majority of locomotives with type "E" superheaters has a ratio of 0.41 to 0.42. The examples which Mr. Muhlfeld cites in favor of the type "A" superheater refer to small locomotives. Likewise, all European locomotives, which have mostly type "A" superheaters, are of comparatively small size. The difficulty occurs only when locomotive heating surfaces reach 4000 to 4500 sq ft, for which the type "E" superheater seems to be indispensable.

Mr. Muhlfeld is aware of this advantage of the type "E" superheater, because he says: "The particular feature of the type 'E' superheater has been its increased superheating surface, which reflects favorably on the boiler capacity." This is

[46] Presumably the average for a trip, as this is the only firing rate that can be determined on a road test.

[47] See his numerous publications; for instance, "Lokomotivversuche in Russland," Berlin, 1926.

exactly the reason for singling out this type of superheater by the author, because "boiler capacity" is the main consideration in the problem analyzed by him in the paper. As to the disadvantages of the type "E" superheater enumerated by Mr. Muhlfeld, they are of no import to the author from the point of view of the paper—as long as, notwithstanding these disadvantages, type "E" superheaters are used in the majority of road locomotives of recent build ("modern locomotives"), the author's duty is to evaluate these superheaters.

The author notes with pleasure that Mr. Muhlfeld has no criticism to offer regarding the suggested method. He probably realizes that this method can have a broader application than the Cole method. The power and tractive effort of the Delaware & Hudson locomotives with high-pressure water-tube boilers, mentioned in Mr. Muhlfeld's discussion, cannot be readily figured by the Cole method, because their ratios of cylinders and heating surfaces are quite different; but as soon as the evaporation of these boilers, and the steam rates of compound or triplex expansion engines of the locomotives are known, the evaluation of a locomotive of this type will be just as easy as of any other locomotive.

Mr. T. C. McBride is of the opinion that the increase in evaporation capacity of a boiler equipped with feedwater heater, found by the author to be 7 per cent, is underestimated, and that 15 per cent would be a more correct figure. He may be right in that the extreme 15 per cent figure calculated by Mr. McBride on the basis of heat saving is correct when everything is in first-class condition and the locomotive is working at the peak of its capacity. For average conditions 7 per cent is a more acceptable figure, although it may seem somewhat conservative.

Mr. McBride does not believe that road tests for which the author's figures were taken can be sufficiently accurate. But tests made on the Pennsylvania testing plant with I1s locomotive equipped with a feedwater heater of the open type showed a saving in heat fluctuating between 4.7 and 10.2 per cent, of which 7.45 per cent is the average. Therefore, when the evaporation figures found by the author were about 7 per cent above the Cole evaporation figure, he thought that the most simple way of introducing the feedwater heater into the ratios would be leaving the Cole figure unchanged and adding 7 per cent to that for locomotives equipped with feedwater heaters—this being in good agreement with stationary test results. The author believes that 7 per cent is a fair figure for average operating conditions, for the performance curve on the basis of available experimental data.

Mr. G. F. Starbuck raises the question of the application of the recommended method to limited cut-off locomotives and locomotives equipped with a booster. As it has been stated in the discussion of Mr. Vincent's method, the recommended method is applicable to the moderate limited cut-off locomotive. This has been proved by the example of the Boston & Albany A-1 engine and other locomotives discussed there. For the ultra-limited locomotive of the I1s type it has been shown that a correction, either by the temporary use of a transition curve or by a change in the modulus for the lower speed (50 mph), might be needed.

As to the booster, the tractive effort of the latter can be added directly to the rated (cylinder) tractive effort, but only up to the intersection point with the boiler tractive effort. This additional tractive effort will have its full value at starting and at very low speeds (several miles per hour), and will gradually have to come down to nothing at the intersection of the rated and boiler tractive efforts for lack of steam. There can be no advantage in using a booster for speeds above the adhesion speed (the highest speed at maximum tractive effort, corresponding to the intersection of rated tractive effort with boiler tractive effort), because when the tractive effort is limited by the boiler capacity, it is more advantageous to make use of the main engine only, which has a higher efficiency than the booster.

In connection with these questions, the author would like to mention that the method is also entirely applicable to switching locomotives, and although in some cases the tractive effort of such a locomotive will be lower than that obtained by the Cole method, the smaller figure of the method recommended in the paper is the correct one. This figure will be smaller than Cole's only for locomotives where the boiler percentage is below a figure close to 100. The Cole method in this case gives exaggerated figures.

I do not quite agree with Mr. H. B. Oatley when he says that "the new method offers formulas somewhat more complicated than have been used hitherto." This would be true if we exclude the figuring of boiler evaporation from the Cole method, and compare only the Cole figuring of cylinder horsepower and tractive effort on the basis of the Cole factors with the recommended method, in which, in addition to the moduli, the boiler evaporation must be also figured. However, ordinarily the Cole method requires the figuring of the boiler percentage, and in this case the knowledge of the boiler evaporation is also required.

Mr. George W. Armstrong is right in calling my attention to the discrepancies which might be found if the curves according to my method are compared with test results of locomotives equipped with improved drafting arrangements—and this is true whether the improvement be a more efficient smokebox arrangement, or the annular-ported exhaust nozzle, or other improvements. Mr. W. A. Pownall also called attention to this fact, giving figures obtained from the Timken locomotive, which gave exceptional results at high speeds. This is true, as it has been stated at the beginning of the discussion; the recommended method cannot take care of such improvements which have not yet become a composite part of a conventional locomotive. When all locomotives, or at least a great majority of modern locomotives, will be equipped with an improved standard drafting arrangement, the figures will have to be revised, but this will not affect the method itself.

Mr. L. K. Sillcox's criticism is expressed in the last three paragraphs of his discussion. It is preceded by a very interesting and valuable analysis of conditions of good combustion, essentials of good design, and elements of correct proportioning of locomotives, and in conclusion it is suggested to increase the Cole factors by about 10 per cent. This suggestion has no connection with the preceding analysis, and is even in contradiction with some of his statements, as for instance, with the following just remark: "Merely cylinder diameter and stroke are of but little service for guidance as to the actual amount of steam a locomotive will require under different conditions of operation, and such ratios as cylinder volume to grate area, cylinder volume to heating surface, and the like have no meaning whatever."

Table 15 is given by Mr. Sillcox in which new factors are suggested, differing from Cole figures by 9.2 to 9.5 per cent. They are marked "test;" it is claimed that they are based on recent tests and that the difference between them and Cole figures represents the advantage of the locomotive "constructed in 1933 as compared with 1910," when Mr. Cole devised his method.

The author is not familiar with the tests to which Mr. Sillcox refers, and as no particulars of the tests or any data are given, the author is not in a position to dispute or confirm the suggestion of raising the Cole factors by 9.2 to 9.5 per cent for all speeds. He may only state this—when the need for a revision of Cole factors became apparent, the first thought was to increase Cole factors in a certain proportion. This was tried, but it was impossible to establish a uniform rate for all cases. This can be easily concluded from Figs. 10 to 15, in which the Cole curves,

together with test performance curves, are shown. At low speeds (50 to 80, or 110 rpm; piston speeds approximately 250 to 400, or 440 fpm) they were found in some cases above performance curves, and their further increase was not desirable (Figs. 10, 12, and 13), while in others the whole curve lay below the performance curve (Fig. 11), and still in others the curves touched each other at 50 rpm. The reason for this was evident—these locomotives had different boiler percentages. The next thing the author tried was to change the Cole curves in relation to the boiler percentages. He got more consistent results, but then it occurred to him that by doing so he eliminated the Cole values altogether, because the cylinder horsepower was thus introduced twice, in the numerator and the denominator, and these two values canceled each other, leaving only a value proportional to the evaporation. Then the natural thing to do was to consider the evaporation only—what he did in his method.

The author explained in his paper the reasons for preferring to figure the locomotive characteristics on the basis of boiler dimensions rather than cylinder sizes. It is not necessary to repeat here the arguments, but it suffices to say that if we agree to limit ourselves to locomotives of a certain period and type, any essential part of a well-proportioned locomotive may be chosen as a yardstick for measuring its power. Superheating surface, weight, even length of a locomotive, could be selected for that purpose, and it would be found that the ratios of power to each of the enumerated dimensions fluctuate very little in modern locomotives. Nobody would seriously consider measuring the power of a locomotive by its length, but in the author's opinion, there is more justification in measuring it by the heating surface of the superheater (of a certain type) than by the size of cylinders. In Table 22 horsepowers of all locomotives cited in the paper are referred to the product $p_b \times A$ (boiler pressure times piston area),[48] which represents the main factor in figuring the power of a locomotive according to Cole and also to Mr. Sillcox. The only difference between them is that in Cole's formula these products are multiplied by certain factors, while Mr. Sillcox would increase these factors by 9.2 to 9.5 per cent.

The ratios of column 3 of Table 22 vary from 0.0230 to 0.0294, or 28 per cent. In the same table Cole evaporation figures E_c (not counting the increase due to feedwater heaters) and the ratios of power to these figures are also given for comparison.

TABLE 22

[48] A. L. Co. Handbook, 1917, p. 54.

[49] Not capacity; read from charts, and may slightly differ from recorded figures.

They fluctuate only 12.1 per cent—much less than ratios in column 3.

The dependence of Cole's method upon cylinder sizes will always make the correctness of his figures a function of boiler percentages. For switching and limited cut-off locomotives with comparatively small boilers and large cylinders, any revised Cole figures will be exaggerated, while for high-speed locomotives with small cylinders, such as in the New York Central 4–6–4 engines, the opposite will be the case. At the same time, the real source of power, the boiler, will not be taken into account. Mr. Sillcox's reasons for his recommendation to preserve the Cole method and modernize his figures are "familiarity, confidence, and universal acceptance" of the method. In the author's opinion, if it is agreed that the Cole method is not based on correct premises, the enumerated advantages of the Cole method are of little importance. As the art progresses, Cole figures will have to be revised from time to time, and while this in itself is not a handicap, the difficulty is that test results give no indication how to proceed with the revision of Cole factors. A summary rise of all, or even of several, factors will always be a very approximate solution of the question. Tests will always determine the two fundamentals: improvement (1) in boiler evaporation and (2) in steam consumption, irrespective of the boiler and engine design—whether Stephenson or water-tube firebox, high-pressure or low-pressure steam, simple-expansion or compound- or triple-expansion cylinders, or even a turbine instead of cylinders. As soon as these data are known, they can be immediately and directly applied to the suggested method and new constants determined, because the method is based on the same two fundamentals: boiler evaporation and steam consumption. It can not be done with the Cole method. This makes the method suggested in the paper flexible and really universal, although, maybe, not universal in Mr. Sillcox's sense.

Mr. F. E. Russell is of the opinion that by referring mean effective pressure to piston speed we would "stick to fundamentals," whereas using rotary speed we introduce an approximation. The author, by referring to Sir J. Alfred Ewing and W. E. Dalby, greatest living authorities on steam-engine theory, tried to prove that piston speed is not a fundamental in steam-engine performance. He has never seen anything in favor of this, except Mr. Cole's supposition, and does not find in this factor anything more than the "familiarity" due to long usage, as pointed out by Mr. Sillcox. Furthermore, in his paper he showed that the suggested method can be used on the basis of piston speed if desired, although it involves some more work.

The author appreciates the reception given by the various discussers to the author's paper and their valuable discussions. He is very grateful to those who, like Mr. Riegel, stated the results of checking the recommended method against actual test results, and would welcome statements of other railroad engineers regarding the application of the author's method of figuring horsepower and tractive effort to modern locomotives in comparison with actual test results.

Canadian Pacific Railway's Multi-Pressure Locomotive 8000

Its Steam-Generating System

By F. A. SCHAFF,[1] NEW YORK, N. Y.

The conventional type of locomotive boiler with stayed surfaces is generally considered as not suitable for pressures above approximately 300 lb per sq in. Therefore some sort of water-tube construction is essential for pressures materially higher. On the Canadian Pacific locomotive 8000 the Elesco multi-pressure system seems to adequately meet the high-pressure requirements, but offers corollary advantages contributing to ease of maintenance. The system consists of three units: (1) the closed circuit, (2) the high-pressure boiler, (3) the low-pressure boiler. An outstanding feature of the water-tube construction is the use of distilled water in the closed circuit, so that no scale can be formed in the water tubes which are in contact with the fire.

THE development of steam generation has been characterized by a steady trend toward higher steam pressures. At the beginning of the century, locomotive boiler pressures had risen to 180 or 190 lb from 150 or 160 lb per sq in., which had been considered high pressure during the preceding decade. By 1910, 200 lb was generally regarded as the limit for simple-expansion locomotives, although during the compound era 215 and 225 lb per sq in. had been used to some extent. With the introduction of superheated steam there was a lull in the advance of pressures as the advantages gained by the use of superheat were adequate to meet the then requirements of added capacity and fuel economy. In more recent years the insistent demands for greater economy and higher sustained locomotive capacity, with heavier loads and faster schedules, caused designers to again increase the working steam pressure and also to provide for higher steam temperatures.

The locomotive boiler in all its major features has changed but little, save in size, since the days of the "Rocket," "Old Ironsides," and "John Bull." It is true that proportions have been changed and many devices have been added which have materially increased the efficiency, but in the main, the boiler is as it was a century ago. Brotan in Europe and others, following in his wake, built water-tube fireboxes in order to better provide for higher working pressures. This trend evidenced itself in America through the introduction of the Jacobs-Schupert firebox on the Santa Fe, the Baldwin locomotive No. 60,000, the McClellan firebox on the New Haven, and more recently the water-tube fireboxes on the Delaware & Hudson. The Gresley-Yarrow water-tube boiler on the London & Northeastern in England and the Winterthur locomotive in Switzerland represent constructions which aimed at suitability for higher working steam pressures.

With the present state of the art it is generally considered that the conventional type of locomotive boiler with stayed surfaces is not suitable for pressures above approximately 300 lb per sq in. It is essential therefore to utilize some sort of water-tube construction for pressures materially higher than this figure.

The Elesco multi-pressure system as used on Canadian Pacific No. 8000 seems to adequately meet not only the requirements for substantially high pressure, but offers corollary advantages contributing to ease of maintenance. The system consists of three separate units:

(1) The closed circuit
(2) The high-pressure boiler
(3) The low-pressure boiler.

Closed Circuit

The shaded part of Fig. 1 shows the closed circuit, a water-tube boiler, forming the firebox and combustion chamber of the locomotive. The bifurcated seamless steel tubes are 2 in. and $2^1/_2$ in. in outside diameter. The cross-section shows that the furnace walls are formed by one straight riser tube and one bent crossover tube changing alternately.

The tube ends are rolled into the firebox ring at the bottom and at the top into the steam separator drums. A special feature of the boiler is that the downcomer tubes are not located within the gas path, but outside of the wall of riser tubes, thus insuring a positive water circulation without the dangerous reversals of flow encountered on some designs of water-tube boilers. The tube system is filled to approximately the center of the steam separator drums with distilled water, which serves as a heat carrier.

The steam generated is taken from the steam space of the separator drums and carried by short riser pipes to the heat-transfer elements located in the main steam drum on top of the firebox. During its flow through these elements the steam, by losing its latent heat to the lower temperature feedwater of the high-pressure boiler, condenses, thus generating indirectly the high-pressure live steam used in the high-pressure cylinder. The condensate flows out of the lower part of the heat-transfer elements through the downcomers or condensate tubes to the water collectors at the bottom of firebox and combustion chamber. There it again enters the riser tubes, thus completing the circuit. As distilled water is used and the system is sealed, no scale can be formed in the water tubes which are in contact with the fire.

This is probably the outstanding feature of this design, as one of the principal difficulties with water-tube construction in locomotive boilers has been the necessity for careful and frequent

---

[1] President, The Superheater Company. Mem. A.S.M.E. Mr. Schaff was born in Nelsonville, Ohio, on May 24, 1884, and was educated at the Culver Military Academy and Purdue University, and has the degrees of B.S. and M.E. He is the president of The Superheater Company; vice-president, The Superheater Company, Ltd.; president, American Throttle Company, Inc.; director, Locomotive Feed Water Heater Company and Leslie Company.

Contributed by the Railroad Division and presented at the Semi-Annual Meeting, Bigwin Inn, Lake of Bays, Ontario, Canada, June 27 to July 1, 1932, of The American Society of Mechanical Engineers.

Note: Statements and opinions advanced in papers are to be understood as individual expressions of their authors, and not those of the Society.

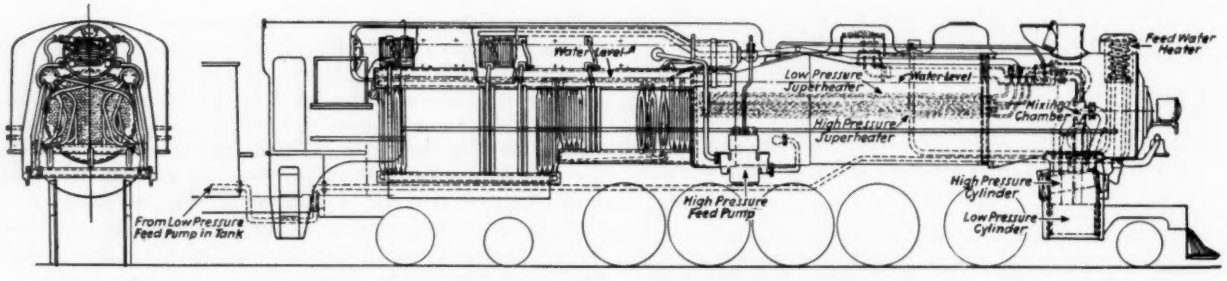

FIG. 4 MULTI-PRESSURE LOCOMOTIVE, STEAM-GENERATING SYSTEM
(Combination of the three systems.)

cleaning of the tubes to avoid accumulation of scale. This cleaning is a slow and expensive operation, requiring the locomotive to be out of service a considerable portion of the time. With the indirect system as used on the 8000, the water tubes will never require cleaning. Thus aside from the time and labor saved, there is the further advantage of avoiding the breaking and remaking of numerous high-pressure joints at the washout plugs etc.

The flow of water and steam in the system is a natural circulation depending upon the hydraulic head of the liquid and unassisted by mechanical means. There is no fixed steam pressure in the closed circuit, but it depends upon the steam output of the locomotive. Under normal conditions the boiler carries about 1350 lb per sq in.; under peak loads it may rise to 1600 lb.

The pressure in the closed circuit is such that the required temperature differential is obtained and the heat flow from the closed circuit steam to the high-pressure boiler water produces and maintains the 850-lb pressure in the high-pressure boiler. The two safety valves of the closed circuit are set at a pressure of 1700 lb per sq in., in order that there shall be an adequate range which will preclude the loss of water.

Fig. 2 will make clear the arrangement of the high-pressure boiler. The high-pressure steam of 850 lb per sq in. is generated in a seamless forged nickel-steel drum 39 in. in inside diameter, located above the closed circuit and protected from contact with flames and firebox temperatures by the cross-over tubes of the closed circuit, by a plate of heat-resisting steel, and by lagging. The high-pressure steam is generated indirectly by means of the heat-transfer elements in the boiler drum. The average water level in the drum is about 7 in. above center line, so that from 80 to 90 per cent of the elements are covered by water. The steam flows through two dry pipes located at the highest part of the boiler and perforated at their upper circumference. They emerge as one pipe at the front end of the drum, lead to a shut-off valve, and from there to the high-pressure superheater header in the smokebox of the locomotive.

Fig. 3 shows the third part of the system, the low-pressure boiler, carrying 250 lb per sq in. pressure. It is similar to the barrel part of an ordinary boiler with a circular rear flue sheet riveted to the boiler shell instead of to the firebox. The boiler is fitted with flues $3^1/_2$ in. in outside diameter, containing superheater units of the type-E design $1^3/_{16}$ in. in outside diameter. The units are divided into two groups near the vertical center line, those on the right-hand side composing the high-pressure superheater and those on the left-hand side forming the low-pressure superheater. Both superheaters are made of the same material, and corresponding units have like dimensions. Maximum interchangeability is therefore provided.

Fig. 4 shows a combination of the three systems as an illustration of the water and steam flow in the boilers. Ordinary feedwater is drawn from the tender tank by a standard feed pump, and forced through the exhaust-steam feedwater heater in front of the stack to the low-pressure boiler, which it enters at a temperature of 200 to 220 F. The low-pressure boiler serves partly as an evaporator for the low-pressure steam and partly as an economizer for the high-pressure boiler.

The high-pressure feedwater is drawn by the high-pressure feed pump from the low-pressure boiler at approximately 250 lb per sq in. pressure and 400 F temperature, and delivered to the high-pressure boiler drum. Besides using the less expensive and lighter heating surfaces of the low-pressure boiler for preheating the high-pressure feedwater, this procedure has the advantage that most of the scaling matter remains in the low-pressure boiler, where it can be easily cleaned out. Only a small amount of foreign matter is carried over into the high-pressure drum. Inasmuch as the high-pressure drum is not exposed to flame, any foreign matter which may be deposited in the drums or on the heat-transfer elements is of a soft nature and can be readily washed off through the clean-out holes provided along the top of the drum.

The steam generated in the high-pressure boiler at 850 lb per sq in. pressure flows through the outside dry pipe to the superheater header in the smokebox, then through the units of the type-E superheater through the multiple-valve throttle to the high-pressure cylinder located between the frames underneath the smokebox. Steam from the low-pressure boiler at 250 lb per sq in. in pressure passes through a tangential drier and a conventional dry pipe to a low-pressure superheater header in the smokebox. From there it passes through the low-pressure type-E superheater to the multiple-valve throttle, then to two mixing chambers located in the smokebox.

These mixing chambers are formed by increasing the diameter of each low-pressure steam pipe. The low-pressure live steam is mixed with the high-pressure exhaust steam by means of a perforated nozzle located in this chamber. The mixture flows to the two outside low-pressure cylinders. By this means the high-pressure exhaust steam is reheated in a simple manner, and the difficult problem of oil separation, so vital for all types of separate reheaters, is avoided. The exhaust from the low-pressure cylinders is utilized in the usual way for drafting the engine and preheating the low-pressure feedwater.

The high-pressure and low-pressure superheater headers are of the type-E throughbolt design. They are separate, but cast integral. Each header is fitted with a multiple-valve throttle, the high-pressure and the low-pressure differing only in so far as the high-pressure throttle has valves of considerably smaller diameter on account of the increased pressure and greater density of the high-pressure steam. The two throttle camshafts are linked together in such a manner that each low-pressure valve opens ahead of the corresponding high-pressure valve. The camshafts are operated by one throttle lever in the cab, the throttle operation being exactly the same as with a normal locomotive.

The boiler heating surfaces and the cylinder sizes and cutoffs are so calculated that full pressure is maintained in high-pressure and low-pressure boilers during operation. In order to prevent popping of the high-pressure safety valves when the throttle is closed, and for accelerating the steaming of the low-pressure boiler at firing-up, a crossover line is arranged which allows superheated high-pressure steam to be passed into the low-pressure boiler. Flow of steam through this line is controlled by a cone-seated valve.

There are three water gages on the boiler. The one for the closed circuit is placed outside of the cab, to be observed only at the beginning and end of each run to ascertain that no water has been lost in service. During the run the system is controlled indirectly by two thermocouple pyrometers, which show the temperature of the steam and give an indication of the performance of the closed circuit.

Inasmuch as the low-pressure boiler tubes are only in contact with gases of relatively low temperature, together with the absence of the crown sheet of the normal type of boiler, the safety of the design is apparent.

As before stated, the water in the tubes forming the firebox and combustion chamber is scale-free. Overheating of tubes due to scale formation, a quite common failure on ordinary high-pressure boilers, is therefore entirely eliminated.

An additional safety factor is the relatively low energy stored in the multi-pressure boiler, in spite of the higher steam pressures. All three units together contain only approximately 70 per cent of the Btu found in a normal pressure locomotive of equal capacity. The separation of the boiler into three units increases the

safety still further, as all three units are not likely to be damaged at the same time. In case of a failure of a water tube in the closed circuit due to faulty material or leakage, the energy of the escaping steam will be only about 15 to 20 per cent of that liberated by a corresponding failure on a standard-type boiler. As considerable care has been taken to prevent steam from entering the cab, in case of a tube rupture, the damage therefore will certainly be negligible, compared with a crown sheet or arch tube failure in an ordinary locomotive.

The engine is expected to be more economical than the present type of locomotive. The savings are derived from the higher working capacity of the high-pressure steam which can be generated even at a slightly lower expense of fuel than normal pressure steam, since for 1 lb of steam at 250 lb pressure, 1201 Btu are required, against only 1195 Btu at 850 lb pressure. Furthermore, the boiler is designed for steam temperatures at the superheater headers of about 750 F, which also contributes to the increased economy.

Table 1 shows some of the characteristic dimensions of five locomotives of this type. Three of these are for fast passenger service. The New York Central locomotive is designed for fast freight operation, and the Canadian Pacific engine is specifically intended for heavy grade work.

The Canadian Pacific engine 8000 is the largest of the five locomotives which have thus far been constructed, and in which the multi-pressure indirect steam-generating system has been employed.

Fig. 5 is a view looking forward through the firebox to the combustion chamber. The formation of the firebox roof by the alternately crossing riser tubes is shown. The tubular floor of the combustion chamber is also clearly depicted. These floor tubes take water from the front of the firebox ring and deliver it to the combustion-chamber crossheader shown in the background. The steam and water mixture from this header rises through tubes to the separator drums in the same way as from the other riser tubes.

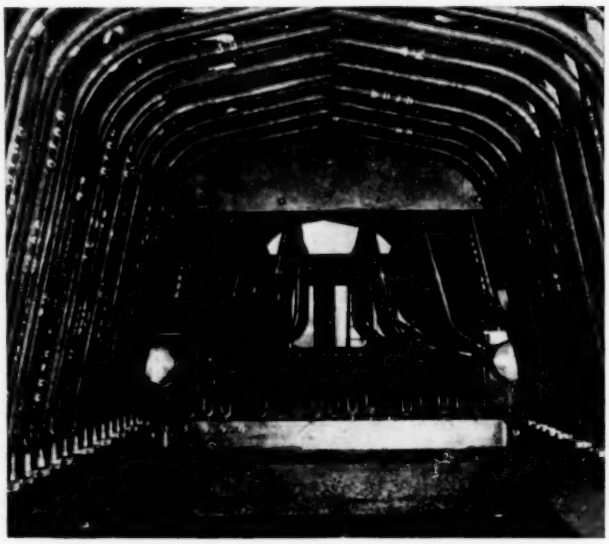

FIG. 5 INSIDE OF FIREBOX, LOOKING TOWARD COMBUSTION CHAMBER

Fig. 6 is a view looking through the combustion chamber to the back head. The combustion-chamber cross-header is shown in the foreground, and the riser tubes, just referred to, are clearly seen. In this view also the front end of the separator drums can be seen. The shutoff valve on the front end of the high-pressure boiler is prominent.

Fig. 7 is a quarter side view of the assembled closed circuit and high-pressure boiler. Attention is called to the condensate

TABLE 1 COMPARISON OF MULTI-PRESSURE LOCOMOTIVES

Road	C.P.R. (Canada)	N.Y.C. (United States)	P.L.M. (France)	L.M. & S. (England)	G.-St. (Germany)

downcomers which convey the closed-circuit water as it leaves the heat-transfer coils, down to the firebox ring, or to the combustion-chamber lower drum, the latter being shown in the central foreground.

The yoke-shaped pipe leading over the front end of the high-pressure boiler is a closed-circuit cross-equalizing pipe connecting the two separator drums and maintains equality of steam pressure in these drums.

Fig. 8 is another quartering view of the closed-circuit and high-pressure boiler showing the back head and also the supports for carrying the back end of the separator drums and high-pressure boiler.

Fig. 9 shows the high-pressure boiler finished and ready to be placed in position. This is a seamless bottle-shaped forging with projections on the side with holes for the reception of the heat-transfer riser tubes which bring the steam from the separator drums to the heat-transfer coils located in the high-pressure boiler. These openings are shown as the upper row of holes on the side. Openings in the row below are for the connections leading the condensate from the heat-transfer coils down to the firebox ring or combustion-chamber lower drums. The openings on the top are for inspection and washout purposes.

Fig. 10 shows the heat-transfer coils, 16 in number, alternately emerging on the right- and left-hand side of the high-pressure boiler. Steam enters these coils through the tube connection, and flowing through the coils downward, becomes condensed and leaves through the lower openings to the downcomer tubes.

The low-pressure boiler is shown in Fig. 11. The smokebox end is in the background. The major portion of the boiler is of conventional shape. The rear end, however, is reduced in diameter and carries a heavy cast-steel member which receives the front ends of the high-pressure boiler and of the separator drums.

Fig. 12 shows the firebox tube sheet of the low-pressure boiler and the saddle casting previously referred to. Heavy caps are applied after the high-pressure boiler and separator drums are in position and securely bolted down, thus providing a firm and rigid attachment between the low-pressure section and the closed-circuit and high-pressure boiler.

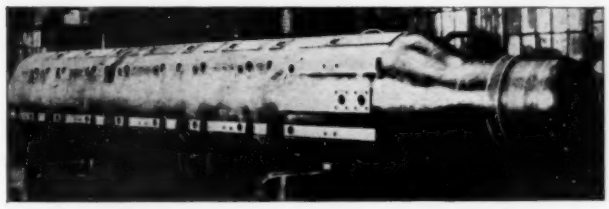

FIG. 9 HIGH-PRESSURE BOILER, RIGHT SIDE

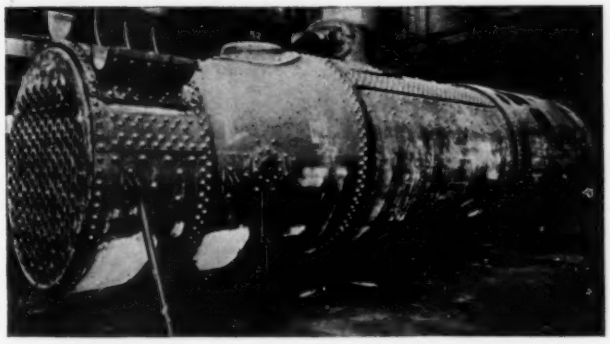

FIG. 11 LOW-PRESSURE BOILER, RIGHT SIDE

Fig. 13 shows the smokebox after the superheater, steam pipes, stack extension, and exhaust pipe have been applied. The vertical pipe just to the left of the center line is the high-pressure steam pipe from the throttle to the high-pressure chest. The high-pressure exhaust pipe is shown on both the right and left side, and carries steam upward and outward to the mixing chamber, where the steam enters the low-pressure steam pipe. The low-pressure steam pipes are shown in the conventional position leading from the superheater header on both the right and left side downward to the low-pressure steam chests.

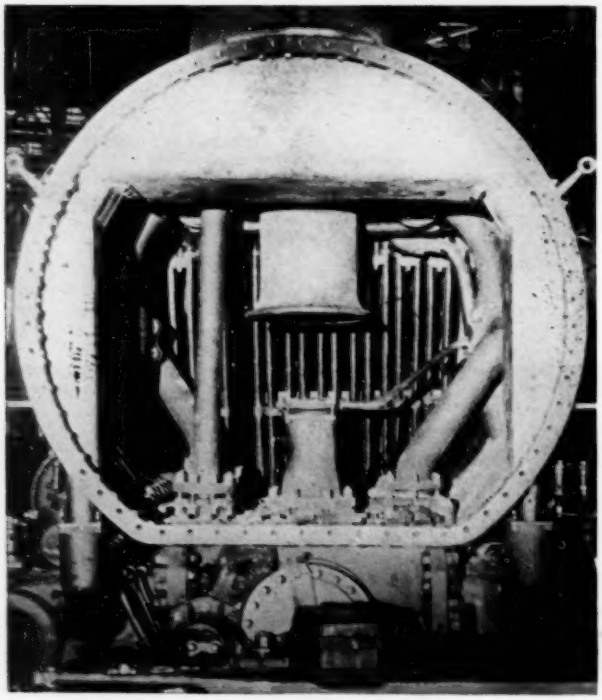

FIG. 13 SMOKEBOX

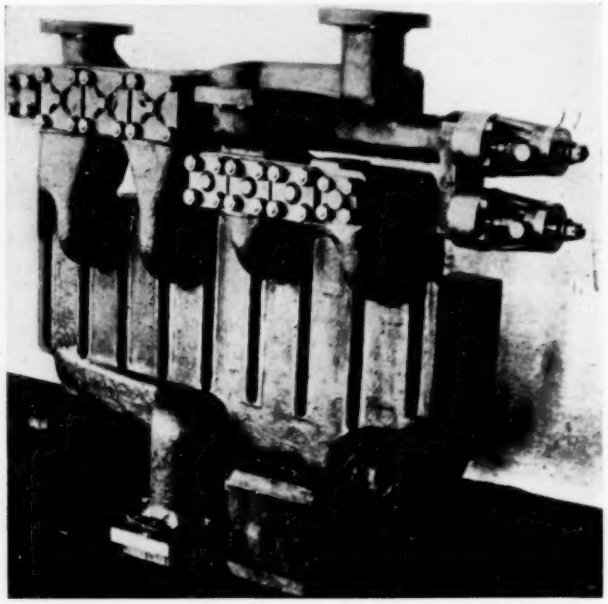

FIG. 14 COMBINED SUPERHEATER AND MULTIPLE-VALVE THROTTLE HEADER, TOP VIEW

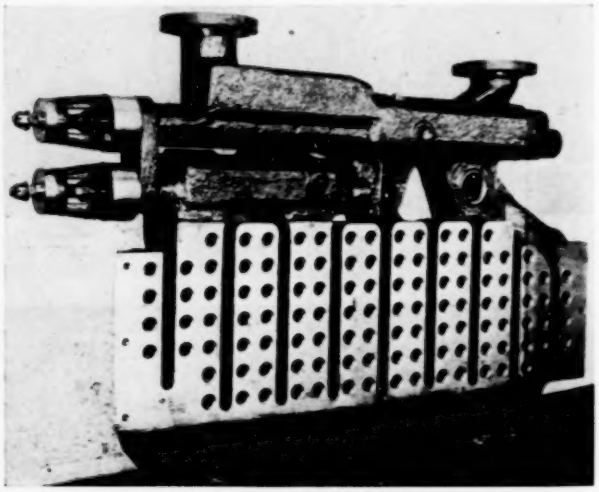

FIG. 15 COMBINED SUPERHEATER AND MULTIPLE-VALVE THROTTLE HEADER, BOTTOM VIEW

The superheater header is shown in Fig. 14. This is a top view with the low-pressure steam connection at the extreme bottom conveying steam into the low-pressure section, which is at the left as one views the picture. The high-pressure steam is led in through the opening at the lower right-hand part of the casting. The low-pressure throttle is at the upper left-hand corner and consists of a three-valve multiple throttle of conventional design. The high-pressure throttle is also a three-valve multiple design generally of the conventional form, but utilizing smaller valves on account of the greater density of the high-pressure steam.

Fig. 15 is a view of the lower side of this combined double superheater header and multiple-valve throttle casting.

Canadian Pacific Multi-Pressure Locomotive

Its Machinery, Locomotive Chassis, and Tender

By J. B. ENNIS,[1] NEW YORK, N. Y.

The remarkable thermal efficiency of the multi-pressure locomotive of the German State Railways has commanded the attention of the entire railroad world. The introduction of this type of locomotive to American practice involves far more than the mere reproduction of the German machine, for the difference between the problems of availability, maintenance, and proportionate output on the two continents is profound. The author gives the reasons for the adoption of the type of engine selected to introduce the multi-pressure principle to American service, and describes the leading features of the construction of the chassis and cylinders.

THE steam-generating system of the Canadian Pacific multi-pressure locomotive has been described. This paper will tell the manner in which the design of the machinery and of the locomotive as a whole has been worked out to utilize this system. It was the intention from the start to deviate as little as possible from conventional lines of locomotive design, and to use as many parts of the Canadian Pacific 2-10 4, two-cylinder locomotive, class T-1, as practicable. This locomotive, built by the Montreal Locomotive Works in 1929, is the most powerful freight locomotive of the Canadian Pacific Railway; its total weight is 370,000 lb, its weight on drivers is 312,800 lb, and its tractive effort is 77,200 lb without booster. The multi-pressure locomotive was supposed to be not less, and if possible more, powerful than locomotive T-1, without increasing the number of wheels. Therefore the requirement to adhere in general to the design of the T-1 locomotive was natural.

In two major respects, however, novel features had to be introduced: in the locomotive engine and in the structural connection of the boiler and locomotive chassis.

Regarding the locomotive engine, it was estimated that 63,000 lb of steam would be furnished, of which 56.0 to 47.6 per cent would be high-pressure steam of 850 lb per sq in. and the remainder of 250 lb pressure. Both high- and low-pressure steam were supposed to be superheated, and it was expected that the total temperature of the first would be between 600 and 800 F, while that of the latter would fluctuate between 550 and 725 F, depending upon the rate of firing.

In order to utilize the heat contained in the steam in the most efficient manner, it is necessary to use double expansion (compound) for the high-pressure steam; and the most practical combination of the two-stage expansion with one-stage expansion of the low-pressure steam, generated separately, is the one applied in the Schmidt-Henschel locomotive of the German Reichsbahn—namely, the mixing of the exhaust from the first stage of the high-pressure expansion with the low-pressure live and superheated steam, using this mixture for the second stage of the expansion. By doing so, the necessity of interstage heating for the high pressure is eliminated, resulting in simplification of the locomotive.

It is obvious that more than two cylinders are necessary for this scheme. The cross-compound system is not possible in view of the excessive size of the single low-pressure cylinder for a locomotive with 320,000 lb weight on drivers. Either three or four cylinders are necessary, and then several cylinder arrangements could be considered, such as:

(1) A tandem compound arrangement, having the advantage of the outside location of all four cylinders without the disadvantage of a crank axle, the drawback, however, being heavy reciprocating parts, resulting in poor balancing, the inaccessibility of piston-rod packings between cylinders, and the undesirable lengthening of the front part of the locomotive, with ensuing increase in weight.

(2) A four-cylinder compound arrangement, such as used in the high-pressure locomotive of the French Paris-Lyons-Mediterranean Railway. This would require a two-crank axle, which, in view of the power of the locomotive, it would be impossible to construct in the limited space between the frames.

(3) A three-cylinder arrangement with a single-crank axle, as used in the Schmidt-Henschel locomotive, with a middle high-pressure and two outside low-pressure cylinders.

(4) A three-cylinder arrangement, differing from the foregoing by making one inside low-pressure cylinder between frames and two outside high-pressure cylinders. This also would require too large a cylinder, which it would be impossible to place inside the frames.

Thus of all the four arrangements, the most practical seemed to be the third; and although this necessitated the use of a crank axle, it was thought that as the power on the middle pin is less than in the three-cylinder 4-12-2 Union Pacific locomotive, a satisfactory three-cylinder arrangement could be worked out.

Having decided on this, the next question was the distribution of power. The most natural thing to do would be to divide the power equally between cylinders. It was not so much the division of tractive effort at starting as the proper division of power under running conditions, for the over-all efficiency would be more affected by the latter than by the former. On the other hand, it was rather desired to get slightly less tractive power from the middle cylinder so as to protect the middle main pin.

The three-cylinder arrangement with two working pressures offers a very convenient means for equalizing power without exceeding stresses in the middle pin, by introducing a longer cut-off in the middle cylinder. By doing so, the size of the cylinder can be made smaller, and thus the piston thrust in the middle cylinder can be kept within limits. However, this would mean either introducing a complication in the valve gear or using an independent valve motion for the middle cylinder, whereas from the start it was agreed to use the Gresley valve motion, as in the majority of three-cylinder locomotives built in this country. In view of this, it was decided to make the cutoffs in all three cylinders equal by using the Gresley gear, and to compromise between division of power at starting and under running conditions in such a way as to keep the diameter of the middle cylinder as small as possible.

[1] Vice-President, American Locomotive Company, in charge of engineering. Mem. A.S.M.E.

Contributed by the Railroad Division and presented at the Semi-Annual Meeting, Bigwin Inn, Lake of Bays, Ontario, Canada, June 27 to July 1, 1932, of The American Society of Mechanical Engineers.

Note: Statements and opinions advanced in papers are to be understood as individual expressions of their authors, and not those of the Society.

A study of indicator cards for different cutoffs and various cylinder sizes was made, in connection with service conditions and boiler capacities, and it was found that the ratio of volume of the two low-pressure cylinders to that of the high-pressure cylinder should be 5.4. This determined the following dimensions for cylinders: $15^1/_2$ in. in diameter and 28 in. stroke for the middle high-pressure cylinder, and 24 in. in diameter and 30 in. stroke for the two outside low-pressure cylinders.

On the basis of 850-lb and 250-lb pressure in the two boilers, 63 in. diameter of driving wheels, 85 per cent coefficient in the tractive-effort formula, and making allowance for the areas of the high-pressure piston rod and piston-rod extension, the tractive effort was estimated to be 83,300 lb, corresponding to 3.84 adhesion factor. A study of tangential efforts in this three-cylinder locomotive proved that this factor should not cause slipping of the locomotive.

In view of some uncertainty in distribution of power under actual conditions which this experimental locomotive will have to

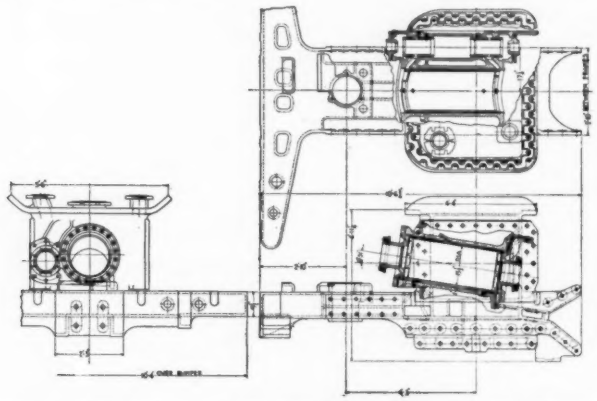

FIG. 1 HIGH-PRESSURE CYLINDER WITH BUMPER AND BUMPER BRACKET

meet, provision was made for the possibility of a slight change in the sizes of cylinders by making bushings in the cylinders of sufficient thickness. A 1-in. bushing was made for the high-pressure cylinder, which would permit of enlarging the cylinder diameter from $15^1/_2$ in. to 16 in., if this should be required in the future. The low-pressure cylinders were provided with $1^1/_4$-in. bushings, permitting an increase in diameter to $24^3/_4$ in.

CYLINDERS

The middle cylinder is shown in Fig. 1. It is of the same type as used on ordinary three-cylinder locomotives, with cylinder barrel, steam chest, and boiler saddle cast in one piece. In this case the front bumper and bumper bracket are cast integral with the cylinder.

Special precaution has been taken to make the bolting of the cylinder as rigid as possible. A great number of bolts and two $1^1/_4$-in. by 3-in. keys are provided for the connection of the cylinder casting to the frames, outside cylinders, and smoke box. In addition, keys 3 in. wide are used between the middle and outside cylinders for securing the cylinders in longitudinal direction.

The cylinder is made of cast steel to a special specification, with silicon content of 0.40 per cent and manganese of 0.82 per cent. The cylinder barrel is inclined at an angle of 8 deg 31 min to the horizontal in order to permit the middle main rod to clear the front driving axle, the second being the crank axle. The cylinder bushing is made of high-grade cast iron of a composition insuring good wearing qualities. The steam chest is horizontal, as is usually the case in three-cylinder locomotives with Gresley valve motion, and has two high-grade cast-iron bushings for the high-pressure 6-in. piston valve. Steam is admitted between the piston-valve heads (inside steam admission) through a $4^1/_2$-in. steam pipe. The exhaust is directed through two 5-in. openings, one on each side of the cylinder, into the two mixing chambers, where it meets the low-pressure superheated steam and whence it is further directed into the two low-pressure cylinders.

The exhausts from the outside cylinders have to pass through the middle cylinder into the exhaust pipe and nozzle. A rectangular $5^1/_2$-in. by 10-in. opening is provided on each side of the middle cylinder in the fitting surface. In order to insure tightness between the middle and outside cylinders, special copper-wire interwoven asbestos gaskets are used. Provision is made for passing the booster exhaust through a specially made passage in the saddle, and further into the exhaust pipe, in case of the future application of a booster. The openings for the booster-pipe connections are for the present blocked off by welded-in plates.

The outside cylinders are of regular design, with high-grade cast-iron bushings $1^1/_4$ in. thick, as already stated. The cylinders are made of manganese-silicon cast steel of a composition similar to that of the high-pressure cylinder.

CYLINDER HEADS, PISTONS, ETC.

High- and low-pressure cylinder heads and steam-chest covers are made of cast steel, except the front low-pressure steam-chest covers, which are of cast iron. The high-pressure cylinder heads and steam-chest covers are secured to the cylinder by chrome-nickel studs.

The high-pressure piston, in view of its comparatively small size, is of the solid-head type, as shown in Fig. 2. It is made of cast iron to special specification. The width of the piston is 8 in., and there are six snap packing rings of cast iron, $^1/_2$ in. wide and $^5/_8$ in. thick. Experience with German high-pressure loco-

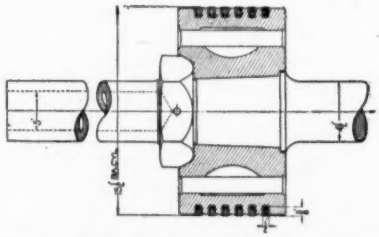

FIG. 2 HIGH-PRESSURE PISTON AND ROD

motives had shown that, for proper packing of high-pressure steam, a large number of narrow rings is necessary.

It is common practice in America to omit the extension piston rod, as this is not needed for proper guiding of the piston. While this omission would be possible also in the high-pressure cylinder, it was thought that, for better equalization of pressures on both sides of the piston, it would be more advisable to have the piston rod extended in front of the piston, with the same outside dimension of $4^1/_2$ in. as in the back portion. The front extension has a hollow boring of 3 in. diameter in order to save weight. The piston rod is forged of medium-carbon steel. It is comparatively short, having a length of $66^1/_2$ in., counting from the middle of the piston fit to the center of the crosshead wristpin.

The crosshead is of the common single-guide, three-bar type (Dean design), made of cast steel, with a long cast-steel shoe.

Pistons for the outside cylinders are of the regular Z-type, made of cast steel, have no extension rods, and are connected to alligator-type crossheads. Each piston has a cast-iron 6-in.-wide bull ring, with two narrow $^3/_8$-in. by $^3/_4$-in. cast-iron snap packing rings.

Rod Packings

The original high-pressure piston-rod packings were of special German design, as used in the Schmidt-Henschel locomotive of the Reichsbahn. In principle it is the standard German packing used on regular locomotives, differing from that only in the number of rings, six being used instead of three for each stuffing box. It was found necessary to replace this packing by that of the "King" type.

Rods

Out of a number of middle main rods tried on three-cylinder locomotives in America, a light and simple rod was chosen, as shown in Fig. 3. The body of the rod is integral with the lower portion of the strap, the upper being bolted to the rod by one $2^{3}/_{4}$-in. bolt in the front and three $1^{3}/_{4}$-in. bolts in the back. A floating bushing, made of bronze in three pieces, fits the 12-in. middle pin of the crank axle with small radial and side clearances between the crank-axle cheeks. The crosshead end of the middle main road has adjustable bronze bearings.

The outside main rods, connected to the third or main axle and all side rods are of the regular C.P.R. design, the low-pressure main rod having adjustable bronze bearings at the front end and floating bushings at the back end, revolving in a stationary solid-steel bushing. Side rods have floating bronze bushings in stationary cast-iron bushings on the main and intermediate pins and solid bronze bushings on the front and back pins. All main and side rods are of I-section and are made of nickel steel.

Valves and Valve Motion

The high-pressure steam valve is of the plug type, having two

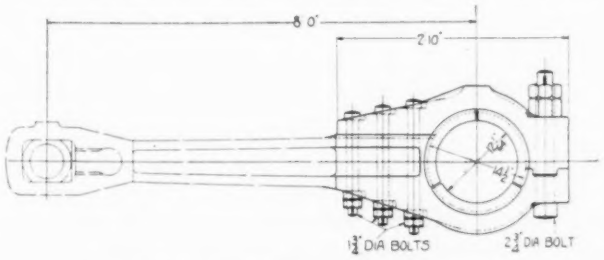

Fig. 3 High-Pressure Main Rod

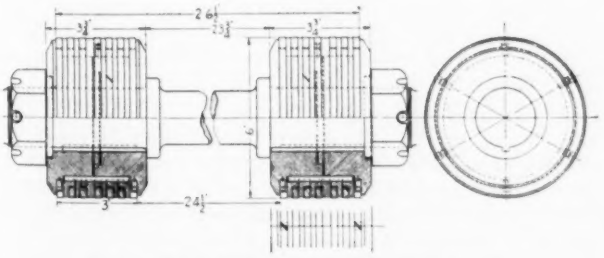

Fig. 4 High-Pressure Distribution Valve

heads, each made of two halves, with six cast-iron bull rings and seven narrow cast-iron snap packing rings, all assembled on a common forged-steel valve stem with an extension (Fig. 4). The low-pressure valve is of the common spool type, assembled on a valve stem with extension.

The valve-stem packings, both for the high- and low-pressure valves, are of the King type, which is standard on the C.P.R. The high-pressure valve-stem packing has no contact with high-pressure steam in view of the valve being of the inside-admission type.

The valve gear for the outside cylinders is of the Walschaert type and gives $7^{1}/_{2}$-in. valve travel. The valve motion for the inside cylinder is derived from the two outside gears by the combined Gresley valve motion frequently used on three-cylinder locomotives in America. The Gresley levers have ball bearings in the main fulcrum and in the connection between the two levers. The gear is shown in Fig. 5. As already stated, the travel and cutoffs are the same in all cylinders.

The reverse is of the screw type, which is standard on the C.P.R. No power reverse is used.

Firebox Framing

It already has been mentioned that the second novel feature introduced in the design is the connection between the boiler and

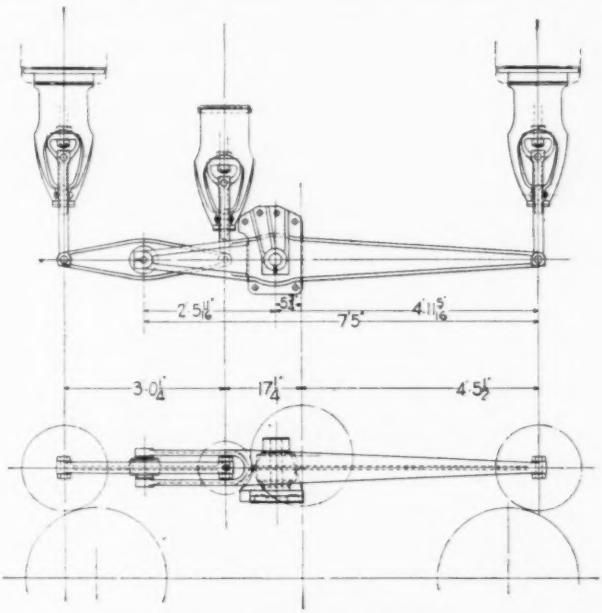

Fig. 5 Gresley Valve Gear

the locomotive frame. In the ordinary locomotive the boiler forms the backbone of the locomotive structure. The boiler barrel is rigidly bolted to the cylinders at the front of the locomotive, while the firebox, which is a part of the boiler, is connected with the rear of the frame. Flexibility is allowed in the conventional structure in the longitudinal direction, permitting free expansion of the boiler, while sidewise the boiler is rigidly held by the frames.

In the multi-pressure locomotive the low-pressure boiler is in principle of the same design as the conventional boiler. The high-pressure boiler in itself, however, does not offer sufficient rigidity to the locomotive structure. It was therefore necessary to enclose the firebox and the combustion chamber in a special framing which would form a rigid connection between the boiler and the locomotive frame.

Moreover, a water-tube firebox requires an airtight casing which will not permit outside air to enter the firebox, except the air that is admitted for proper combustion through the ashpan. These two aims have been attained in the following ways:

Support *A* (Fig. 6), with semi-circular brackets for the high-pressure boiler and separator drums, is riveted to the rear portion of the low-pressure boiler. The drums are kept in position by rigidly bolted caps *B* and *C*. The rear parts of the drums, with support *D* bolted to them, can freely slide on the upper part of the structure. Shoes *N* and rollers *O* are provided for this purpose.

On the under side of the low-pressure boiler, opposite support

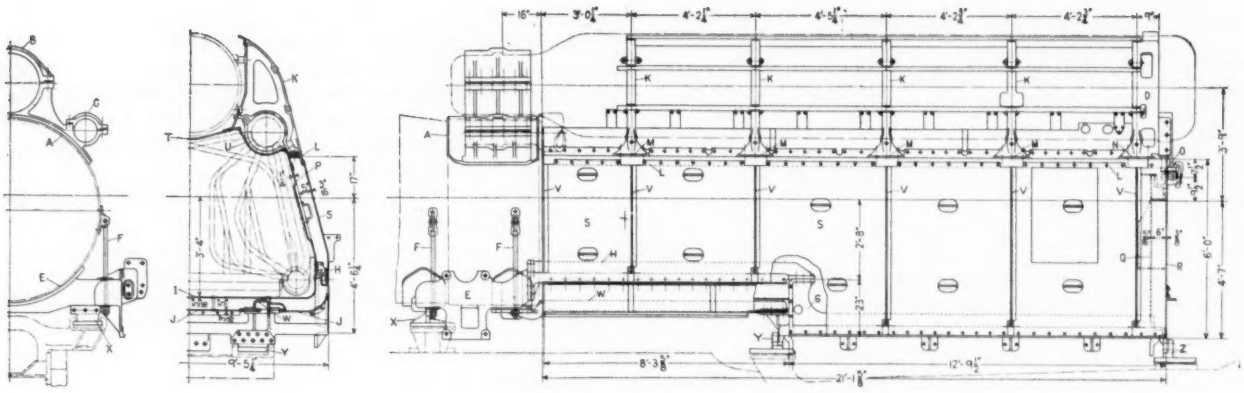

FIG. 6 FIREBOX FRAMING

A, a saddle *E* is bolted, which is in addition suspended by tierods *F*. Supports for the high-pressure pump and airbrake pump are built integral with the boiler saddle. The firebox ring is surrounded by a rectangular casting *G* called the foundation ring,

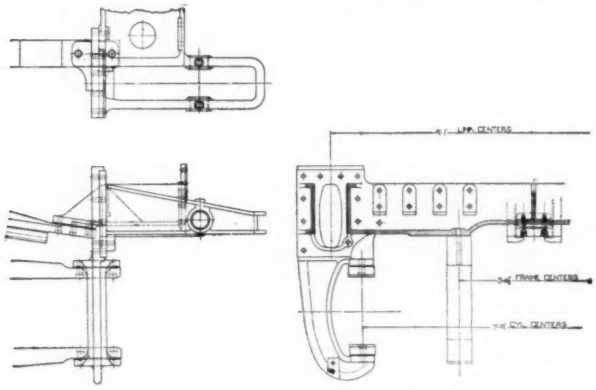

FIG. 7 GUIDE-YOKE AND LINK-SUPPORT CROSSTIE

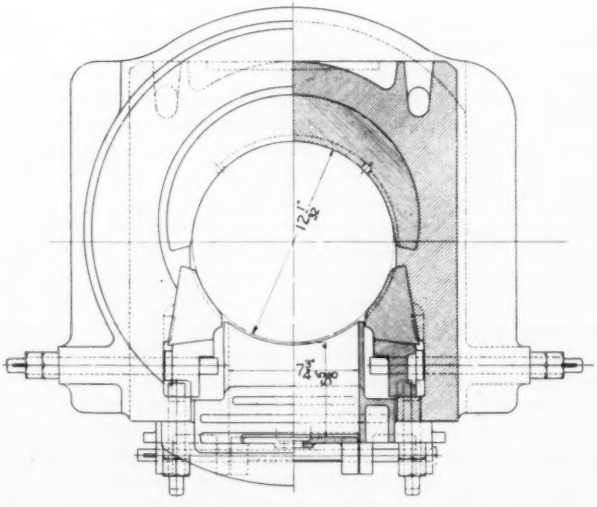

FIG. 8 DRIVING BOX, CRANK AXLE

which is connected with saddle *E* by two side-support members *H*, one on each side of the firebox. The rear end of the foundation ring has a built-up vertical wall for slides *N* and rollers *O* of support *D*.

Thus a skeleton of a substantially rectangular box has been built around the firebox and combustion chamber, rigidly bolted to the rear end of the low-pressure boiler. The whole box, the remaining parts of which are described farther on, is supported by the frame and can freely slide on it, permitting the boiler as a whole to expand longitudinally. The following parts complete the box:

Eight castings *K*, four on each side, are bolted to the high-pressure drum and embrace the separator drums. They can freely slide on two support members *L*, one on each side of the firebox, with slide plates *M* in between. Side supports *L* are further connected by vertical columns *V* to side members *H* and foundation ring *G*. Between these supports, on each side of the locomotive, a vertical wall is built of two rows of removable steel plates *P* and *S*, the inner plates *P* made of heat-resisting steel. The vertical wall for support *D*, already referred to, is also made of ordinary steel on the outside and heat-resisting steel plates on the inside.

In addition, two tiebars *W* are bolted to boiler saddle *E* and foundation ring *G*. Three expansion slides permit this structure to expand along the frame; one slide *X* is bolted to the boiler saddle *E;* another slide *Y* is bolted to the front lug, while the third slide *Z* is attached to the rear lug of foundation ring *G*.

The foregoing structure, needed for carrying the weight of the high-pressure boiler, for permitting its expansion, and for imparting sufficient rigidity to the boiler as a whole, is further completed by several plates in order to make it airtight. Plates *T* and *U* of heat-resisting steel are placed underneath the high-pressure and separator drums and tied by angles between themselves and plates *P*. Heat-resisting plates *I* and ordinary steel plates *J* bolted to members *H* and tiebars *W* finish the encasing of the firebox.

High-pressure and separator drums are insulated by high-temperature lagging, and approximately half of the space between heat-resisting plates *P* and *Q* and steel plates *S* and *R*, next to the heat-resisting plates, is filled with the same lagging. The low-pressure boiler is lagged with magnesia blocks and jacketed in the ordinary manner.

FRAME

The general design of the locomotive chassis, including frames, wheels, brake rigging, etc., is similar to that of the Canadian Pacific 2-10-4 locomotive, class T-1, except for the parts that were affected by the difference in the type of boiler and machinery. As a matter of fact, a great number of parts and the tender as a whole are practically identical.

The locomotive frame, however, for this experimental engine was not a locomotive bed, as in the T-1 class, but of the built-up type, consisting of two frames (right and left) $6^1/_2$ in. thick, made of nickel cast steel. The distance between frame centers is $40^1/_2$ in. crosswise. The frames are rigidly bolted to the sides of the

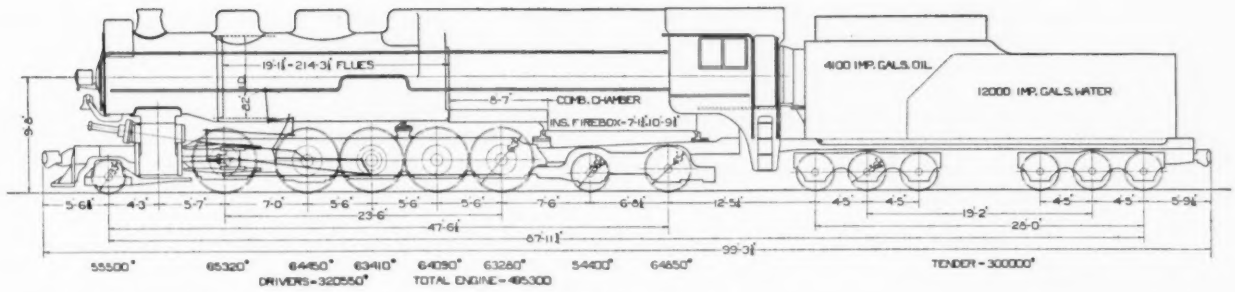

FIG. 10 WEIGHT DIAGRAM

middle-cylinder casting. The outside cylinders are secured to the frames by bolts, some of which pass through both cylinders and frame.

As has already been stated, the middle cylinder is integral with the front bumper and bracket. The frames behind the cylinders are connected by a number of crossties, as in all built-up locomotive frames. They are all made of cast steel.

The guide-yoke crosstie is of a special design, in view of the attachment of the middle crosshead guide. It is also made integral with the link support and is therefore called "link support crosstie." The guide yokes for the outside guides are bolted to this crosstie, as shown in Fig. 7.

The pedestal caps for the second driving axle, which is the crank axle, are of cast steel, while the other pedestal caps are made of forged steel.

All frame fillings for the spring rigging are made of cast steel. Shoes and wedges are made of cast iron.

TRUCKS AND BOXES

Driving boxes are made of cast steel and are equipped with cast-bronze wearing faces and bronze bearings. The crank-axle driving boxes (front intermediate) are of the Alco design, with supplementary adjustable brasses (Fig. 8). The boxes on the main (third driving axle) and on the back intermediate axle are of the Grisco type, with permanent additional brasses. The front and back driving boxes are of the regular design, with bronze bearings.

The locomotive is designed to negotiate 18-deg curves. For this purpose the front axle has the Alco lateral-motion device, with a play of 1 in. on each side. The front engine truck is of the Commonwealth two-wheel, cast-steel, outside-bearing type, with $7^1/_4$-in. lateral movement, while the trailing truck is of the four-wheel, cast-steel, Commonwealth type, with the $10^1/_4$-in. lateral displacement necessary for 18-deg curves. All truck boxes are of cast steel and are equipped with bearing brasses.

SPRINGS

The spring rigging is of the three-point suspension type, the front engine truck forming one group with the first three driving axles, while the right and left rear drivers, with the wheels of the trailing truck, form the second and third groups. All suspension springs are of the semi-elliptic design, made of steel with 0.65 to 0.75 per cent carbon content, with steel equalizers and case-hardened pins in case-hardened bushings. All spring shoes are made of cast steel, while spring saddles are of nickel cast steel.

WHEELS AND AXLES

All locomotive wheels have separate wheel centers made of cast steel and shrunk-on steel tires with retaining rings. All straight axles are made of carbon steel.

The middle pin and axle ends are made of nickel steel. The two disks, sometimes called cheeks, are forged of carbon steel. The middle pin has a diameter of 12 in. and is 7 in. long. The journals of the crank and other axles are as follows:

Crank axle, main axle, back intermediate, in.	12×14
Front and back, in.	$11^1/_2 \times 14$
Engine truck, in.	7×14
Trailing truck, front, in.	7×14
Trailing truck, back, in.	8×14

Following the example of the German Reichsbahn locomotive, the cranks were spaced at approximately 120 deg, this for the sake of torque uniformity. As was expected, this crank setting resulted in an uneven exhaust sound. The engine, being of the

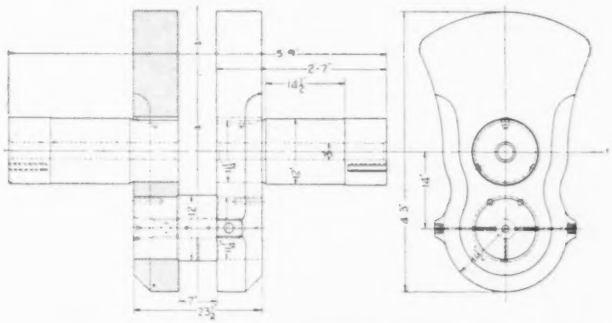

FIG. 9 CRANK AXLE

compound type and having only four exhausts per revolution, sounds "lame" at low speeds, but at speeds above 15 mph the un-uniformity of the exhaust vanishes.

The crank setting is of course corrected for the inclination of the middle cylinder and for the difference in strokes of the high- and low-pressure cylinders. For the middle crank it is 129 deg 12 min with the left-hand crank and 110 deg 48 min with the right-hand crank, the right being the leading one. The angle between the two outside cranks is exactly 120 deg. The crank axle is shown in Fig. 9.

All straight axles are hollow-bored. The crank-axle ends, middle pin, and all crankpins are also hollow-bored. All crankpins are made of carbon steel except main crankpins, which are of nickel steel. All journals and crankpins are ground.

The counterbalances for the reciprocating weights are distributed evenly between all driving wheels except the main. The total percentage of counterbalancing of the locomotive, figured by the static method, is 34.75 per cent. The counterbalance pockets on all wheels, following the C.P.R. practice, are filled with lead, on the main wheels to the limit of their volume capacity.

BRAKES

All driving and trailer-truck wheels of the locomotive have brakes operated by a Westinghouse automatic-brake equipment, with $8^1/_2$-in. cross-compound air compressor. The driving-wheel

brakes are divided in two sections, the front section operating the three front axles from two 14-in. by 10-in. cylinders, while the back portion operates the two rear pair of drivers from two 12-in. by 10-in. cylinders.

The trailer truck has a separate brake applied to all wheels, using two 8-in. by 12-in. cylinders.

Three main reservoirs are used on the locomotive, with a total capacity of approximately 80,000 cu in.

Cab and Auxiliaries

All steam auxiliaries are operated by low pressure, except the two high-pressure pumps, which are operated by high-pressure steam. There are two cab turrets—one for superheated and one for saturated steam. The first has connections to the high- and the low-pressure feed pump, the air pump, the blower, the oil-burner operating valves, the mechanical lubricator-heating coil, the headlight dynamo, and the whistle. The second turret has valves to the steam-heating line and to the injector.

The cab has sufficient inside room and does not differ much from an ordinary cab. The arrangement of apparatus in the cab is the same as usual, except only for those gages, pyrometers, handles, etc. which are necessary for the high-pressure boiler. The low-pressure water column and gage have connections which extend from the low-pressure boiler into the cab; the column and water gage in the cab are of the ordinary construction.

The top and bottom cocks of each of the two high-pressure water gages in the cab can be shut off simultaneously. The cocks of the closed-circuit water gage placed outside the cab can be likewise closed by a handle in the cab.

Drawbar

The drawbar between engine and tender is of the Unit safety type, both bars of laminated C.P.R. construction and made of nickel boiler steel. There is a radial buffer between engine and tender.

Tender

As previously stated, the tender is of the standard C.P.R. type, and in all respects is identical with that used for the C.P.R. 2-10-4, two-cylinder, class T-1 engine. The frame is of the cast-steel Commonwealth water-bottom integral type, with six-wheel Commonwealth trucks. The truck boxes are of malleable iron, while the wheels are of the solid rolled-steel type.

The tank is of the rectangular type, having a water capacity of 11,500 imp. gal and a maximum oil capacity of 4100 imp. gal. The tender tank has a recess in which the low-pressure feedwater-heater pump is located.

The tender brakes are of the conventional clasp type, operated from two brake cylinders 14 in. by 12 in., with Westinghouse distributing valve, feed valve, and other equipment. The brake is designed for 80 per cent of the sum of the light weight of the tender and 25 per cent of the load.

Lubrication

The following locomotive parts are lubricated by oil from a 14-feed mechanical lubricator: middle and outside crosshead shoes through the corresponding guides, the middle guide delivering oil also to the wristpin and front end of the middle main rod, high-pressure and low-pressure steam chests and cylinders, right-hand high-pressure and low-pressure feed pumps and air pump, and high-pressure piston-rod packings. The left-hand high-pressure feed pump is served by a hydrostatic lubricator.

All driving boxes, including those of the crank axle, have regular cellars with perforated plates for grease lubrication. Engine and tender truck boxes are lubricated by oil and waste. Outside main rods, middle main rod, and side rods have hard-grease lubrication from Alemite-type cups. The remainder of locomotive and tender parts, such as valve motion, driving and truck-box pedestals and hub faces, all engine and tender-truck center plates, engine center pin, lateral-motion device, radial buffer between locomotive and tender, etc. have soft-grease lubrication.

It is evident from the foregoing description that, aside from the high-pressure feature, the locomotive does not differ from the conventional engines. As stated at the beginning, the aim was to introduce no more novelties than absolutely necessary, to retain the general appearance of an ordinary locomotive, and to make possible the use of the methods of operation of the steam locomotive to which generations of railroad men have become accustomed.

Fig. 10 shows the weight diagram and the general outline of locomotive and tender. In Table 1 are given the principal dimensions of the locomotive, which bears road number 8000, and engines of class T-1.

Canadian Pacific Railway Multi-Pressure Locomotive 8000

Its Construction, Operation, and Maintenance

By H. B. BOWEN,[1] MONTREAL, QUE., CANADA

Higher steam pressures and temperatures have marked the progress toward greater power at reduced cost. Locomotive development has not kept pace with stationary practice in the use of higher pressures. After studying all available information on new types of locomotive and after investigating improved types of locomotive abroad, the Canadian Pacific Railway Company decided to construct a heavy freight locomotive for service on its severe mountain divisions. Its 2-10-4 multi-pressure locomotive 8000, which is described in the paper, was the result.

INCREASING steam pressures and temperatures have to a great extent been the measure of the progress made in the development of greater power at reduced cost. While locomotive development has made marked advances, it has nevertheless lagged behind stationary practice in utilizing the manifest advantages of higher pressures. Conventional locomotive design, with a large-diameter fire-tube boiler construction, definitely restricts the maximum pressure that can be used, and the Canadian Pacific Railway Company has gone nearly as far as practical in the increasing of steam pressures with the conventional form of locomotive-boiler construction.

All obtainable information concerning new types of locomotives had been studied, and such designs as had been transformed into reality had been investigated thoroughly. In 1929, the author, during a trip to Europe, investigated carefully all of the available examples of new and improved types of locomotives. Conferences with the Superheater Company and its associate organizations, both in the United States and abroad, resulted in further investigations being made of locomotives in England and on the Continent which were constructed and which utilized the multi-pressure system of steam generation. Conferences with officials of the German State Railways, the London, Midland & Scottish in England, and the Paris, Lyons & Mediterranean Lines in France, had served to focus attention upon this type of steam-generating apparatus. Subsequently, further conferences with the American Locomotive Company and the Superheater Company resulted in the decision by the railroad to construct a heavy freight locomotive suitable for service on its severe mountain divisions; and its 2-10-4 type locomotive 8000, which has been described, is the result. This locomotive is termed the T-4-A class and is, so far as its running gear is concerned, a close duplicate of the T-1 class locomotives which are now the standard locomotives for the service referred to. While the T-4-A is slightly heavier as to total weights, it is nevertheless very closely the same as the T-1's in so far as weight on drivers is concerned.

The three-cylinder arrangement has permitted satisfactory operation with a somewhat lower factor of adhesion, and consequently has a somewhat larger tractive effort. High pressures and temperatures are not only attractive from the standpoint of improved thermodynamic performance, but in themselves bring about desirable changes in construction and performance. For example, higher pressures necessitate multi-cylinder construction in order to fully utilize the steam expansively. This immediately gives a more uniform torque, and permits lowering the adhesion factor between the driving wheels and the rails, which in turn provides for the better utilization of weight. Higher pressures give a better steam flow and reduce proportionate pressure drops. It is customary to allow a 15 per cent drop in boiler pressure in figuring the maximum tractive effort. This loss, however, is reduced as the pressure rises, giving greater proportionate tractive efforts. Higher pressure means smaller cylinders, removing some of the restrictions due to large cylinders as determined by customary boiler pressures. The higher density also provides for the use of smaller pipes for feeding both cylinders and auxiliaries, which is a most grateful relief to those who have struggled in trying to fit in the maze of complicated piping required by even the comparatively simpler conventional type of locomotive.

Multi-pressure locomotive 8000 is the joint production of the Superheater Company, the American Locomotive Company, and the Canadian Pacific Railway Company, which are respectively responsible for the high-pressure steam-generating system, the three-cylinder arrangement and valve motion, and the general locomotive proportions and design and construction. It was built at the Canadian Pacific Railway's Angus Shops, Montreal, and was turned out for operation in July, 1931. During the ensuing few months the engine was used in freight service between Montreal and Smith Falls, in order to determine its operating characteristics and particularly to develop the arrangement of oil burners, which it was anticipated would have to be somewhat different from the standard burner arrangement used on the Western Lines.

Construction was commenced in November, 1930. The machinery, together with the low-pressure boiler and firebox framework, was erected in a complete unit, while the closed system and high-pressure boiler were assembled on a jig especially constructed for this purpose in the boiler shop. Work on these separate units progressed simultaneously, and on April 10, 1931,

---

[1] Chief of Motive Power and Rolling Stock, Canadian Pacific Railway Company. Henry Blane Bowen was born in Derbyshire, England, May 17, 1884. He was educated in the Manchester School of Technology and École de Commerce, Lausanne, Switzerland. He served a special apprenticeship at Crossley Bros., Ltd., Manchester, 1901–04; entered railway service, May 15, 1905, as an apprentice at Angus Shops of Canadian Pacific Railway Company, Montreal; transferred to Winnipeg as draftsman, December, 1906; foreman of wheel and tender shop, Winnipeg, August, 1908; shop engineer, Winnipeg, 1909; chief draftsman, mechanical department, Winnipeg, 1911; promoted to works manager, Weston Shops, Winnipeg, January, 1920; assistant superintendent of motive power, Lines West, July 1, 1928; and in his present position September 1, 1928.

Contributed by the Railroad Division and presented at the Semi-Annual Meeting, Bigwin Inn, Lake of Bays, Ontario, Canada, June 27 to July 1, 1932, of The American Society of Mechanical Engineers.

Note: Statements and opinions advanced in papers are to be understood as individual expressions of their authors, and not those of the Society.

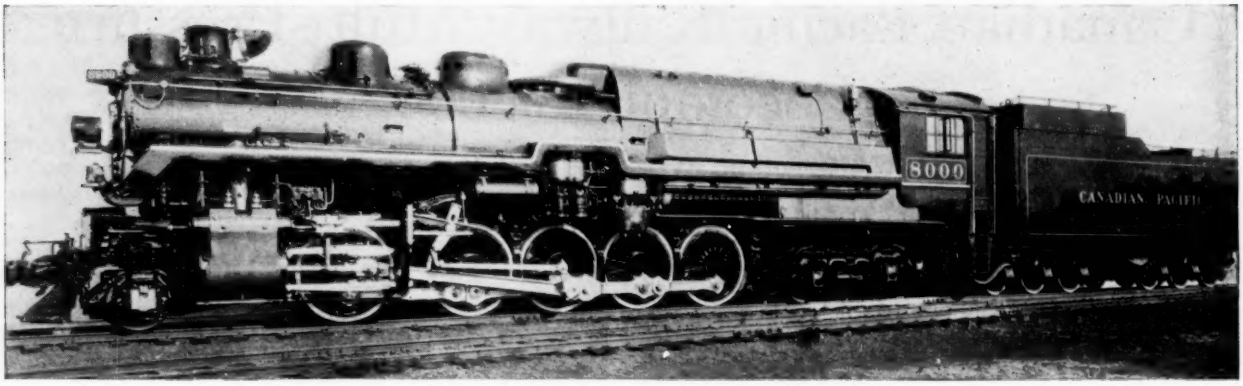

FIG. 1 MULTI-PRESSURE LOCOMOTIVE BUILT AT ANGUS SHOPS, LEFT-HAND VIEW

(Cylinders: High-pressure, one, 15½ in. by 28 in.; low-pressure, two, 24 in. by 30 in. Diameter of drivers, 63 in. Tractive effort, 90,000 lb. Boiler pressures: Closed circuit, 1350 lb; high-pressure, 850 lb; low-pressure, 250 lb. Weight on drivers, 320,550 lb. Weight of engine, 495,300 lb. Weight of engine and tender, 795,300 lb. Total length of engine and tender, 99 ft 3⅜ in. Water capacity, 12,000 imperial gal. Oil capacity, 4100 imperial gal.)

the closed system and high-pressure unit being completed, they were subjected to a hydrostatic test, each being found tight under the required test pressure. On April 13 the closed circuit and high-pressure unit were released from the jig and transferred to the machinery and low-pressure boiler unit. With the addition of cab, fixtures, fittings, and piping, the engine was ready for steam test. This test, involving the closed circuit and high-pressure and low-pressure boilers, was carried out in two stages—that is, it was thought desirable to work gradually to the maximum. Accordingly, the first test was discontinued when a pressure of 500 lb per sq in. was reached in the high-pressure boiler. Full pressure of 850 lb per sq in. was reached on final test.

Quite apart from the improved performance, the designing engineer probably receives more satisfaction from the surmounting of the many constructional difficulties always encountered in a new development. On account of its large size, many novel and ingenious features of construction had to be used for locomotive 8000, a few of which are of general interest.

The firebox ring serves as a header for the lower end of the high-pressure generating tubes. A complete casting with the likelihood of non-uniform walls and porosity was not favored, and finally this problem was solved by using four separate forgings drilled as in gun practice, with ends formed so that the circular extensions of one part slipped into lateral circular openings in the ends of the other two pieces. Corresponding wall holes gave the proper openings for circulation. The internal members were expanded into the outer members and then solidly welded in position, the openings in the ends of the headers being closed by solid plugs threaded and welded. This construction has proved most satisfactory and is a successful solution of a problem that initially gave considerable concern.

The closed steam-generating system with its evaporating tubes required most careful study to find a way of rolling in the tubes in the header in an absolutely uniform manner. These tubes are expanded into the header against small grooves in the header-tube opening. These grooves must be well filled and the rolling tight enough to withstand any possibility of leakage. A large number of tubes were expanded into test blocks, tested, and sawed apart. It was finally found that the tube was truly and thoroughly rolled in when it was expanded to the extent that the tube elongated 0.04 in. in a set distance above the tube opening. A small spring-plunger micrometer gage was then fixed by a quick-acting clamp to each tube, and the plunger was allowed to bear against the header. This method gave automatically the set distance, and the rolling was continued until the spring plunger extended sufficiently to indicate on the dial of the gage 0.04-in. growth in tube length. This method has proved thoroughly practical and has given most reliable results, ensuring uniformity of tube rolling. It might be interesting to mention here that when initial hydrostatic test was given the closed circuit, the pressure was raised at short intervals to a maximum of 2125 lb per sq in. At this pressure there was not the slightest indication of a leak.

The water gages in the closed generating system and high-pressure boiler were not successful with the rectangular glasses, which difficulty entirely disappeared with the use of sheet mica instead of glass, the mica resisting the heat, being flexible enough to withstand distortion, and being sufficiently transparent to give in the narrow opening a good indication of the water level.

Various features show excellent examples of how metallurgical developments have permitted constructions that would not have been possible with the materials of construction available only a few years ago. Stainless steels for valves and valve seats have surmounted the limitations of bronze and the corrosion defects of ordinary steels. Stainless-steel plates have provided a direct baffle for the oil flame to prevent the flame coming in direct contact with the drums. These plates, while resistant to high temperatures, have given some trouble on account of expansion which necessitated some changes in clearance. Low-carbon nickel steel for seamless-drum construction has permitted high factors of safety with reduced weight. Nickel-steel boiler plate also in the low-pressure boiler has given the requisite strength, with approximately 30 per cent reduction in weight. Nickel-steel forgings have provided toughness and resistance to abuse and impact, with minimum weight in various driving and motion parts.

It is customary on the Canadian Pacific Railway to operate locomotives by the pool system; that is, the engine is turned out for a train and the crew is assigned to it in the order in which they booked in from previous trips. This means that there are no steady engineers on any locomotive. Naturally it is desirable to make the operation of all locomotives as simple and as uniform as possible. This was kept in mind in all controls for locomotive 8000, and in spite of there being two superheaters and two throttles for the high- and low-pressure cylinders, the throttle mechanism was worked out so that only one throttle lever is used for opening both throttles. The operation is identical with that of an ordinary locomotive. The low-pressure boiler is fed with a standard "Elesco" CF-1 feed pump and is provided with a Hancock inspirator as an auxiliary. Incidentally, the CF-1 pump for the low-pressure boiler is located within a compartment provided in the tender tank—a location that had pre-

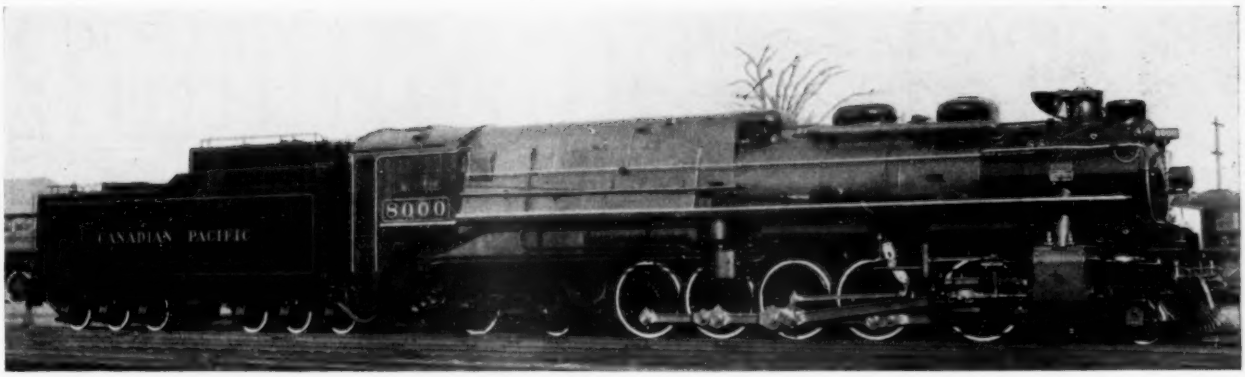

FIG. 2 MULTI-PRESSURE LOCOMOTIVE BUILT AT ANGUS SHOPS, RIGHT-HAND VIEW

viously been tried out with considerable success and advantage. The high-pressure boiler is fed with a specially designed CF-1 boiler-feed pump adapted to high-pressure service. A duplicate of this pump is also provided as a standby and auxiliary in connection with feeding the high-pressure boiler. The high-pressure water pumps are located one on either side of the boiler. The cut-off control in the valve motion is a straight duplicate of that of an ordinary three-cylinder locomotive. The oil-burner control is also identical. The only deviation is the two additional water gages on the high-pressure boiler for indicating the varying water levels and the two additional feed pumps for feeding this boiler. The crossover valve is an addition, and there are other features that require periodic checks by the engineer, but these have all been so simplified that it has not constituted any objection from the standpoint of simplicity of operation. In fact, after the initial period the locomotive was turned into the regular pool and is now handled by any engineer who may be assigned to it on any individual run. There has been keen interest on the part of the engineers and a desire to be assigned to locomotive 8000.

The most difficult operating problem on the Canadian Pacific Railway is the movement of both freight and passenger traffic over the Mountain Subdivision in British Columbia. Numerous heavy grades are encountered, the worst of which is 22.5 continuous miles of almost uniform 2.2 per cent grade, combined with numerous curves up to 12 deg.

In 1929, 20 new locomotives were put in service on this subdivision, of the 2-10-4 wheel arrangement, using 275 lb boiler pressure and two simple cylinders. These locomotives immediately introduced new standards of economy and performance, and by no means the easiest problem was selected when the Canadian Pacific Railway Company decided to construct for direct comparison a multi-pressure locomotive of substantially the same weight, wheel arrangement, and proportions as the T-1 class locomotives now handling traffic on this subdivision.

Locomotive 8000 burns oil as fuel, and the proportions of the flash pan and the size, number, and location of oil burners constituted a real problem, as there was practically no precedent on which to base the design. When the engine was originally turned out, several experiments were made with the location of a single burner and a double burner, and after a considerable amount of experimenting, proper locations for two burners were decided upon, one of which amply provides for ordinary demands, with the second one being cut in when required by abnormal conditions. It will be appreciated just how difficult this problem was when it is understood that three separate boilers—the closed system, the high-pressure boiler, and the low-pressure boiler—are all supported by the one firebox and combination of burners, and that a balance in the heat distribution must be maintained between these three heat-absorbing units throughout a wide range in steam demands of the locomotive. This has been partially offset by introducing a bypass valve from the high-pressure to the low-pressure boiler so that excess steam can be bypassed without losing it through the safety valves. Even as yet this bypass arrangement is used to some extent, but of course the ideal solution to be accomplished is the final adjustment and balance of component features of operation so as to obviate entirely the necessity of any bypassing. This can of course only be accomplished by close observation and adjustment of the locomotive in operation until the final proportions and adjustments are definitely determined. Originally the crossover valve gave trouble in that it caused severe disturbances of the water due to bypassing the high-pressure steam, which was overcome by a change in design of the valve outlet into the low-pressure boiler.

Proper draft adjustments and boiler conditions are somewhat more difficult to secure with locomotive 8000, as the exhausts are secured only at uneven intervals. This is due to the low-pressure cylinders having cranks at 120 deg instead of 90 deg, as in customary practice. There being no direct exhaust from the high-pressure cylinder, the uneven effects of the exhaust on the draft conditions of the engine are more noticeable at low speeds. This has been greatly improved with better combustion and increased superheat temperatures by installing baffle plates in the smokebox with apertures to more evenly diffuse the draft, a change in stack diameter, and changes in the exhaust nozzle. While great improvements have been effected, the problem is so different from an ordinary locomotive that further ones can be expected.

In operation the locomotive has thoroughly lived up to expectations in the matter of uniform torque, marked advantages in hauling heavy loads at low speeds due to more even torque, smooth running, development of maximum tractive effort, and slipping far less than the T-1-A engines under adverse rail conditions.

At the present time there is no doubt as to the increased maintenance cost of the multi-pressure engine over that of the conventional simple engines operating over the same division. This is generally true of engines radically different in design and construction, as the shop men lack experience on this type of engine and must become acquainted with the various details which are different from those on the engines they have been maintaining. Many experimental changes are also continually in progress at present which are apt to be mistaken for regular maintenance. Boiler men that are not acquainted with the new boilers require more time to wash out the two systems than they will when thoroughly acquainted with this work.

The safety valves presented a difficult problem in that their dimensions were strictly limited and that they must operate

under conditions of vibration and exposure not met with in stationary practice. The valves originally applied were not altogether successful. The valves on the closed-circuit system gave trouble largely on account of the actual details of construction, which has been overcome by rebuilding the valves in the railway shops by the use of a new form of seat and valve. The high-pressure safety valves also required a change in form.

The check valves in the water-delivery line to the high-pressure boiler gave trouble on account of the very high concentrated load on the valve, it being almost impossible to maintain it in a tight condition for any length of time due to the pounding it received. The solution was a twin check valve, with the proper capacity provided by two valves side by side in the same body, so that the total load on each valve of reduced diameter was little greater than the load on the single valve used in conventional practice.

Although over one year has elapsed since the engine was first put into service, the breaking-in period being on the Eastern Lines, its transfer in knocked-down condition and re-assembly on the Western Lines, and the various adjustments required while the engine was in regular operation on its assigned location on the Mountain Subdivision, it has not been possible to give a complete summary of the operating performance of the locomotive over the entire period since the locomotive was built. The engine performance has been closely followed by observers, and results show that a fuel saving of 14.8 per cent has been effected on this division under regular service conditions at slow speeds on 2.2 per cent grades between Albert Canyon and Glacier eastbound and Beavermouth and Glacier westbound. Tests conducted on the Eastern Lines over the level Winchester Subdivision, between Montreal and Smith Falls, showed fuel economies of 2.5 per cent under higher speed and heavy tonnage.

(*Erratum: In the next to the last line on this page, 2.5 should read 25*)

Progress in Textiles

NOTWITHSTANDING that the textile industry in practically all branches has been operating under a materially reduced schedule, all of its plant executives have been searching for means to eliminate waste and to develop improved machinery and methods, so that even in 1932 some of the mills and textile plants have been operating successfully. A depression may therefore really develop into an important industrial revival.

During the last few years textile-machinery builders have been greatly improving and standardizing their products and developing new mechanisms and processes that have materially benefited the industry. In fact, this has been carried on to an extent not before witnessed in 25 years.

Much progress has been made in scrapping obsolete mills and mechanisms, as well as the processes themselves, and much more remains to be accomplished.

Such buildings as have been erected have been mostly small additions to existing textile mills, and little of new design or construction has been noticed, but the new machinery and processes that have been developed require very little actual floor space as compared with the old methods, and this argues well for the development in the years that are to come.

An important trend that apparently will terminate in a most satisfactory condition is the seeming willingness now of the actual leaders of the textile industry to meet and discuss their several problems, whereas in the past this has been difficult to accomplish. And it is earnestly hoped that during the coming year the engineering executives connected in any way with the textile industry may make it possible to bring into a still more closely knit group the textile executives of every branch of the industry so that the basic problems of machinery, development, policies, and processes may be more thoroughly discussed and worked out. For to the farseeing engineer there is every evidence that most of these problems now so jealously guarded by the several branches of the industry are in reality only problems common to the industry as a whole when viewed by the impartial technically trained engineer.

Dyeing and Finishing

An outstanding engineering achievement in the textile field is the development of the two-motor all-electric dye jig. This mechanism was developed by an English engineer, and the American rights were acquired by a textile-machinery manufacturing firm that has greatly improved the original machine. This all-electric jig gives constant cloth speed, constant tension controllable at will from no tension to any tension required, and also automatic reversing and stopping after a predetermined number of ends, making it a valuable addition to the textile-producing mechanisms.

A simple mechanical fabric guide is operated by a selvage finger moving with the fabric, its claimed advantages being immunity to moisture or lint and adaptability to either wet or dry fabrics and the successful handling of delicate fabrics.

A light-running dye jig adapted for light-silk, rayon, cotton-and-silk, rayon-and-silk, and fine cotton fabrics is an individually driven, self-contained unit and, because of the absence of pulleys and belting, it is claimed that the operator can move freely on all sides of the jig. The mechanism has been designed to secure silent operation and low upkeep costs. It is possible that this mechanism is quite similar to another developed during the last three years. Both appear to be a long step in the right direction in the development of these operations.

In an improved piece-dyeing machine used principally for silk fabrics, the goods instead of being pulled through the liquor in rope form are said to practically float through it in semi-open form. The mechanism is designed to reduce the pull to a minimum, thereby eliminating marks and insuring good penetration.

A machine for shrinking cloth without the application of tension accomplishes this through automatic festooning of the goods. It is asserted that with these feeding and looping devices the materials can be fed in the flat, open condition, without the danger of wrinkles or marks. Another claim is natural drying without heat or air circulation, although heat or air may be used if desired.

Another conditioning machine for restoring the moisture content has been offered to the finishing industry and is claimed to be equally effective on worsteds, woolens, cottons, silks, and rayons. Close control and the handling of a large volume of goods in minimum space and time are claimed and also that the mechanism can be operated in range in connection with other machinery.

In the Palmer Sanforizing unit brought out last year, recent developments that are in fact decided improvements over the older methods accomplish the shrinking of heavy fabrics such as denims, moleskin, and auto-top materials through an ingeniously designed and arranged feeding device, sprays, and steamers, together with individual motor drives and feeding machines and the clutches.

A metal-clad piece-dye tub introduced about the first of the year will apparently replace the old-time wood tub on account of accessibility in cleaning when changing colors.

Dyeing of a yarn package either from the inside out or the outside in is a feature of a new ultra-package-dyeing machine. The advantages claimed are in the ready flow of the dye liquor, the distribution of the dye liquors over the material, the special carriers, the tank design, and the dyestuff agitator, and also the low steam consumption and minimum space requirements.

A textile drier developed abroad after several years of effort is based upon a novel method of air circulation and the manner of conveying the material. Negotiations for the manufacture of the drier in this country are now under way.

A highly mechanically perfected mechanism for the continuous dyeing and slashing of cotton and rayon warps has been patented, and it is believed that the model recently turned out is the first really practical one that has been produced. It has many novel features and is of beautiful construction. It will be necessary, however, to withhold comment until the machine has been in use for a few months so that it may be observed under actual operation.

Cotton

A new jig has been designed to give a better penetration of the dyestuffs in the cotton-finishing industry. This jig will apparently replace the older type of jigs and padders on the cotton and possibly on the silk fabric. The more satisfactory penetration should result in better color. In this apparatus

---

Presented at the session of the Textile Division, Thursday morning, December 8, 1932, during the Annual Meeting, New York, N. Y., December 5 to 9, 1932, of The American Society of Mechanical Engineers.

Compiled by the Progress Report Committee, W. L. Conrad, Chairman.

Personnel of the Executive Committee of the Textile Division for 1932: Henry M. Burke, Chairman; Paul A. Merriam, Vice-Chairman; M. A. Golrick, Jr., Secretary; H. V. W. Scott, William L. Conrad, Clifford H. Ramsey, Associates: Reynolds Longfield, Harry D. Learnard, A. W. Benoit, Albert Palmer.

the squeeze rolls are inside the dye tank, and may therefore be partially or completely submerged in the dye liquor, overcoming the objection that in some operations the squeezing on the selvage and body of the fabric has not been uniform, resulting in uneven color.

A lubricator for bobbin winders has been developed in Europe. This mechanism, combined with a special stretch device, insures thorough and uniform lubrication, with friction eliminated.

What has been described as an entirely new machine for the twisting of wool, worsteds, rayon, cotton, and other yarns has been announced. This mechanism is claimed to give increased uniformity of twist, together with a materially increased production; in fact, it is claimed that more product is possible than is obtainable in existing frames. It is also claimed that this mechanism combines both the principles present in today's methods of twisting, and a further claim is made that the manipulation of this machine is very simple and the frame is said to be suitable for twisting crepes and all yarns where medium or hard twist is required. It is particularly advantageous for the twisting of cotton crepe yarn, wool crepe, single yarn twist, and knit silk crepe yarn.

A novelty twister for producing a wide range of fancy yarns has been introduced during the past year. The heads of this mechanism are so arranged that two or three lines of independently driven under-rolls may be used with each line of rolls having more than one speed a head, and these lines of rolls may be timed to run at the same speed or at different speeds and are centrally controlled. This mechanism has many other advantages that make it of special interest to the cotton industry.

A novelty tester has been produced for portraying graphically the inherent evenness characteristics of various slivers and coarse rovings, and the manufacturer has outlined a method of evaluating the graph prepared by this instrument.

The general tendency of the manufacture of looms for cotton and worsted goods has been to standardize in the manufacture of this machine, and these parts are now interchangeable, as they are on other modern equipment. These new weaving machines have been developed with the idea of showing a return on the investment when they are purchased for the replacement of old machinery.

The single-process picker has become almost the standard for picker rooms. Two- and three-process pickers are today considered obsolete. In the card room the long-draft system has been applied to roving frames, and it is understood is being used in a few mills at the present time. The long-draft spinning system is now being used extensively as replacement becomes necessary or additions are made, and it is claimed that it may be now considered as the standard type of spinning.

Spinning frames are being redesigned and are now being made to produce large packages suitable for use direct in the warper creels, thus doing away with spooling. These spinning frames are equipped with knee brakes, moving thread boards, and improved features in many parts.

Old-style spooling and warping have been largely eliminated and has been replaced with either automatic spoolers and high-speed warpers or with high-speed winders and warpers. The elimination of the spooler or winder from this process is forecast.

For mills that comb their cotton, a new and improved comber is available that gives a much greater production than heretofore.

Process Development

One of the important developments during the year in the process field is the commercial production of cuprammonium rayon by a particular process. This radical change in rayon production methods has been described in detail in some of the leading textile journals, and its adoption would indicate a revolutionary feature in the rayon industry.

There is also reported the possibility of the production of acetate yarn by another organization, but up to the present time few actual details of this process have been made available, although it is understood that it is an improvement and simplification of older methods.

Silk

There has been developed this year the 2 × 1 shuttle-changing automatic silk loom, and this improvement has also been applied to the so-called super-silk loom. This is an electro-mechanical mechanism and permits both shuttles of this loom to be replaced with new shuttles without stopping the loom, the necessity for changing shuttles being indicated by an electrical detector. This type of detector, however, cannot be used except under certain conditions, but an internal detector, which is a part of the shuttle, has been developed that will fill the needs of all general conditions. This internal detector shows great promise, especially with very fine rayon yarn. The 2 × ' shuttle-changing silk loom is particularly adapted to fine rayon goods where bobbin-changing looms have been found to be impracticable.

An improved coning machine equipped for silk throwsters has been placed on the market and is said to produce a desirable package economically and at an exceptionally high spindle speeds, and the arrangement of the spindle units is declared to promote flexibility and in the allotment of spindle per operator to meet changing mill requirements.

Wool

An interesting aging machine of conventional design has been introduced into the wool industry and would seem to be well adapted for the purpose. This mechanism is provided with heat-retaining insulation as well as vapor-tight bushings and other devices for retaining the necessary heating requirements.

A single-apron stock drier of improved design has now been developed and, inasmuch as this machine is built in sections and can be furnished in any length and in a number of widths, it would appear that this mechanism would offer many advantages. The conveyor for carrying the stock to this machine is declared to be of new and improved construction, and the machine is adapted for fine stock, with the conveyor drive equipped for variable-speed control. Other improvements and attachments combine to make this mechanism very interesting.

The woolen industry has apparently accepted and installed tape condensers in greater quantity than ever before, thus indicating that this machine is an improvement in the industry.

Spinning frames are now in use in the place of mules, and it is understood that more are being installed as tradition gives way to experience.

It is understood that a new line of French drawing machinery is in process of manufacture, and the announcement of the introduction of this mechanism may be looked for in the near future.

Printing

A multi-color warp-printing machine is announced. In this machine yarns in warp form can be printed in from one to four colors by means of the new multi-color mechanism. Direct basic or acid colors may be handled in this machine. For vat dyeing a steam or aging chest, along with a two-compartment wash box, is provided. These machines are designed to be mounted directly behind the slasher so as to print the warp as it leaves the section beam in its full width.

Knit Goods

Several new features and a number of improvements are embodied in recent models of a full-fashioned hosiery machine that has been offered to the trade. Many of the new devices of this machine are really improvements over a similar machine offered a short time ago. For single-operation work the single-narrowing machine is now replaced by a full-narrowing machine, and it is now possible to make the diamond toe on single-operation hosiery.

Another full-fashioned hosiery machine has been developed and is what might be styled a jacquard machine that will produce an openwork pattern over the entire width of the stocking, and it is reported to produce this at an unusually high speed. The machine is designed to make single-unit stockings that do not have to be transferred, and it can also be used either as a legger or footer to make stockings in the usual manner with French foot or English instep. And the speed of this machine, depending on the gage and the yarn employed, is 70 to 75 courses per minute.

Still another hosiery machine recently developed is a new wrap machine of individual-needle type and makes possible the using of a very large number of different colors. This machine will turn out hose with high splice, double sole, and plated body. Any type of warp yarn may be used.

It is understood that some years ago a patent was taken out covering the manufacture of non-run hosiery, but up to quite recently little has been heard of this improvement. It is now expected that this device will be rapidly perfected and that very shortly the product will be placed on the market. This will fill a very important position in the knitting industry, and it is hoped that it will eliminate the many objections that have been raised to the products of the present-day knitting machines, notably the run feature of knit goods.

Sanforizing Process

By SANFORD L. CLUETT,[1] TROY, N. Y.

The paper describes a machine that will treat a fabric so that its dimensions in warp and filling will be what is desired after the fabric is subjected to laundry washing or other cleaning process. The causes of the shrinkage of a fabric when subjected to full laundry treatment being mostly mechanical, an effective treatment to prevent shrinking may be found in some process of mechanically rearranging the fibers of the fabric (including changing the count of warp and filling) to the same extent that the fibers would rearrange themselves if subjected to a full laundry washing. Data are given of characteristic runs of different fabrics in the Sanforizing process.

THE Sanforizing process and the mechanism for it were designed primarily to treat a fabric so that its dimensions will remain substantially unchanged when the fabric is subjected to a laundry washing or other cleaning process. It is common experience that finished textile fabrics change in length or width when laundered; this change is generally a shrinkage. The principal reasons that shrinkage occurs are as follows:

(*a*) Practically all textiles are woven under tension, generally in both warp and filling. For obvious reasons textile machinery is designed to operate this way.

(*b*) In the bleaching and finishing of textiles, from the moment that the webs are sewed together for putting through the rope or open-bleach processes until they are finally bleached and finished, they are stretched every time they are transported from one station to another. This pulling tends to stretch and straighten out the warps and thus narrow the goods. Narrowness is counteracted at one or more stations during the finishing process by pulling the goods out in width through the use of expanders or tenters, or both. As a rule when the material is pulled out or held out in width the warps are still held under tension; thus the pulling out in width also puts tension on the warps as well as on the filling. The result is that most finished woven fabrics are elongated during the finishing process.

(*c*) When textiles are manufactured into garments, the material may be subjected to more or less stretching in length or in width.

(*d*) As a result, such fabrics are only awaiting a favorable opportunity to change their dimensions. This opportunity occurs if the finished fabrics are dampened with or immersed in water. The water acts as a lubricant and allows the fibers to readjust themselves. The fibers also swell; and as the yarns are twisted this swelling causes a shortening of the yarns. The combination of swelling and shortening of the yarns, owing to the twist, further causes a shrinkage of the fabric because of a rearrangement of the position of the yarns. The most general cause of garment shrinkage is the laundry wash wheel or other mechanical manipulator of wet garments. During laundry washing a garment is tumbled about in hot soapy water, generally with a heavy charge of goods, and the yarns are not only further allowed to contract, but they are forced and pounded together by the action of the water and of the other garments in the wheel; there is a fulling effect somewhat similar to that which takes place when wool is washed. Also caustic and bleaching solutions may be present in the wash wheel and have a further shrinkage effect on the material. It has been observed that woven fabrics shrunk by water alone will, when subsequently subjected to a full laundry wash, shrink an additional amount varying from $^1/_2$ in. to the yard to as much as 2 in. to the yard. In fabrics in which the yarns are only partially or altogether unbleached, the fibers are generally water repellent. These fabrics as a rule not only have a high shrinkage factor on washing, but continue to shrink in subsequent laundry treatments until the waxes and gums are entirely eliminated.

Methods of Preshrinking

In order to minimize the laundry shrinkage of fabrics as far as possible, several methods of preshrinking have been in use for many years. Among these may be enumerated:

(*a*) Wetting or soaking the fabric and drying it with as little strain as possible on the warp and filling.

(*b*) Chemical shrinking.

(*c*) Washing the fabric.

These three hold important places in the shrinking art. However, the process to be described has been built on the principle that inasmuch as the causes of the shrinking of fabrics when they are subjected to a full laundry treatment are mostly mechanical, the most effective treatment to prevent shrinking may be found in some process of mechanically rearranging the fibers of the fabric (including changing the count of warp and filling) to the same extent that the fibers would arrange themselves if subjected to a full washing in a laundry.

Process for Anticipating Shrinkage

The Sanforizing process is, broadly stated, one for predetermining the superficial dimensions of a fabric and at the same time conserving, and usually improving, its finish. It may be so applied as to shrink or to elongate either the warp or the filling, or both, in any desired combination of dimension change. For example, any one of the following dimensional effects may be attained:

(1) Warp shrunk, filling shrunk
(2) Warp shrunk, filling unaffected
(3) Warp shrunk, filling elongated
(4) Warp unaffected, filling shrunk
(5) Warp unaffected, filling elongated

---

[1] Vice-President, Cluett, Peabody & Co., Inc. The author was born in Troy on June 6, 1874. He was a student in Albany Academy in 1889, was graduated from Troy Academy in 1894, and received the C.E. degree from Rensselaer Polytechnic Institute in 1898. Mr. Cluett was with the Walter A. Wood Mowing and Reaping Machine Company, Hoosick Falls, N. Y., as chief engineer, assistant superintendent, vice-president, and vice-president and general superintendent, 1901–1919, and since then with Cluett, Peabody & Co., Inc., as director in charge of engineering and research and now as vice-president. He designed the one-horse and two-horse vertical-lift mowing machines; all steelwork for the Government locks on Big Sandy River, Kentucky, in 1900; valves for St. Andrews Rapids locks, Manitoba, etc.

Contributed by the Textile Division and presented at the Annual Meeting, New York, N. Y., Nov. 30 to Dec. 4, 1931, of The American Society of Mechanical Engineers.

Note: Statements and opinions advanced in papers are to be understood as individual expressions of their authors, and not those of the Society.

(6) Warp unaffected, filling unaffected
(7) Warp elongated, filling shrunk
(8) Warp elongated, filling unaffected
(9) Warp elongated, filling elongated

In the great majority of cases preshrinkage is an end in view; and discussion will therefore be confined to that aspect of the process. The procedure consists of the following:

(*a*) Precisely determining the changes that take place in the longitudinal and transverse dimensions of the fabric when it is subjected to a full laundry wash.

(*b*) Applying the process to bring about these dimensional changes.

(*c*) Giving to the fabric by the operation of the process an enhanced commercial finish.

The standard method of determining the changes that take place in the dimensions of a fabric when subjected to a full laundry wash is as follows:

A 20-in. test sample is cut from a web of the cloth to be shrunk, and 18-in. in both warp and filling is marked off accurately on it in indelible ink. The sample is subjected to normal laundry washing treatment: a 5-min. rinse in either cold or warm water, preferably in water at 140 deg. fahr.; the water is drawn off; hot water and sufficient soap are added to give a good running suds, which is run in the wheel for 30 min., and then drawn off; a 10-min. rinse is given in clear water at 140 deg. fahr., followed by two 5-min. rinses, each time drawing off the previous rinses before adding fresh water; a final 5-min. rinse with water containing about one-eighth of 1 per cent of 56 per cent acetic acid is given. This is done to neutralize thoroughly any small traces of alkali remaining in the goods. After washing, the sample is squeezed by hand without stretching and placed on a screen in a dry room. After drying, the sample is dampened slightly with a spray of water and pressed with a hot iron. During the pressing, care is taken not to rub the cloth, as is customary in hand ironing, but simply to press out and smooth the cloth without stretching.

The changes that take place in the marked 18-in. sample are noted and are recorded on a card for both warp and filling in terms of inches and decimals of an inch per yard of fabric. These changes are called the "PWS" or "potential wash shrinkage" of this particular fabric, elongation being marked with the plus sign and shrinkage with the minus sign. This record serves for setting the Sanforizing machine so that it will change the warp and filling dimensions of the material to be treated by the amount that has been indicated by the sample test.

A similar test piece is cut from the finally treated fabric to determine whether the process has been accurately carried out. It is, as a rule, not difficult to attain stability of a fabric to within $^1/_4$ in. per yard in both warp and filling.

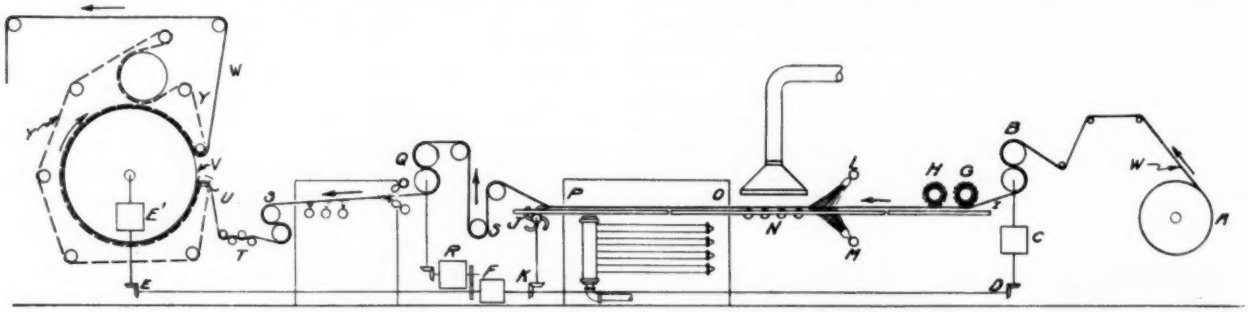

FIG. 1 DIAGRAM OF SANFORIZING MACHINE AND ITS OPERATION

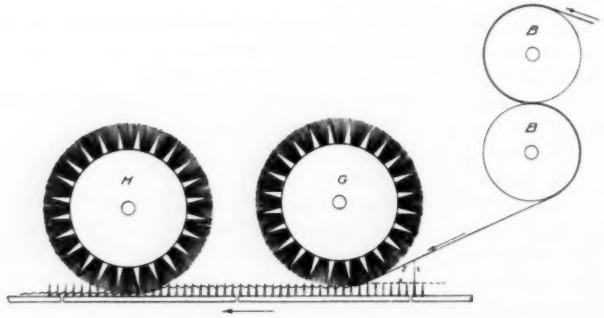

FIG. 2 BRUSHES FOR PRESSING THE FABRIC UPON HOLDING PINS

SANFORIZING MACHINES

The process, in its essentials, can be carried out with various species and types of apparatus. The machinery comprises a combination of types which has, after extensive tests, demonstrated efficient adaptability and adjustability economically to satisfy the requirements and solve the problems presented by a wide range of fabric conditions. The machine and its operation (see Fig. 1) may be briefly described as follows:

The fabric to be treated (marked *W*) is brought to the machine at *A* on a roll or loose on a truck. The material is passed over one or more bars to open it and eliminate wrinkles and is seized at *B* by two grasping (or feeding) rolls that are driven through a variable-speed gearing *C* from a main-line shaft *D-E*, which shaft is driven by a motor *F*. The motor, driving through one shaft, ensures synchronization throughout the machine. The material passes from the feeding rolls *B* to a tenter *I-J*, and is fed onto pins or into other gripping devices at *I*, which are mounted on the chain of the tenter, the tenter chain being driven from the main shaft at K. If it is desired to shrink the goods in the warp, the variable-speed gear *C* is adjusted to feed the goods to the tenter at a faster rate than that of the tenter chain, with the result that the material, seized by the tenter pins or clamps, is slack and undulated in the direction of the warp. The algebraic differential between the velocity of feed at the feed rolls and the velocity of the tenter chain is the measure of warpwise dimensional alteration to be attained in the tentering machine.

Fig. 2 shows the manner in which material is applied for positive warpwise preshrinkage. *G* is a vertically floating revolvable brush. In starting, the goods are passed under this brush and on the pins close to the selvage edge of the material; the brush of its own weight drops until the goods are stretched taut between the brush *G* and the feed rolls *B*. As the machine is started and the pins move forward in the direction of the arrow, the brush *G* drops to a point where in the small triangle *xyz*, the side *y* is to the side *x* as the velocity of the surface of the feed roll *B* is to the velocity of the tenter chain. As the chain with the material on the pins passes from under the feed brush *G*, the excess

material takes the form of ripples somewhere between the points and the bases of the pins. A second vertically fixed brush H, rotated by the passing pins, presses the goods down on the pins.

Referring to Fig. 1, the material passes on the tenter past the brush H and is moistened from above or from beneath (sometimes both) by water sprays L and M, which may be operated to deliver any desirable quantity of moisture, and at about this point the tenter chains diverge so that a slight stretch is given to the filling threads. As the material progresses through the tenter the tension thus imposed on the filling threads tends to straighten

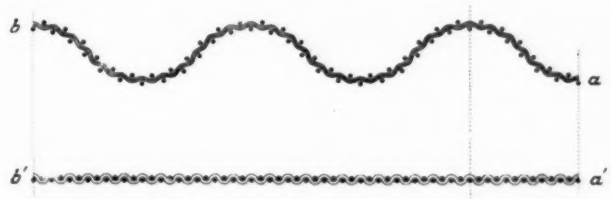

FIG. 3 METHOD OF SHORTENING THE FABRIC

them, and to cause a largely increased accentuation in the weave undulations of the warp threads. This action shortens the fabric, as illustrated in Fig. 3, in which ab shows a cross-section along one of the warp threads near the middle of the fabric before the filling threads are stretched, for a distance of, say, 2 in. in a straight line. As the filling threads are pulled they tend to become straight, causing the warp threads to assume an accentuated crinkle, as shown between a' and b'. All of the wave in the fabric between a and b has now been converted into increased undulations or crinkles in the warp threads. There are the same number of filling threads between a' and b' as there were originally between a and b, but the fabric itself is shorter by an amount equal to the excess feed.

The assumption of this new relation by the warp and filling threads is greatly facilitated by the moisture from the spray at L and M, and may be still further assisted by steamers at N, through which just sufficient steam may be supplied to properly diffuse the moisture through the fabric.

The tenter chains carrying the cloth holders (pins in this case) diverge just sufficiently to cause the fabric to become smooth, and completely take up the excess material fed to the machine at B. Forward movement of the chains now carries the fabric into a drying chamber O-P, where the moisture is driven out, so that dry fabric emerges from the chamber at P. This drying is very rapid as the moisture added by the sprays L and M and the steamers N is only about 10 per cent of the weight of the fabric.

As the fabric emerges from the drying chamber it is doffed from the pins by a high-speed revolving starfish-shaped wheel at J. At this point the material has been preshrunk in the warp and stretched in the filling.

The material is carried away from the tenter at J by a second pair of grasping rolls Q, which are operated through a variable-speed drive at R, which drive is direct from the main shaft D-E. The compensating roll S controls the variable-speed drive R so that the surface speed of the grasping rolls Q just corresponds to the amount of material delivered from the tenter at J. No undue tension is imposed on the material between Q and J.

The material now passes from the grasping or feed rolls Q to a modified Palmer drier equipped with a rather thick woolen belt and with other important new adjuncts to be described. Immediately after leaving the feed rolls Q a spray is applied, generally to the under side of the fabric, and sometimes steam also with the spray, to soften it and the adhesions that may have occurred in it from the use of sizing. Only sufficient moisture is added to render the material pliable and soft. This softening of the material as a whole causes a decrease in the width of the fabric. If the fabric has been tightly stretched in the tenter, the width shrinkage under the influence of the moisture at Q is considerable. The material is drawn away from the feed rolls Q at U. The speed at which the material is fed into the modified Palmer at U is in excess (say, about 6 per cent) of the speed of delivery of the material at Q. This causes a slight stretching of the material between Q and U so that it is desirable to place at S two rollers mounted on ball bearings which are revolved by the fabric and which tend to keep the filling straight. During the passage of the fabric from Q to S, the moisture and steam, together with the tension, exert a narrowing effect on the material. To prevent the fabric becoming too narrow, a series of adjustable scrimp bars or expanders is inserted at T, which may be so operated as to hold the goods out so that they enter the modified Palmer feed the exact desired width.

At this point U, however, the warps have become slightly straightened from their condition of high crinkle when the web was delivered to the point U, and it is now not only necessary to dry and finish the material, but also desirable in the case under consideration to put back the preshrinkage in the warp. This is accomplished by that part of the machine shown in Fig. 4, as follows:

Referring to Fig. 1, the differential between the surface velocity of the large heated drum of the modified Palmer and the rate of input of fabric at B (to the tentering machine) is the measure of

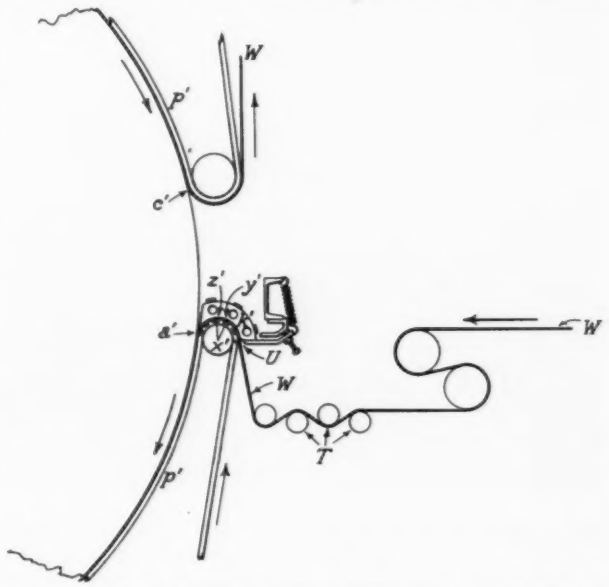

FIG. 4 PART OF MACHINE WHERE PRESHRINKAGE IN THE WARP IS RETURNED

the final, or net, warpwise preshrinkage attained. A variable-speed drive from the main shaft is provided at E', for adjustment of this differential. If the preshrinkage (warpwise) imposed in and by the tentering machine is to be exactly restored in the modified Palmer, the surface velocity of the modified Palmer will be adjusted to equality with the velocity of the tenter chain. If, however, it is intended to impose, in the modified Palmer, a larger percentage of warpwise preshrinkage than that produced in the tentering machine, the velocity of the drum will be by so much the less. The large drum (see Fig. 4) drives the belt p', with the result that the surface of the belt in contact with the large drum assumes the same speed as that of the drum. The material W, having passed through the adjustable scrimp bars T,

runs onto the belt at U, at which point the belt is flexed around a relatively small revolving cylindrical roll x', thereby stretching the surface of the belt at y' between the points U, y', and a'.

It may be assumed for purposes of this exposition that the median longitudinal plane Z' of the belt travels at constant velocity equal (or very nearly) to the surface velocity of the large drum. At y', where the belt is abruptly flexed, the speed of the outside surface of the belt is to the mid-section speed of the belt as the radius y'-x' is to the radius z'-x'.

The material W is caused to adhere frictionally to the surface

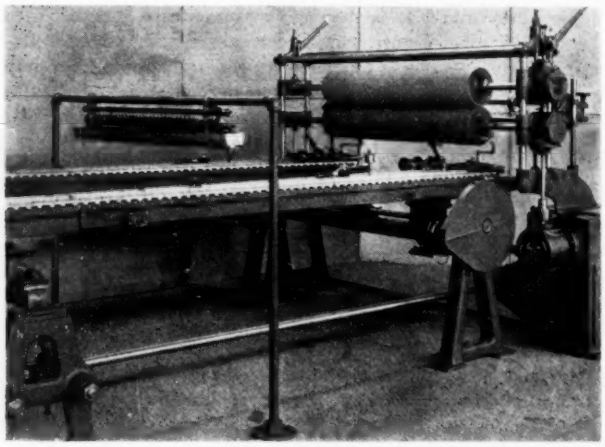

FIG. 5 INTAKE END OF SANFORIZING MACHINE

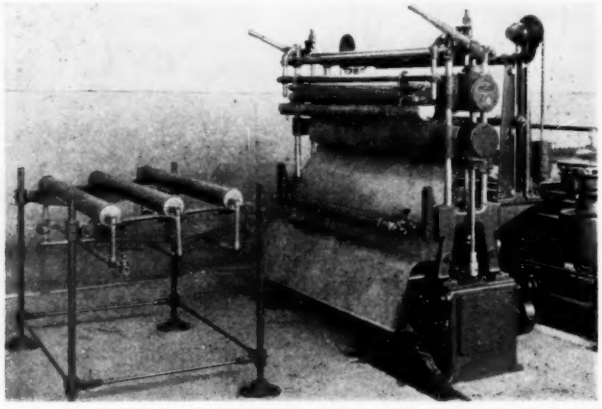

FIG. 6 TAKE-OFF ROLLS AT END OF TENTER, WITH THE ATOMIZER AND STEAMER

of the belt between U, y', and a' by the light pressure of an electrically heated iron k' which rests on the fabric mostly by its own weight, and which extends across the full width of the machine in short sections of 4 in. or more. The material W on coming to the point a' is fed at the higher velocity, as stated, to the surface of the hot drum, which is moving at the slightly lower velocity, approximately equal to that of the mid-section Z' of the belt, and the material would at this point wrinkle were it not for provision for maintaining fixity of the web to the belt surface up to, at, and through the line where the curvature of the belt reverses; these being, in actual apparatus, the maintained pressure of the irons k' and the location of the nip-line between roller X' (which is hung so as to press toward the large drum) and the large drum. When the belt reverses its flexure, its supporting surface shortens longitudinally at a', and inasmuch as the material W is held practically fixed to the belt surface, it also shortens with the belt surface and travels along between the hot drum and the belt until it emerges at point c'.

But inasmuch as the velocity of the surface of the drum and of the belt at c' is less than the velocity of the fabric feed at B (Fig. 1) by an amount equal to the shortening that is desired in the fabric, the fabric at c' is shortened by exactly this amount; the heat from the hot drum has dried the fabric so that it emerges at c' (Fig. 4), containing only a small amount of moisture, generally in the form of steam vapor.

The fabric during these operations has become shortened in length and decreased in width. The weaving undulations in the yarn have become accentuated, resulting in a "bead" that gives increased diffusion of reflected light. The drying of the fabric against a polished hot drum has moreover given to the fabric a smoother appearance and better "hand" than it had originally. It will further be noted that this process disturbs to only a small extent the fibers of the yarns, in consequence of which and be-

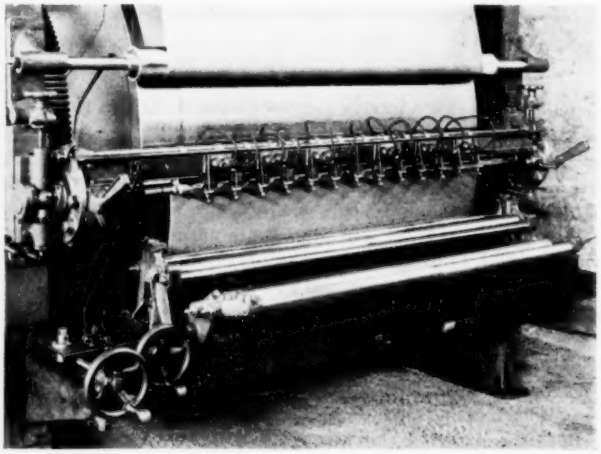

FIG. 7 MODIFIED PALMER FEEDING MECHANISM

cause of the increase in yarn crinkle a diffused luster is obtained. This is a natural luster which is ordinarily enhanced by the subsequent dampening and ironing that occur during the manufacture of a garment.

There may be or there may develop, of course, situations in which the modified Palmer and its adjuncts will be sufficient to perform the shrinkage operation without the use of the Sanforizing tenter frame. In the Palmer machine, modified and equipped as described, if a belt of increase thickness is employed, an increase in the rate of feed of fabric at U will be obtained, while the rate of delivery of the fabric from the modified Palmer will remain unchanged; but whatever the thickness of the Palmer belt and the resulting ratio of input fabric length to output fabric length, that ratio is fixed, and will be appropriate to only one fabric, and will serve only one predetermined purpose, for the inflexibility of this portion of the complete apparatus is contrasted with the inevitable non-uniformity in most carefully woven fabric. However, it has been found, in practice, that for the purpose of handling a large variety of fabrics previously finished in a large variety of ways, the combination of the whole machine, as shown in Fig. 1, has a much greater range, capacity, and adjustability than the section between the second feed rolls Q to and including the modified Palmer. The tenter prepares the material for the first operation in connection with the modified Palmer, straightening the filling threads (if previously curved), bringing all of the fabric to the most convenient and constant width, and at the same time shrinking warpwise

to almost any degree desired (up to 3½ in. per yard in the present machinery).

Referring to Fig. 4, the ratio of the outside surface speed of the belt at y' is to the mean speed of the belt as the distance y'-x' is to the distance x'-z'. For example, if the cylindrical roll x' has a radius of 1.5 in., and an extra heavy belt 0.34 in. thick be used, the distance x'-z' then becomes 1.5 in., plus 0.34/2 in., which equals 1.67 in. The distance y'-x' becomes 1.5 in., plus 0.34 in., which equals 1.84 in. The shrinkage or the shortening of the fabric on passing to the drum, expressed in terms of percentage, will be

$$\frac{1.84 - 1.67}{1.84} \times 100 = 9.24 \text{ per cent.}$$

This, multiplied by 36, gives a shrinkage of 3½ in. per yard of fabric. If the large drum is made relatively smaller, the surface of the belt against the drum becomes more compressed, resulting in a further shortening of the fabric held between the belt and the drum.

To operate individually the apparatus comprising only that from the second feed rolls Q to and including the modified Palmer, so that fabrics may be shrunk in warp and filling to a predetermined extent, it is only necessary that the belt of the machine, as illustrated, be sufficiently thick in comparison with the cylindrical roller x' to take care of the maximum shrinkage that it may be desired to impose on a fabric. Smaller degrees of shrinkage or shortening of the fabric are obtained merely by the adjustment of the variable-speed drive R controlling the speed of the feed rolls Q, so that the surface speed of the feed rolls Q is in excess of the surface speed of the hot drum by an amount equal to the desired shrinkage. If the speeds were exactly equal, there would be no shortening of the fabric; the latter would simply be stretched between Q and U an amount equal to the amount that it is shortened between U, a', and c'.

TABLE 1 CHARACTERISTIC RUNS ON SEVERAL SAMPLES

[a] Denotes a gain.

Table 1 gives the data of characteristic runs of different fabrics in which it will be noted that while the warps are, in all the examples, shortened during the Sanforizing process, the material in the filling dimension has in some cases been lengthened.

As hitherto ascertained, rates of production, varying with the class of goods, on the machine equipment described are as follows:

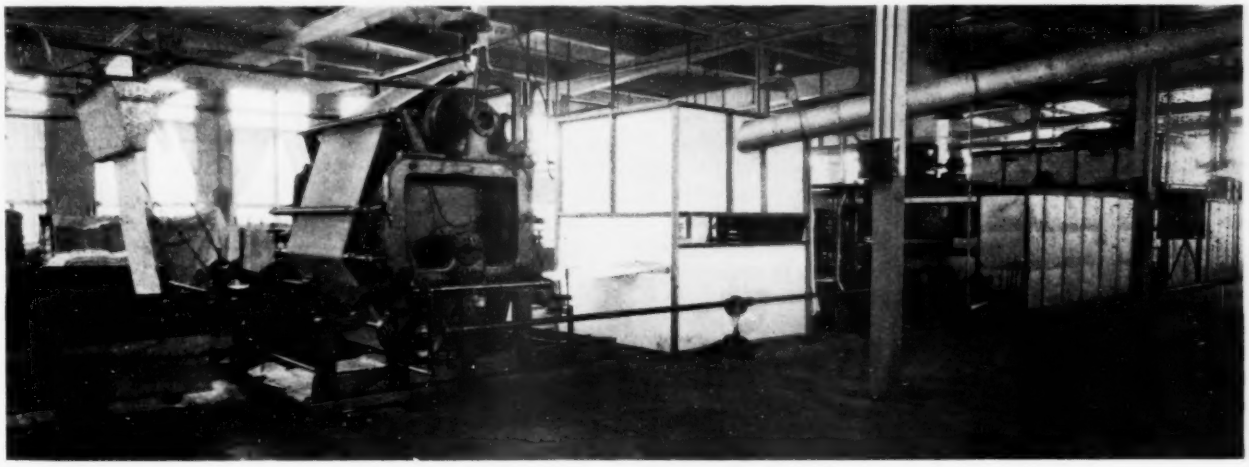

FIG. 8 SANFORIZING MACHINE IN OPERATION

Print cloth, 60 to 90 yd. per min.
Broadcloth shirtings, 60 to 80 yd. per min.
Duck, 8-oz., 30 yd. per min.

Three men are required to operate the equipment. Electrical controls at either end of the equipment are provided for the main drive and the moisture sprays.

Discussion

G. W. PAULSON.[2] The impression may have been gained that this process is a simple one and that the machinery might be installed and put in the hands of a few handy men around the mill to operate.

It so happens that the writer is the man who has to function as the "go between" to see that machinery installed is operating satisfactorily and that proper results are obtained, and he, there-

[2] Cluett, Peabody & Co., Troy, N. Y.

fore, is interested in the type of men selected to operate these machines.

The operating technique can be readily acquired by any one of average intelligence. On the other hand, there are hundreds of types of fabrics to be considered, and it is essential that, previous to Sanforizing, information be obtained as to how these fabrics had been finished and how much it is necessary to shrink them so that they will not change in dimensions when submitted to a laundry treatment. Men should be chosen to operate the machines who are above the average in intelligence.

TEX-55-3

Cause and Effect of Recent Advances in Textile Machinery

By EDWIN D. FOWLE,[1] NEW YORK, N. Y.

There is an important general advance in the improvement of textile machinery. The cause is mainly in the necessity which the machinery manufacturers face of developing equipment for replacement rather than for expansion. A slight falling off in the rate of development began this year, due largely to the great expense which the work entails, but the rate is still far above normal. If the industry will refrain from employing high-production machines to increase total output, that is to say, if it will use such equipment strictly to decrease operating costs, it will have a splendid opportunity to eliminate or reduce the overproduction which now hampers it. This is because continual renovation of the better mills will close the less efficient ones, and because reduced costs, followed by reduced selling prices, will widen the market.

A REPRESENTATIVE of a prominent textile-machinery firm early in 1931 declared "We have brought out more improvements the past year than in any like period in our history." The same statement might truthfully have been made by a number of other equipment builders; it could certainly have been made for the textile-machinery industry as a whole.

The year referred to, 1930, may receive special attention from students of industrial history as marking the apex of an astonishing advance in the improvement of textile machinery. For decades previous to 1929, developments appearing on the market were, as market reporters say, spotty. There were a few outstanding ones, it is true, but they appeared sporadically at comparatively long intervals and affected a relatively small number of processes. There was no general movement toward improving the technique of textile manufacturing in all departments of the mill, such as became evident in 1929 and 1930.

Several of the developments which took place before that period were of tremendous importance and probably were as vital to the industry as any of the multitude which followed them. Among the more recent of these earlier inventions were the first generally acceptable, and accepted, long-draft cotton spinning, single-process picking, high-speed warping, woolen ring spinning, and wrap-stripe circular-hosiery knitting. No doubt these innovations helped to awaken the majority of textile engineers to the possibility of improving many other processes of the mill. It would not be surprising if, in those comparatively cool and collected days, the average importance of the developments which were brought out exceeded the average of those which were the product of the subsequent more hectic, mad-scramble age, in which builders vied with each other to make the most startling announcements of new products. But, although this may be true on a basis of averages, it is probable that a number of the later improvements are individually the equal of the best which the earlier period produced.

While it would be difficult to reach any definite conclusions regarding the relative merits of improvements made at different periods, it is easily possible to compare their numbers. Since many changes in equipment were too insignificant to afford any appreciable advance in the art, it seems wise to take as a basis for comparison only those which the textile press considered of sufficient importance to mention in its columns. The years 1926, 1927, and 1928 were typical of those which preceded the upward swing, and over that period the number of developments so mentioned averaged 64 per year. In 1929 the number rose to 107, and in 1930, to 203. In 1931 it has fallen off somewhat, and it is estimated at this writing that it will be somewhere around 165. The reasons for this decline will be discussed later. Although these figures indicate that the era of development first showed results in 1929, it must be understood that the work of research and experimentation, which is the true basis of it, actually began several years earlier.

To mention all of these developments here would be to recite a rather wearisome catalog, and those who wish to obtain a detailed picture of the progress which has taken place are referred to the annual summaries which have been made by the Textile Division of The American Society of Mechanical Engineers, and by *Textile World*.

It would be of doubtful service at this time to endeavor to pick out the most vital of these stepping stones of progress, because the brief period which is now of principal concern, and in which the industry is still involved, began too recently to permit a mature judgment to be passed on the exact value of the inventions it produced. Certain developments, however, which are of sufficiently new departure to appeal particularly to the imagination include the single-unit full-fashioned hosiery machine, the sanforizer, the continuous kier, the "geyser" skein-dyeing machine, and the garnett-card. Who can say, however, that these innovations will prove of more importance to the industry than certain machine improvements which adhere more closely to established principles, such as the enormously increased capacity of the rulling mill, the adoption of the variable-speed-motor drive for the full-fashioned-hosiery machine, the introduction of the flexible top comb and the auxiliary top nipper knife to the cotton comber, the application of more blades and a cloth-turning device to the woolen and worsted shear, the redesign of cotton, worsted, and silk looms for greater speed, and so on almost, it seems, indefinitely.

It should be pointed out that included in the developments counted for comparison and otherwise referred to in this paper are only those which apply strictly to textile machinery, as compared with general industrial equipment applicable to a number of industries. Important advances have been made in the latter

---

[1] Associate Editor, *Textile World*. After some practical spinning and weaving experience in the experimental cotton mill of the United States Rubber Company, Mr. Fowle attended Lowell Textile Institute, where he received the degree of Bachelor of Textile Engineering. During a part of his attendance at the Institute he was in the employ of the Nashua Manufacturing Company. Following graduation he conducted an investigation of textile-mill wastes for the Commonwealth of Massachusetts, and then joined the editorial staff of *Textile World*, with which he has been connected for the last seven years.

Contributed by the Textile Division and presented at the Annual Meeting, New York, N. Y., Nov. 30 to Dec. 4, 1931, of The American Society of Mechanical Engineers.

Note: Statements and opinions advanced in papers are to be understood as individual expressions of their authors, and not those of the Society.

class, but any detailed discussion of them here would not be pertinent to the subject.

Causes of Advance

Having given some idea as to the importance of the advance which has recently been made, it is logical to consider the causes which were responsible for it. It appears to be a fact, in certain respects unfortunate, that the mills themselves are responsible for comparatively little mechanical progress. The reasons for this are not difficult to understand. It is not easy for them to make basic changes in their machinery, and they are not equipped to build and experiment extensively. Their organizations are not especially trained in basic mechanical principles and they often do not have free access to other mills from which to cull ideas. Rather than devote time and attention to the fundamental development of machinery, they are more apt to make the most of their equipment as it stands. Even those mills which are the exception to this rule, and there are several, cannot carry on a complete program of development totally unaided.

Thus it is that responsibility for mechanical progress in the textile industry lies at the door of the machinery builder, and to him one must turn for an explanation of any irregularities which occur in such progress. When the war boom collapsed in 1921, the momentum of the expansion which the mills had conducted carried the machinery builders fairly comfortably for two years. Few mill men realized that the poor condition of business would be more than temporary. Surely the expansion should be continued while the industry awaited the return and higher upswing of the business pendulum. The machinery builders had also expanded. For some time their activity was sustained by hope. Gradually they began to trim their sails by consolidating their plants, closing certain departments, and economizing in other ways.

At the same time they found it advisable to take another step. Since lack of expansion had killed the demand for the old lines of machines, their main hope lay in developing something which mills would wish to employ in order to improve the quality of their work or to reduce their operating costs. In this way mills would be induced to scrap their present equipment and make further purchases of machinery.

No doubt careful study was made of those factors which render a new machine popular. Concisely stated, these are improved production, quality of product, flexibility, durability, and dependability, together with decreased first cost, upkeep cost, labor cost, power consumption, floor space, and danger. Consequently there began to appear upon the market ingenious new machines having one or more of these qualifications.

Managers of machinery plants who believed that only temporary measures were necessary, as well as some philanthropic managers, entered a program of research largely to supply work to idle hands. Others, always eager to undertake such work, found, in slack business, a golden opportunity to devote time and attention to an activity dear to their hearts. Still others were driven to adopt such programs in order to meet the competition from firms which had already done so.

Just as in the textile industry proper there has lately been introduced a younger and more alert type of direction, so in the machinery industry has conservative, tradition-adhering management largely given place to a less restrained, more progressive type. This in itself is responsible for some of the advance. At the same time, and partly as a result of the newer type of management, more attention has been given to merchandising problems by both textile and machinery men, with the result that manufacturers both have come into closer contact with the users of their products, and have developed a better understanding of their needs. More thorough knowledge of the factors involved in style changes, for example, has influenced builders supplying equipment to certain branches of the industry (such as, notably, the knitting branch) to develop machinery capable of meeting more accurately the changing tastes and demands of the public. Recent trends toward novelties in textile products have also made their demands upon the inventing genius of the machinery builder.

Another and later, though much less important, stimulus was possibly the three textile-machinery shows of 1930, held respectively at Boston, Philadelphia, and Greenville. Naturally every exhibitor at such affairs strives to make his booth the center of interest and the main topic of discussion among the visitors.

The 1931 Recession

The slowing down in rate of development which has taken place this year is not particularly marked, and the rate is still far above normal. The causes which created and fostered the advance are still active, but an important opposing influence has taken effect. This is the failure of the machinery companies, thus far, to obtain full return on the investments they have made in development work. Naturally their resources are not unlimited, and it is necessary that a reasonable return be obtained before much further progress can be made.

Many mill men seem to entertain the notion that a new machine is the immediate result of a brilliant idea suddenly conceived. Such is not the tempo of modern achievement. New equipment of originality is today the result of long and expensive research and experiment. Large engineering staffs are required. One machinery firm, for example, has in recent years expanded this department to eight times its former size. Much extra drafting work is required. Considerable material and effort are wasted in following through fallacious ideas or delusive lines of reasoning. Many apparent accomplishments are found to be failures from a practical standpoint, as was the case with some of the innovations exhibited at last year's shows. To go into production on new lines often calls for expensive purchases of new machine tools on the part of the equipment manufacturer. A further expense is the many new parts which the builder must carry in stock for any new machine.

Some mill men might look on the selling prices of new machines in a more tolerant mood if they understood the actual cost of the development behind them. One of the more active machinery firms has spent approximately $600,000 in improving and originating machinery during the last four years. This expenditure was distributed mainly over 34 new products, making the average cost per machine around $17,500. Another, considerably smaller concern, spends on work of this character, many times over $10,000 a year. On five new machines recently developed by still another company the total expense for engineering, drafting, and experimental work alone amounted to nearly $36,000, exclusive of new machine tools, overhead, and selling expense. The latter item is of considerable importance in connection with new machinery.

The following comments from a machinery builder are pertinent: "On one of our new departures from the stereotyped machines of the past, we have spent eight years in bringing it to perfection. This involved practically the entire shop at one time or another. The amount of research work, both mechanical and chemical, preliminary design, new patterns, and subsequent changes in these patterns, not to mention complete scrapping of original machines to replace something else that has been discovered during the manufacture of the first machine, all added together form but a small total of the amount of expense in money and labor that is involved in such work."

The mill men are not prepared mentally or financially to absorb this cost at once. They can do so only gradually over a long period of time. The builder must, accordingly, price his machines

attractively. One builder, for example, has sold the first 11 machines of a new model at a loss of around 25 per cent. It is no wonder then that progressive builders find themselves without sufficient funds to maintain the pace of development work for an unlimited period.

Other factors are to a less extent responsible for the recession. The furore of development in 1929 and 1930 left many rough spots which must be ironed out before further new departures in the same direction can be made. A number of innovations have still to prove their worth in practice. In some cases adjustments in preceding and following processes must be made before a specific development can find a permanent status. It appears also that the human mind is capable of only a limited progress in a given time and that inventive genius, particularly when under such pressure as has lately been the case, requires periods of rest. Furthermore, failure in attempted accomplishments, although stimulating to some minds, are more likely to be discouraging and to foster inactivity. Finally, the mills are confused and embarrassed by too radical a shake-up in established ideas and methods and must be given time to accept the new developments.

Effects of Advance

The probable effects of this general advance in machine improvement are interesting to contemplate. Purchases of machinery will undoubtedly be stimulated, but whether the increase will be sufficient to repay the builder for his effort for some time to come is debatable. At least the majority of firms are certain to survive long enough to reap benefits from it.

The resulting activity will be of some immediate benefit to general business. Probably 70 per cent of the money spent by textile mills for new machinery is absorbed by the employees and, under normal conditions, the stockholders of the machinery companies, while the remainder goes to the industries which supply the iron, steel, wood, leather, rubber, brass, copper, coal, oil, paint, and other raw materials. All workers in those industries are purchasers of textiles, and the money they spend for other things reaches other textile consumers.

The most general tendency in new machinery is toward increased production. Often an operation is now carried out at more than double the old rate of speed, thanks in some cases to the application of new mechanical principles and in many others to such simple improvements as the adoption of anti-friction bearings. The fear has been expressed that the textile industry, already overproducing, will find any improvement in the efficiency of its individual units more disastrous than helpful.

Any manager who makes the mistake of believing that in these times the benefits to be derived from high-production machinery lie in increasing output is steering toward disaster. It is exceedingly essential that high-production machinery be used to give the same, or less, total mill output. Of course this output will be attained at reduced cost. The possibility of cost reduction lies mainly in minimizing the requirements for labor, upkeep, and power.

All improved machinery does not offer increased production. Some affords mainly an improvement in quality of product or in the ease by which changes may be made in the type or character of product. No danger is seen in the installation of such machines, unless the improvements they offer are not sufficient to make the investment returnable within a reasonable period of time.

It has even been suggested that the machinery producer is forcing the obsolescence of present equipment to his own benefit, and to the detriment of the industry. Already short of funds, it is argued, the mills are suddenly called upon to make new and unexpected expenditures, which they cannot afford. There are two answers to this criticism, both exonerating the builder from exerting any detrimental influence, although not denying that he naturally has his own interests at heart.

In the first place, the purchase of improved machinery is not in the long run an expense to the mill. If it is worth installing, it pays its own way, returning to the mill all which was spent on it, and adding more. Often it permits a reduction in selling price on the mill product, with the result that the market is widened and overproduction is, in effect, reduced or eliminated.

In the second place, it is only the mills in at least a fair financial position which can afford to purchase the new equipment. Continual renovation of these plants will widen the gap between them and those competitors which are less efficient or which are faced by insurmountable obstacles, such as unfortunate location, for example. The result of this will be that one of the most frequently proposed solutions to the textile tangle will be accelerated—the mills which are not capable of operating profitably against the competition of their stronger neighbors will be forced more promptly out of the picture. Again, overproduction will be reduced or eliminated and the major cause of the disastrous price cutting from which the industry has long suffered will be removed. The mills which remain, therefore, will be able to sell what they produce at a fair profit.

Therefore, in the possibility of the mills failing to recognize the importance of reducing costs without increasing total output lies the only danger. The mills may feel that an up-to-date plant can afford to increase its production in order that it may assume some of the business of the departing inefficient plant. It must be remembered, however, that shaking off the shackles of ruinous competition is, like the working of that law of evolution known as the survival of the fittest, a gradual process. Any appreciable attempt to take advantage of it too early will obliterate all the potential gain which it creates. Instead of eliminating only the inefficient mills, it will become necessary to eliminate many of the better ones as well.

Furthermore, it is unfortunately true that the elimination of a mill does not necessarily remove from competition all the machinery which it contains. In this connection it is interesting to note that, of the machinery in the many knitting mills of Brooklyn, New York, which have gone out of business in recent years, practically all of it is in operation today, although in different hands. Far too little scrapping of machinery is undertaken by the textile industry, not only in the case of mills which close down, but also in that of mills which replace obsolete machinery with new. It takes a long-distance view into the future for a manufacturer to appreciate the ultimate importance to himself of reducing his replaced machinery to scrap. Its resale value for active production is naturally tempting in view of the fact that the income so received reduces in effect the actual cost of the new equipment. Yet more farsightedness in this respect is needed, and one must live in hope that before very long this fact will receive the full recognition it deserves.

It is therefore unsafe at this time to draw up a workable estimate of any decrease in production which the current improvement in machinery may cause. Instead, it is safe to assume only that, under any circumstances, there is likely to be an overproduction for some time to come, and that consequently an attempt to increase the output of plants must not be made. It will be far better to err on the side of creating underproduction than to maintain present conditions.

Another effect of the advance is an intensifying of the problem of allowing properly for obsolescence. Recent study of the methods employed by mills for anticipating and deciding upon replacement of machinery has disclosed an appalling carelessness and even lack of understanding regarding this matter. Depreciation reserves appearing on income-tax returns do not actually exist. No systematic methods for keeping track of the condition

of various units of the mill machinery are adhered to. Many mills make no special effort to investigate and study new equipment. Very many lack the knowledge of costs needed to calculate when a new machine is capable of paying for itself. The current advance in machinery improvement is bringing home, as nothing else could, the vital necessity of paying attention to these things.

Due to the fact that even the stronger mills are in a none too healthy condition financially, one more result of the advance is likely to be the general adoption of a policy of buying equipment on long-term credit. Since the machinery builders lack the resources to supply an unlimited amount of credit, the assistance of credit companies must be solicited.

Discussion

ALBERT PALMER.[2] In the weaving-machinery business the period of activity described by the author began in 1924. In that year, for the first time in 20 years, the number of weaving patents issued exceeded 300. The number increased annually to over 400 in 1926 and then dropped somewhat during the succeeding years. The average annual number issued, however, from 1924 to date is almost twice the average annual number issued during the 10 years prior to 1924.

Coincident with this increase in the number of new inventions was the activity of redesigning existing equipment. In the essentials of construction, looms were no different in 1924 than they were 40 years earlier; in fact, some of the parts used on looms built in 1924 were made from patterns that were about 40 years old.

As the author says, the incentive and the opportunity to produce new looms came with the recession which started in the industry during the latter part of 1926. Realizing that there are thousands of worn-out weaving machines in operation that should be replaced, the builders undertook to construct machines that would produce at a low cost the highest quality of goods and that at the same time would give great flexibility as to the type of fabric woven.

To redesign completely a machine like a loom costs between $75,000 and $100,000. That such a large amount of money is required can be appreciated when consideration is given to the work that must be done.

In a relatively simple machine such as a cone-harness non-automatic silk loom there are about 770 pieces, of which 33 per cent are castings, 14 per cent are shafting and forgings, 6 per cent are wooden parts, and 47 per cent are miscellaneous items such as studs, collars, pins, etc. Each of these pieces must be considered from the standpoint of cost, quality, and suitability to the purpose for which it is used. In practically every instance changes are necessary, with the result that money must be expended, not only for the original study of the part, but also for drawings, patterns, jigs and fixtures, and often for machine tools by which to make the new parts.

The mills in general do not realize that the selling prices of new machinery at the beginning do not include any profit or even a share of the development expense. In fact, until quite a substantial number of units have been built, the selling price does not even cover the factory cost, mainly because the plant has not been converted to the new line of manufacture.

The chief problem of selling new machinery is to obtain a sympathetic hearing from the textile industry. While many mill executives are anxious to improve their methods, there are others who actually resist the efforts of machinery builders to introduce new ideas. Instead of welcoming the opportunity to cooperate, they place the burden of proof on the builder and force him to work under the most unfair odds. The result is that the builder is put to unreasonable expense, and sometimes, because of the opposition of mill employees, is obliged to withdraw from the project entirely.

The author's statements with regard to the necessity for preventing an increase in the productive capacity of the industry are correct. So are those with reference to the matter of obsolescence and the handling of depreciation reserves. That more knowledge concerning these matters of cost is needed is demonstrated by contact with the industry.

EUGENE SZEPESI.[3] The progress made in the construction of textile machinery within the past few years is of vital importance, not only because it represents a technical advancement of the textile industry, but also because these events bring to the foreground the fact that the economic ills of the industry have been consistently ascribed to consequences, instead of to the originating causes.

The builders of machinery and equipment have been accused for the past quarter of a century of backwardness. This was unquestionably true, because if we survey the technical progress of the American industries, we find with minor exceptions the textile industry decidedly behind the other branches of industrial arts. But this is already an effect and not a cause. The originating cause is due to the attitude of the producing factors of the industry, because no progressive development can be expected in any industrial branch where a 20- or even a 30-year-old equipment is considered just as good as new. This fallacious conception is mainly responsible for the past backwardness of technical developments in the industry as well as for its chronic economic plight. Behind this is hidden much of the overproduction of unprofitable merchandise, because the unflexible equipment cannot respond quick enough to the changes of the demand. There is also the horizontal overexpansion of the industry during the past decade instead of a vertical replacement, which helped to bring about the present situation. And last, but not least, the universal transgression of the economic laws, expressed, as an over-depreciated equipment, with the funds expended on everything but its original purpose, has acted as the keystone to the present situation.

With all these facts in mind, the notable advance made by the makers of textile machinery within the past few years, no matter how gratifying, comes unfortunately too late to serve as the chief medium for the economic rehabilitation of the industry. No question about it—it will be contributory, but on the whole it can play only a minor role.

To begin with from a financial point of view, the industry was never less prepared than it is today for a radical replacement of its basic equipment. It needs no argument, the equipment made today is far superior to the cross-section still in use by the industry at large, but as it is today, the difference of the cost of production on new equipment and of the equipment in use is not sufficient to warrant an immediate discard of most of the equipment. This means that the replacement procedure must be gradual, and a decade is by no means a too conservative estimate for a visible effect of such new equipment on the industry. Even this will be possible only if the machine manufacturers succeed through coordinated and intelligent effort in eliminating the present detrimental practices and misconceptions concerning depreciation which is so deeply rooted in the industry.

To make a visible progress in the replacement of old machinery, the rates of depreciation must be increased by the individual manufacturers and the accumulated funds systematically applied for its only purpose, the replacement of equipment.

Without such intermediate steps, the machine manufacturers

[2] Research Assistant, Crompton & Knowles, Worcester, Mass. Jun. A.S.M.E.

[3] Consulting Engineer, New York, N. Y. Mem. A.S.M.E.

cannot continue their costly experiments and the investments essential for the production of improved equipment. Without sufficient sales in sight for new equipment a reaction is bound to follow.

There we have a wheel within a wheel with an undeserved disappointment in store for the makers of textile machinery, unless they can work out the economic phases of their distribution problem through a collective action, which as far as is known, has not yet been undertaken.

Now for the other phases of the economic possibilities of the textile industry As has been stated, the advance made in the construction of the basic textile machinery represents only a part of the probable improvements of production and the reduction of operating costs.

The handling of the product between the basic conversion operations is hopelessly behind times if compared with other industries, and it is amazing that machine manufacturers have so far failed to recognize the golden opportunity of business that would follow the development of up-to-date and scientifically constructed secondary equipment for the textile industry.

The equipment used in our mills for the handling of laps, sliver, roving, yarn, and cloth has not been improved for generations. It is not an exaggerated estimate that 50 per cent of waste and imperfect products is due to negligence and improper handling of the product between the operations. Similarly, production losses during the spinning conversion and weaving operations are to a notable degree due to the same cause. Improvements in this direction would bring about a notable advantage in quality of product, increased production, and lowered cost of production, and at a decidedly lesser investment of additional capital than would be required by the replacement of the basic equipment—hence, more in conformity with the present economic ability of the industry.

Finally, there is another direction toward better and more production, particularly of the spinning operations, which is today only superficially exploited by the industry. This is the functionalization of the roving and spinning operations. If this opportunity would be exploited to its fullest possible extent, the results would in many instances mean as much as the replacement of the old equipment by new ones, but with the continuation of the present methods of operation.

The principle of this possibility is the functionalization of the service to the machinery in such a manner that the complex duties of the spinning operators are separated in such a way that a worker looks only after one particular service. Using this principle the workers are not assigned to a definite number of machines, but move from machine to machine continuously in the form of an endless chain.

For instance, according to this inverted conveyor principle (because instead of the machines moving to the worker, the worker moves to the machines) the "piecer-on" devotes her time exclusively to the mending of broken thread, followed at a proper distance by another "piecer-on." The distance between them depends on the size and the grade of the yarn, and is determined by the minimum allowable time a spindle should be permitted to remain idle—hence, maximum production and minimum waste are the consequence. Should the roving run on occasions below the standard, this fact is immediately known, because the distance between workers will increase, and a reserve operator can be immediately inserted into the chain to take care of the deficiency, and thus reestablish standard production, standard quality, and standard waste immediately.

The same principle is used for all of the other functions of the spinning operations, such as the replacement of the roving, the cleaning of rails, clearer rolls, etc., and the cleaning of the machine itself.

This is only a sketchy illustration of the possibilities of functionalization of many of the operations in the textile industry, and it is up to the members of the engineering profession engaged in the textile industry to bend their efforts toward such constructive directions as functionalization, the improvement of the secondary equipment, and the development of proper plans for the replacement of the prime equipment. This would be their share of contribution toward the economic rehabilitation of the textile industry, not only individually, but also collectively. The engineers should bend every effort to cooperate intelligently with the machine makers as well as with the producers to bring about a well-balanced progress in the future of the textile industry.

Progress in Wood Industries

Wood-Utilization Research at Forest Products Laboratory

Arthur Koehler.[1] A new surface treatment was developed for nails by which their resistance to withdrawal was made from two to three times that of plain nails. This treatment is from 30 to 50 per cent better than the cement coating now commonly used.

It was found that by employing the proper technique, glued laminated beams could be made with horizontal joints that would not fail by shear in the joints. This type of beam construction offers the possible use of high-grade material along the top and bottom, with inner layers of lower grade.

In the search for chemical treatments to control the shrinking and swelling of wood several were found that possessed high effectiveness, but all of these made the wood attract moisture at high humidities and become too damp for practical use. The search is being continued, with the object either of discovering effective chemicals that are not too hygroscopic or of discovering satisfactory ways of reducing the hygroscopic properties of the wood after treatment.

Compounds with the basic radical ammonium, aluminum, lithium, magnesium, tin, or zinc and the acid radical arsenate, arsenite, borate, molybdate, or phosphate were found to be particularly effective in reducing the hazards of wood from the standpoint of ignition and spread of fire.

A detailed discussion of the strength and serviceability of wooden crates was prepared for publication as a bulletin of the Department of Agriculture.

The effect of temperature on the seasoning degrade of beech, birch, and maple small-dimension stock was determined to the end of establishing the maximum temperatures which may be safely used in drying this class of material.

A new wood hygrostat employing the swelling and shrinking of a thin strip of wood for the control of the humidity condition in a dry kiln was perfected.

In the study of lumber storage and handling problems, it was found that the effect on changes in average moisture content of lumber was negligible between unheated open and unheated closed sheds, provided both types of shed afford adequate protection against rain. Some heating was found necessary under most conditions of lumber storage in order to maintain a moisture content in the wood as low as 7 per cent.

Lumber Manufacturing

Frank P. Cartwright.[2] There is a strong trend toward greater refinement or more complete fabrication of lumber at the mill. Examples of this are the guide-line framing and four-square lumber available, the former being marked in feet and inches for convenience of measurement and the latter being squared to exact length.

Wilson Compton.[3] U. S. Census reports on footage of lumber cut in 1931 are not yet available. Estimate has been made by the Federal Reserve Board of production of 16,400,000 ft. It is estimated that replacement growth is from 7 to 10 billion feet a year.

The Timber Conservation Board estimates that consumption of lumber, including domestic and exports in 1931, was approximately 18,710,000,000 ft. Imports totaled about 700,000,000 ft. Some of the consumption in 1931 was of lumber taken from stocks which decreased appreciably during the year. Stocks at the mills decreased from 10 to 20 per cent; at retail yards probably about 10 to 12 per cent, during the year.

The lumber industry in 1932 was at its lowest point in many years in volume of production, prices at the mills, and consumption. This was largely due to the decline in building and especially in residential construction. Building contracts were only about 40 per cent of what they were in 1931, which in turn was a low building year, as compared with 1928 and 1929. The railroads, which customarily use directly about 15 per cent of the lumber cut, purchased only about one-third as much lumber and tie material in 1932 as in 1929 and ordered only a small percentage of new freight cars as compared with that year. The farmer and small-town resident used less lumber than normally, due to low level of farm prices and the farmer's financial inability to erect new buildings or to keep up adequate repairs.

After building, including sash, doors, millwork, interior trim, flooring, etc., more lumber is normally used for boxes and crating than in any other industry. Boxes and crates shared in the general decline in 1932, but less severely than many industries, since its volume depends largely upon the movement of merchandise, of fruits, vegetables, etc.

Pursuant to the recommendations of the U. S. Timber Conservation Board, lumber production has been restricted in line with demand and stocks have been reduced during the year, thus placing the industry in a stronger statistical position than a year ago.

Wood Utilization

Axel H. Oxholm.[4] The most important development is the work on metal connectors for wood construction, the culmination of 14 years of constant research and labor. This is a cooperative undertaking with the Forest Products Laboratory. It is certain that these metal connectors can be worked out to advantage in connection with wooden parts of machinery, agricultural implements, boxes and crates, and perhaps also for furniture. So far we have concentrated on the building construction aspect.

Another matter of considerable importance is the study of nonutilized wood. We have just finished up the New York survey this year, and have previously covered the States of Virginia, North Carolina, and Maryland. We can show a number of excellent examples of how these reports have stimulated the utilization of wood waste.

The prefabrication of houses has received an important impetus, following similar developments in the steel industry. A dozen concerns in this line are now developing plans for standardized prefabricated homes.

Fireproofed Wood

Ernest Hartman.[5] The Forest Products Laboratory is continuing its studies of chemicals useful in the fireproofing of

wood. The results are recorded annually in the proceedings of the American Wood Preservers Association. Further progress has been reported by Committee C-5 of the A.S.T.M. in testing the fire retardance of structural materials. Work being carried on under the direction of Prof. A. H. Beyer, of Columbia University, aims to measure not only the fire retardance of doors of fireproofed wood, but also to measure the heat transmitted, as well as the volume and character of the smoke passed by doors during test. A gas-fired furnace for testing wood-door assemblies has been constructed during the past year in the metropolitan area, still further attesting progress in the field of retarding the ignition and combustion of wood. A special committee of the National Fire Protection Association during 1932 brought in a report in which it is recognized that the fire hazard is reduced as a result of using fireproofed wood. No new processes or materials have been presented during the past year.

Dry-Kiln Progress

Kenneth Redman.[6] The year has been marked by a more widespread use of forced recirculation of the air by means of internal fans—i.e., fans placed inside of the kiln. The kiln manufacturers are advocating air movements far in excess of the 25 ft per min speed which has been suggested by the Forest Products Laboratory as the maximum speed required in drying hardwoods. The slight extra speed in drying is accompanied by large increase in mechanical horsepower to drive the fans, so that it would seem that the laboratory recommendations still remain quite sound practice. Anything that increases the cost per thousand of drying can hardly be classed as an improvement.

On the other hand, forced circulation to insure the 25 ft per min rate is possible at very slight cost. This may be put in for roughly $6 per lineal kiln foot with an electric load of $1^1/_4$ hp per 100 lineal kiln feet. Such an investment is quickly amortized by increased production, whereas a power load of 21 hp per 100 kiln feet as is advocated in certain instances is likely to be a dubious investment.

Between these extremes is a recent effort to introduce a forced circulation into the center of each truck load with a motor-driven unit blowing into a plenum chamber. After a year's trial we will know more about it, but several questionable mechanical features, such as keeping the motor cool, are at once apparent.

In addition to more air movement, the control of such air movement is being given more careful attention, and far better results are being secured.

As regards kiln practice in general, it is safe to state that higher temperatures are being used in most hardwood drying, toward the end of the kiln run. This is not only safe, but invariably results in stock with less stress than where low final temperatures were used.

Furniture Manufacturing

G. Rollo Petrie.[7] It would seem that the most significant progress to be credited to the furniture industry during 1932 was the beginning of the realization that the unit costs of the product have less influence on the net profits than had been previously taken for granted.

During the year, more actual consumer-demand analysis investigations have been instigated than for probably any similar period, and while practically all of these attempts toward research-controlled merchandising have been initiated by advertising agencies or publications and by large retail organizations, it is nevertheless significant that they have been started, as they are certain to be continued and enlarged by their adoption by the industry in general, probably through the trade associations.

Better lumber handling, better machining and gluing practice, and better finishing methods are not only lowering production costs, but are giving the furniture consumer better utilization value in his purchases and more satisfaction with them.

The use to which new furniture can be put, with the pleasure which can be derived from its ownership, is beginning to be made the basis of appeals in the endeavor to influence the spending of more consumer dollars for furniture than for other articles of intimate use and possibly more actual utility convenience.

It has been seen that the proper course to pursue is that of increasing the popular desire for furniture and not that of each individual manufacturer's simply striving to secure a greater portion of the existing demand by price cutting or the sacrifice of quality, or both.

Designs seem to have been toned down somewhat on the average, and a distinctly American motif is more apparent than for some time, both with respect to the popular Early American or provincial pieces and to the increasing popularity of a modified modern type in which the appeal depends on simplicity and a clean-cut balance of each component part.

There is also the appearance of a faint recognition of the fact that because the home across the street has a certain suite made by a certain manufacturer is no reason why an exact duplicate should not be purchased. This trend is belatedly following that of the automobile mass-production idea which showed long ago that the advantages of the production of duplicate items are generally appreciated and the fact that many others own identical units is not a deterrent to pride of ownership.

It would seem as though this realization would tend to bring back the advantages of the large- and medium-sized factories as contrasted with the recent almost actual price control of the small and oftentimes unreliable plants which could afford the rapid and bewildering style changes better than their larger and more stable competitors.

The increased success of efforts toward less frequent market periods is another step toward more efficient marketing and manufacturing methods (through more stable styles), as is also the gaining popularity of the possible advantages of admitting consumers to these central market exhibitions at times which would not conflict with the scheduled dealer buying periods and for the purpose of creating consumer desire by their viewing of the latest "models."

Millwork and Doors

Sern Madsen.[8] An amazing number of patents were granted on new window developments. Probably 99 per cent of them will never be developed further than obtaining the patent. The efforts have been devoted mostly to obtaining narrow center mullions for multiple windows, improved weatherstripping means, balancing means, and means for washing the outside of the window from the inside. These features apply to the double-hung type of window.

There have also been some developments on casement sash. Recently a new type of casement window was brought out, which is provided with a metal-framed pane of glass which is inserted to swing with the window proper and serves as a storm sash or a double-glass arrangement. It can be removed easily for window washing. A metal-framed screen is used inside for keeping out insects. In this window at least is shown a tendency to combine the use of metal and wood to a greater extent. This window comes completely weatherstripped. Dividing bars are aluminum.

An outstanding contribution of the millwork industries has been a new window. This window is very effectively weatherstripped, cannot stick in the frame, will not rattle, and has elimi-

[7] St. Johns Table Company, Cadillac, Mich. Mem. A.S.M.E.

[8] Curtis Companies, Inc., Clinton, Iowa, Mem. A.S.M.E.

nated the use of weights, cords, and pulleys. This window makes possible the use of very narrow trim and narrow mullions. It also has other valuable features, such as improved sealing of frame to wall joint.

Another outstanding development is a "miter-tite" window and door trim.

During the last year there has also been some development in the way of overhead-garage-door hardware. This development really started about two years ago, and now many companies have developed hardware or some sort or other for making one-piece garage doors lift upward and overhead inside the garage.

It is quite apparent that, with reduced volume in the millwork business, millwork manufacturers have devoted more attention to development of new products.

Plywood and Glues

Thos D. Perry.[9] There has been a marked change of attitude on the part of plywood manufacturers in the United States toward the hot-press, dry-glue method of assembling plywood which has been successfully practiced for some years in Europe. This change has found expression in extensive research work along lines of wider markets and simpler processing, and has led to several initial installations of hot-pressing plywood equipment. The industry, as a whole, is only on the threshold of this far-reaching change.

It becomes more and more apparent that the old method of cold-press wet glue was anything but logical, since it required the meticulous drying of all wood parts to approximately normal 5 per cent moisture content preparatory to applying the fluid glue that would carry this moisture content up to 15 per cent and sometimes 20 per cent during the pressing operation. The internal stress and strain introduced during the water-acquisition, wood-expansion step had to be later neutralized or eliminated as far as possible by a very careful redrying, which in turn might set up different internal stresses and strains.

Compared with this illogical process is the new and simpler way with its pre-drying of material to be glued to known moisture content and its application of sheet or powdered glue. This results in a complete and final glue joint in the hot press, giving a sheen or luster to the face veneer, and requiring no subsequent redrying or attempts to neutralize interior stresses or strains. The product comes out much flatter, and the heat element permits a completely waterproof bond.

The glues used in this hot-press, dry-glue procedure may be of the phenolic-resin type, which comes in sheet or powdered form, or animal glue, or a mixture of casein and latex. These latter two are prespread on the cross-band or other glue-receiving member and predried before pressing.

These plywood developments are presenting a wide range of opportunities never before available for plywood products, and it is the belief of pioneers in this new line that the plywood industry will gain immeasurably by these decidedly evolutionary, if not revolutionary, changes in factory processes.

Woodworking Machinery

Chester L. Babcock.[10] The development of woodworking machinery during the last year has been retarded by the lack of demand for equipment due to the economic depression, which has caused the liquidation of several woodworking plants, making available much modern equipment at reduced prices.

The small short-coupled 4-in. and 6-in. electric molders and automatic shapers and multiple carving machines of from 10 to 24 spindles have been in greatest demand, and these types of machines will continue to be improved in an effort to enable woodworkers to lower costs and realize a profit, and yet meet the incessant demand for lower-priced goods.

Blower systems with circuit mains using flight conveyors within the airtight main pipes are gradually, due to economy of operation and adaptability, replacing the systems which depend entirely on air suction, and several have been installed in large and small plants during the past year.

Abrasives

E. C. Schacht.[11] Developments in the coated abrasive industry have been almost wholly concerned with product improvement. Of major importance to the woodworking industry was the general introduction of heat-treated garnet, which has met with universal favor on account of the considerable increase in sanding production which results from the hardening and toughening of the garnet mineral.

Manufacturing processes have been carefully studied with a view to perfecting coatings and controlling the mineral-particle relationships so as to increase cutting efficiency. Factory testing against known standards indicates a much greater coating uniformity, which must be apparent in field applications. The variation from run to run is negligible compared to the tolerance of ten years ago. Another feature which must be readily noticeable and appreciated by the sandpaper user is the improved uniformity of flexibility. This is obtained by securing the optimum moisture content in the coated goods at the time of the flexing operation. Not only is the same flexibility maintained from roll to roll and from run to run, but the correct degree of flexibility is produced for the various classes of goods according to the field application—for example, very flexible spindle paper, finishing cloth, and sheet material for hand sanding and less flexible for flat-belt and drum-sander operations.

The rate of substitution of aluminum oxide for garnet in the woodworking industry did not continue in 1932 as in the immediately preceding years. As a matter of fact, the sales relation of the two products remained almost static. On account of abnormal operating conditions in the woodworking industry, no significance is attached to this relation. It will probably take several years before the ultimate correct field applications are generally made throughout the industry for both minerals.

Dust Collecting

H. A. Colvin.[12] Progress in this field has vitally affected the woodworking industry this year, by greater use of the mechanical self-clearing dust-collecting main, which allows mobility in manufacturing operations. This mobility permits taking advantage of worth-while improvements in methods and in productive machines, allows new machine layouts to meet variations in design and kind of product, avoids excessive expense on the services of supply, and makes possible any desired combinations of machines for less-than-maximum schedules, without increasing the production cost per unit of output.

Education

Thos. D. Perry.[9] A campaign for the annual crop of engineers trained to serve the woodworking industry is proceeding vigorously, with some converts at every turn. It is not an easy matter, however, to overturn or substantially modify the existing engineering curricula in a short time, especially in eras of closely prepared budgets, when every new study must be most carefully investigated.

There are three principal issues that seem to stand out as problems in the minds of the educators:

[9] United Plywood Corp., New Albany, Ind. Mem. A.S.M.E.
[10] Babcock Machinery Corp., New York, N. Y. Assoc-Mem. A.S.M.E.
[11] Behr-Manning Corporation, Troy, N. Y.
[12] Allington & Curtis Mfg. Co., Saginaw, Mich.

(1) Is a specialized woodworking-engineering education desirable or is a general fundamental engineering course better with only a few specialized subjects? In the former case, the expense of instruction is materially increased and the field for graduates correspondingly lessened. In the latter case, considerable adjustment and experience are required before full activity in the industry can be accomplished.

(2) Should there not be greater recognition of wood as a raw material? In most of the fundamental engineering courses wood and its various products have been almost ignored; yet all of the textbooks and courses of study since the establishment of the technical schools seem to have been such as to encourage metal-mindedness and not to recognize the fact that in the industrial world the value of wood used ranks close to that of iron and steel.

(3) Shall courses in woodworking-engineering education be best adapted to so-called forestry schools or so-called engineering schools? There are arguments on both sides of this question.

The chairman of the committee has been working on this subject through the faculties and deans of Purdue University, University of Michigan, Massachusetts Institute of Technology, and University of Iowa.

Investigation of Mechanical Properties of Certain Tropical Timbers

W. Kynoch.[13] All wood material for the work was collected in the respective countries of origin by persons believed to be competent to recognize the woods in the forms of standing trees. The School of Forestry and Conservation has had no control over collection.

A sample from every bolt received has been submitted to Prof. S. J. Record, of Yale University, for examination as to identity. In some cases an element of doubt as to specific identity exists, but in the majority of cases identity is believed to be well established.

All timber reached New York in the form of logs and was there sawed into test-piece blanks, under our direction, in accordance with standard procedure. All material, therefore, was received at Ann Arbor in the form of these blanks, with the exception that cativo, the first wood tested, was received as a log, and a quantity of mahogany for special hardness tests, originating in different districts in Central and South America, was received in the form of planks.

The timber in hand at Ann Arbor for testing at the present time represents 48 wood species, originating in Brazil, British Guiana, Mexico, Nicaragua, Panama, Peru, Philippine Islands, San Domingo, Venezuela, and West Africa.

The methods of testing employed are those specified in "Standard Methods of Testing Small Clear Specimens of Timber," serial designation D-143-27, of the A.S.T.M.

The work in progress on the material in hand falls under the following heads:

(1) Machining of test-piece blanks and manufacture of standard test pieces for the different kinds of tests and determinations.

(2) Mechanical tests and physical determinations as called for in D-143-27.

(3) Mathematical computations.

(4) Miscellaneous items, including monthly and (later) weekly weighings of blanks for air-dry tests and maintenance of the necessary temperature and relative-humidity conditions in the later stages of conditioning air-dry test pieces for testing.

(5) Preparation of reports.

Work on material representing five wood species has been completed. Four of these are Venezuelan woods and one is from Panama. Work on 17 additional species is well advanced, and in this group the testing of the green material of eight species has been finished. Work on several more species has been begun. During the year ending October 31, 1932, a total of a little more than 8000 tests and determinations was made.

A report on the (completed) work on cativo, the species from Panama, was prepared by W. Kynoch in April, 1930, and was transmitted at that time to the United Fruit Company, which supplied the timber representing this wood.

A progress report covering work to May 31, 1932, on the six species from Brazil was prepared by W. Kynoch last spring for transmission to the Brazilian Government through the Tropical Plant Research Foundation, Washington, D. C.

Wood Finishes

Paul S. Kennedy.[14] Development of improved and more economical wood finishes was particularly fruitful during 1932. Probably the most salient features include:

Baking Finishes on Wood. Temperatures of 150 to 160 F convert varnishes (new synthetic-resin type in particular) to harder and more durable films. Possible limitations for general employment are the type of wood unit to be finished, close control of application, and evident necessity of curtailed baking periods. A possible important extension is the use of synthetic-resin enamels on general cabinet work. Many of these bake rather quickly to a vitreous-like surface and have been adopted with success on small baked wood parts, such as brush handles etc., replacing oil- and varnish-type enamels in previous use.

Stains and Fillers. Quick drying, non-grain-raising, fast-to-light stains have made extended replacement of old-type acid and water stains, with important savings and new color effects. Fast-to-light combination stain filler came into use; it reduces cost in many instances, but is overpriced for some production. A filler was finally developed to give perfect adhesion with lacquer, but is at present too costly for most production.

Clears and Flats. Synthetic-resin-base varnishes have been greatly improved, particularly from the standpoint of chemica resistance and case hardening. A new silica pigment "flatting agent" succeeds in eliminating most of the former objections to transparent lacquer and varnish flat finishes, but is rather costly in varnish vehicles.

Outstanding Specialties. Imitation of metal finish has been most successful, particularly with wooden caskets, by the use of so-called opalescent lacquers. Imitation of ebony finish, used principally on pianos, is secured by a unique treatment of pure carbon-black pigment, which permits a black lacquer to dry naturally to a high gloss, and eliminates use of anilines, which have been so troublesome in the past.

Modern Door Construction—Manufacture and Use

By SERN MADSEN,[1] CLINTON, IOWA

Doors, along with windows, constitute the moving parts of a building, and their manufacture must provide for all contingencies that might affect their fit and wear and durability. The many kinds of doors are described, and the author details the methods of construction and the machines that are used. Advice is given for the proper handling of the door from the preparation of the lumber for the mill processes, through all the details of construction and finishing, the shipping of the completed product, and its installation in the building for which it is intended.

NO PART of a building is used more than its doors. With the windows they constitute the only moving parts. For this reason a door must be constructed most carefully. Upon it are imposed all conditions of use and abuse and the effects of dry and wet weather. Up to the middle of the last century most doors were hand made. Woodworking machines with revolving cutter heads, such as planers, molders, and tenoners, were not developed extensively until that time. These early machines as used in door manufacture still left much hand work to be done. Sanding and trimming were largely hand operations.

The doors were built with mortise-and-tenon construction and were generally held together with wooden crosspins driven through the tenons or by wedges driven into the ends of the tenons. Such construction was somewhat slow and the joints were likely to open and allow the doors to sag. Such construction also required an extra amount of lumber for the tenons. Use of glue on tenon joints was of little value because the shrink and swell of wide tenons in the deep mortises would tend to shear the glued joint and destroy its holding power.

Since mortising and tenoning were comparatively expensive, doors were constructed with as few of this type of joint as practical. This no doubt accounts for the prevailing use of the four-panel door during this period.

In these earlier doors the panels were made of solid wood and had raised surfaces in the centers. Naturally the size of panels across grain had to be limited to reduce the bad effects of shrinking or swelling. This led to the use of dividing bars or vertical mullions.

In the early nineties the modern roll-feed drum sander was developed, and it influenced the kind of door to be made. Previous to this doors were finished largely by hand. A type of door planer had been developed that had a head set at a 45-deg angle, and the door was passed under it. Such an arrangement would surface the door with little tendency to tear the grain on the cross-rails. About all such a machine could do was to level the surface. To finish the surface large sander disks were mounted on vertical shafts. The disks were covered with sand paper on the under face, and the doors were sanded by passing them under the disk, which was rotated at a suitable speed. With such methods of finishing and with the mortise-and-tenon joint, the highly hand-decorated doors of the period were a logical result.

The drum sander at once made the plainer types of door more economical to make and influenced its use where the cheaper doors were wanted.

About 1900 the doweled door construction was introduced, and with it came newer designs. The cost of making rail-to-stile joints was reduced, and the five-cross-panel door was a logical result. In this door all rails could be cut and tenoned identically, and only two widths were required. The panels could all be made identical in size and shape, and the assembly of the door was simple.

Use of plywood for panels came at about the same time and made practical the use of larger panels. This resulted in the one-panel and two-panel doors. Extended use of veneers and plywood led to development of slab or smooth-faced doors.

Thus the development of new machines and methods and the employment of new materials changed the whole business of door manufacturing.

The influence of the architect has probably had less to do with changes in the trend toward modern door manufacture than have machinery, methods, and materials.

Modern Door Details

Modern doors can of course be made of almost any desired height and width. The usual height for residences is 6 to 7 ft and the width from 2 to 3 ft. Garage doors average 8 ft wide by 7 1/2 to 8 ft in height. The thickness of present-day doors depends upon the use. Light closet doors, storm doors, etc. may be of 1 1/8 in. thick stiles and rails. Ordinary residence interior doors are 1 3/8 in. thick. Larger residences, offices, public buildings, etc., are fitted with 1 3/4 in. thick doors. Greater thicknesses are often found in public buildings, while as little as 3/4 in. is used for cupboards, cabinets, and the like.

The details of sticking or molding of doors is varied. The common types are shown in Fig. 1, the most common being O. G., ovolo, and rule joint.

Aside from the paneled types there are some newer designs that may be considered among the modern doors. The French door is little else than a swinging sash with the stiles and rails made heavier. The glass is usually held by means of wooden stops nailed in. The slab doors with smooth faces are used extensively in hotels, hospitals, etc. A plain-faced slab door

He has been with Curtis Companies since 1913. Mr. Madsen is a designer of special woodworking machinery. He supervised the rebuilding of the Clinton plant of Curtis Companies. He is the author of various papers for the Wood Industries Division, A.S.M.E., and of several articles for woodworking magazines. He has long been engaged in research and in improvement of products of builders' woodwork and methods of manufacturing.

Presented at the meeting of the Wood Industries Division of The American Society of Mechanical Engineers, Jamestown, N. Y., November 15 and 16, 1932.

Note: Statements and opinions advanced in papers are to be understood as individual expressions of their authors, and not those of the Society.

ordinarily has a thin face veneer, and is often ornamented by inlays. Some have a thicker face veneer and vertical V-shaped grooves to give the effect of heavy plank construction. Openings of various shapes and arrangements are employed for design effects. Plain or leaded glass is stopped into such openings. Another practice is to trim the tops in curved or Gothic designs.

Much of the effect or beauty of these modern doors depends upon the entrance frame. In developing pleasing combinations of door and frame the modern architect has made his contribution.

By different arrangements of panels, rails, etc., modern door-construction methods permit quantity production of doors classified by architects as French, English, Colonial, Spanish, etc. There is at present probably more thought given to the use of best modern construction and manufacturing methods combined with attractive design than at any previous period.

Woods Used in Door Construction

The kinds of wood used for door construction vary about as much as the sources of supply. In the United States the one preferred above all others is the Northern white pine, but the available supply began to dwindle about 1900. It has been replaced largely by California sugar pine and Western yellow

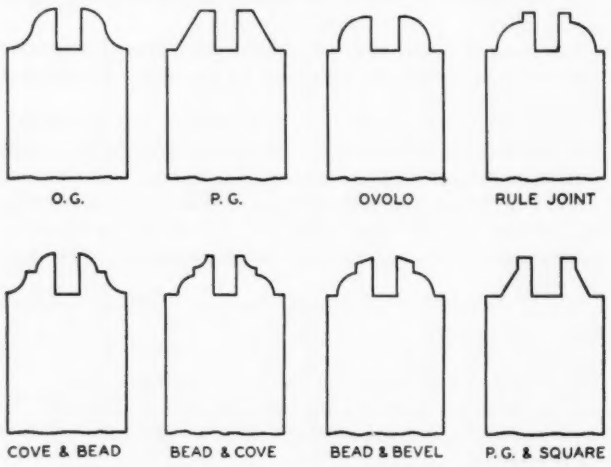

Fig. 1 Common Patterns of Door Sticking

pine (*Pinus ponderosa*). Douglas fir is used to a large extent for fir doors. A wood often used for garage doors is a species of hemlock. The Southern yellow pines and cypress are used to a limited extent. Yellow pine is more subject to "working"—shrinking and swelling and checking.

Other woods such as the oaks, birch, walnut, and mahogany, are either too expensive to use solid or are subject to "working," and their use is limited to veneers applied over built-up cores of the softer pines and firs.

The ideal wood for door construction has these qualities:

(1) Fairly straight grained and machines easily
(2) Least subject to swelling, shrinking, and warping
(3) Suited for taking stains and finishes
(4) Available in quantity at reasonable cost.

The shrinking and the swelling of wood are important factors in door manufacture. A report of the research department of the Western Pine Manufacturers Association gives information on shrinking for Ponderosa pine, most commonly used for door construction.

A moisture increase or decrease of 1 per cent will change a 1 in. width of lumber a maximum of 0.0030 in., an average of 0.0022 in., and a minimum of 0.0013 in. Ordinarily a door in a residence will have a moisture content between 6 and 16 per cent. This might cause a variation in size of $^{5}/_{16}$ in. Such a door would require $^{1}/_{8}$ to $^{5}/_{32}$ in. clearance when hung and when at about 10 per cent moisture content. The average clearance is about $^{1}/_{16}$ in. at each side.

The moisture content of lumber at the time of manufacture into doors should be about that of the door as installed. For doors of pine the general rule is 8 to 12 per cent of moisture, based on oven-dry weight. Lighter woods may contain a higher percentage of moisture than the denser woods. This is important where different woods are used in a door, such as in veneering with denser woods over softer cores or where hardwood dowels are used in pine or fir doors.

Control of moisture content of materials used in door construction is important. Quite generally, pine lumber to be used for doors is dried at the sawmills to less than 8 per cent, and it picks up moisture in transit and arrives at the door factories ready for use, with moisture content of 8 to 14 per cent. Storage in sheds before use will tend to equalize this to between 8 and 10 per cent in summer or 10 and 12 per cent in winter. These values refer to the upper Mississippi Valley.

Such lumber retains its moisture content through the factory processes in the summer months. In the winter it will dry out somewhat in the shop with artificial heat. The exhaust fans cause several changes of air per hour, the outside air entering the shop being heated and dry. Care must be taken that door stock in its machining processes is not exposed long enough to make it too dry. In a general way this dryness of the shop in winter may be used to correct the increased moisture then present in lumber. An atmosphere with as low as 20 per cent relative humidity is not uncommon in a heated woodworking shop in the winter season. Very few shops are equipped to add moisture to the air.

In an unventilated and unheated building the moisture content of pine lumber may rise as high as 16 to 17 per cent. It is therefore important that unheated storage sheds should be well ventilated in the winter. Excess moisture can be corrected by a drying out in the shop.

After doors have been built up, they should be kept in a warehouse where the temperature never goes below the dew point. In winter about 40 F is a safe low limit. If frost forms on a door in the warehouse, it will upon melting be soaked up by the doors. Repeated conditions of this nature will raise the moisture content to excess. The remedy is adequate ventilation and a small amount of heat. Sheds for storing cut stock should be treated in a like manner.

The Northern white pine of the Great Lakes region was originally the preferred wood for door and sash construction, but its growing scarcity increased the cost so that the more plentiful supplies of pines from the Pacific Coast, even with higher freight rates, were more economical. Regardless of cost, it is now the most practical wood available. Increased cost naturally led to a search for cheaper materials or methods. This caused the development of veneered stock for stiles and rails and of plywood for panels, and also largely of slab doors.

Production of Cut Stock

Cut-stock production from lumber is an intricate procedure. Enough 100 per cent clear lumber to be cut into door parts of exact size without waste is not available, and cut stock is therefore developed from various grades of lumber. A board is graded according to the quality and number of clear stiles and rails that can be cut from it by dodging knots, pitch pockets, cracks, stain, and other defects. "Standard Grading Rules" are published by the Western Pine Association.

Most door factories produce their own cut stock from lumber. There are plants devoted exclusively to its production and sale.

The dimensions of cut stock vary greatly. In thickness the stock generally allows for sanding 1/32 in. off each side. In width not less than 1/8 in. is allowed on each edge for dressing or molding. If all stock were straight this might be reduced. Some allowance is also made for removal of feed-roll marks. In length from 1/2 to 1 in. should be allowed for trimming, tenoning, etc.

Dowel stock is usually accumulated from hardwood rippings. Core blocks are developed in the course of producing cut stock. Many use lengths as short as 5 in. The value and the use of core depend largely upon the cost of lumber. As lumber prices go down, a condition is reached where the cost of producing and gluing up core and veneering it is greater than the cost of solid stock.[2]

Adhesives in Door Manufacture

Glues as used in door manufacture are limited to a few general classes, though they may vary widely within each class.[3] Animal glue, made of hides, bones, etc., is used in door construction chiefly for the doweled joints. Casein, made from curdled milk, is used in assembling cores and for veneering or plywood construction. Casein glues are probably the best that have been in use in door construction for 15 years. Vegetable glues have also been used extensively in veneering and core work. Blood-albumin glue requires a hot-plate press and is not used much in door construction. A recent development is a powder that is sprinkled on the wood parts, and when heat and pressure are applied a strong joint is produced. Still another development is a bakelite sheet that is inserted between parts to be glued. A hot-plate press in a few minutes produces a waterproof joint. Much seems to be expected from these later glue developments.

Machining Processes

The Fig. 2 shows the names and relative locations of the parts of a paneled door. This will assist in following the machining processes. The author will attempt to show only one of each type of modern machine.

Assuming that there are in the cut stock the sizes needed for a certain run of doors, the first step is to have the proper quantity counted out and started to the mill.

It is best practice to dress all cut stock such as stiles, rails, and muntins just previous to their going to the machining department. A modern type of direct-motor-driven single surfacer with flat-belt feed is ideal for this purpose. The door cut stock entering the mill divides into three routes:

1 The stiles are to be laid out, bored, and stuck
2 The rails are to be tenoned, bored, and doweled
3 The panels are to be sanded, squared, and raised.

Following this the door is assembled and "squeezed up" in a clamp. The last operations are sanding, inspection, hand work, if any, and trucking to the warehouse.

Each part of the door will be followed individually. In their trips from one operation to another the parts are usually transported on "cars," or platform trucks, about 18 in. high, 2 ft wide, and 4 ft long. Two wheels on an axle, cart fashion, at the center carry the main load. Swiveled casters at each end keep the cars from tipping up. Stakes at the four corners aid in keeping loads in place.

Stiles

The stiles enter the shop surfaced on the two sides, and the two edges are as they come from the saw. About 1/4 to 3/8 in. over width is allowed for dressing and sticking, and the length is about 1 in. more than the door it is to be used in. The stiles are practically the only parts that are laid out, and the only layout necessary is a marking of the dowel holes for the kind of door to be made. All other door parts are made to specified over-all widths and lengths.

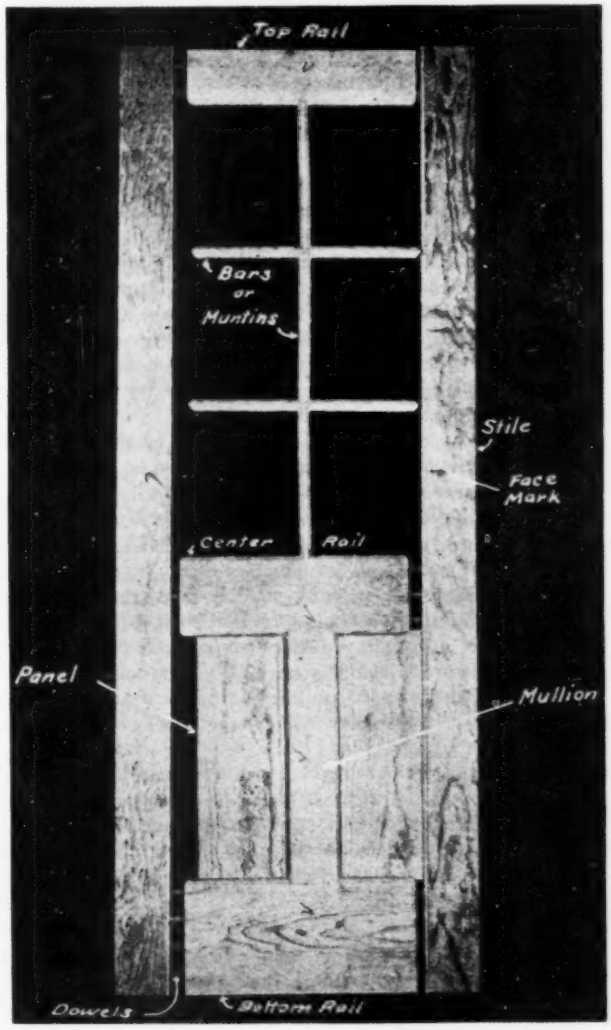

Fig. 2 Location and Names of Door Parts

The spacing of the dowel holes depends upon the number used and the panel sizes and arrangements. Even this layout may be eliminated by using rods marked off for setting up the boring machines.

There are two types of boring machines in general use. For stock doors gang boring machines with 16 or 20 bits in a row are standard equipment. For special doors or small runs it is more economical to set up and bore the holes on a four-spindle machine, where one can selectively bore with one to four bits. These bits are all permanently spaced to standard center distances such as 2 1/4 or 2 1/2 in. On the gang borers the bits are yoked in pairs. Adjoining pairs are spaced by bosses on the yokes so that spacing of all holes is facilitated.

The drills may be vertical or horizontal. The most common types bore from the under side. The drills are of the twist variety, the same as used in metal drilling. It is quite important that the lands of the drill be ground for clearance up close to the leading edge, otherwise the drills will be apt to heat excessively or break off. High-speed steel is preferred to reduce resharpening.

It is necessary to clamp the stiles rigidly between straight and powerful jaws during the boring to correct any bowing or warping. Unless this is done all the holes will not be equidistant from the face.

In doweling the doors all boring should be accurately spaced from the side called the face. Both stiles and rails are therefore face-marked as they pass through the first machines, by a hand crayon or some automatic means.

In the case of the stiles, because of this facing, one must bore rights and lefts, by having "right" or "left" holding jaws or by making one of them stationary while the other moves.

From the boring operation the stiles go through the sticker. This is really a two-head molder, which dresses one edge square and also generally chamfers the corners and molds the opposite edge. The molded edge is the one that was previously bored. The mold is usually symmetrical for paneled doors, the groove at the center being adapted to receive the panel. Glazed doors usually are "stuck," with one side of the mold cut away inwardly to the groove. A mold is later nailed in as needed. For certain doors the rabbeting or cutting away of the mold may be done more expeditiously on a shaper.

The types of door stickers vary greatly. The older machines have roll feeds and have top and bottom dresser heads. The greatest weakness in these machines is that the feeding mechanism is apt to slip and dig into the wood, if for any reason the force required to push the stock through the machine is too great. Crooked or warped stock is not adequately "ironed out," so that the sticking is not always accurately faced throughout the length of the piece. Another fault is that stock bowed edgewise is generally still bowed after sticking instead of being straightened. Besides this there is a tendency, especially on crooked stock, for the piece to kick up as the trailing end passes the feed rolls or chip breaker, with a resultant scalloping or uneven cutting at the ends.

The improved machines make use of a continuous chain feed through the length of the machine. Such machines produce exceptionally straight stock. A piece once started passes entirely through the machine without needing another to push it out. This aids greatly in setting up the machine.

To stick rights and lefts it is customary to run half the bored pieces "other end first." To do the right kind of sticking it is important to have the best types of cutter heads. Before the days of high-speed steel almost any type of head was used. The old flat-ground bit used on a square head has given way to the milled or formed bit that can be sharpened by simply grinding one flat face.

With motors direct-coupled to the cutter-head arbors, less vibration of the machine permits higher cutter-head speeds and faster feeds. With higher speeds and less vibration, the jointing of the bits has become best practice. It is always difficult to properly joint complicated contours on bits. This has been simplified by making the center or grooving bits retractable, so that they may be drawn inwardly out of the way during jointing and subsequently set outward in place again.

Self-centering sleeves or a pair of centering cones help to set up the heads accurately on the arbor. Proper grinding and fitting machinery is necessary to do a good job of setting up the heads. The ideal method would be to set up a head completely sharpened and jointed, then place it on the machine for immediate operation. Unfortunately this idea is difficult of achievement. There are many small difficulties yet to be corrected. Unless jointed on the machine modern heads are generally limited to about 80 ft per min feed at about 4500 rpm. Higher speeds have been and are being used.

Rails

The rail cut stock passes directly to the tenoning machines. Single-end machines are used for small runs and special set-up work. Double-end machines are used for stock runs.

In these machines the stock is sawed to exact lengths and coped to fit the molding or sticking on the stiles. These cuts are also made square with a reference edge, which later is the controlling or facing edge in the sticker. The sticking will be parallel with this edge and therefore square with the ends.

As with the stiles, it is also necessary to mark one side of the rails as a face side. These face marks on stiles and rails must be on the same face on the door when it is assembled. If it were not for this precaution, it would be difficult to make a door that would be flat and level.

To describe a tenoning machine is a long story and has already been done very well in a paper by Mr. Mansfield.[4]

The function of the tenoner in door construction is to shape or form the ends of the rails to fit the sticking and the groove on the stiles. Heads for this purpose may have bits milled to exact pattern, but more often they are ground from high-speed steel of rectangular section. The exact patterns are best determined and made by use of accurate steel templets. Almost without exception a set-up piece is run and tried on the molding of the stile. It is highly important that a tight joint must be provided.

All door-sticking patterns in common use have a flat shoulder or quirk at the outside about $1/8$ to $3/16$ in. wide. This shoulder is important in getting a perfect face fit, since it is at right angles to the surface. A surface joint of this nature if found at an angle other than 90 deg is very difficult to fit up tightly. The tenoned ends of the rail bear slightly harder against these shoulders at each side than at any place between them. This is to insure a tight "squeeze up" at the surface joint when the door is assembled.

The rails now pass to the sticker, which may be the same machine that sticks the stiles. The rigid side of the run for the stock is called the fence side. It is usually the inside or frame side. The rail must be run through the machine with its face-marked side against the fence. Also the edge that was engaged by the lugs on the tenoner chains should run upon the rigid bed surface. In this way a parallel cut is removed, and the edge of the rail remains square with the tenoned ends. Any irregularities are cut out by the opposing or top head.

If the cutter head is correct to profile, then the important part of the set-up is to see that the cut is centered or faced up correctly from the face and that the stock is being cut to correct over-all width. Accurate width is more important on the rails than on the stiles, since they must assemble in the door with proper allowance for panels.

After sticking, the rails are bored for dowels. Small runs or special lots are bored on the four-bit machine used for stiles.

Stock runs are put through a rather complicated special machine known as a "three in one" machine. This machine is provided with a hopper for the rails and a pair of reciprocating bars or chains to advance the stock one piece at a time successively past three stations. At each station the stock stops and is clamped down securely while being operated upon by the machine simultaneously at each end of the three rails.

At the first station properly spaced drill bits advance inwardly and bore the holes for the dowels. From three to five

[4] "Double-End Tenoners and Their Use," by J. H. Mansfield. A.S.M.E. Trans., paper WDI-54-11.

bits are provided, the number of bits used for boring depending upon the width of the rail. The face side of the rail must be down against the solid bed of the machine.

At the second station glue is squirted into the bored holes by two sets of nozzles which enter the holes while a pump forces glue through them.

At the third station a suitable mechanism drives as many dowels as needed outwardly from the bottom of two dowel hoppers.

Thus there are six operations in progress at once, and each in turn is multiplied by the number of dowels. When there are four dowels being driven, there are 24 operations in progress at one time. About 20 rails are doweled complete per minute.

Instead of the machine mentioned, one might use one or more of the improved single-end boring, gluing, and doweling machines.

The rails in passing through the last three machines are held down flat with all twist or warp squeezed out so that the operations will face up correctly. If this were not done, the parts would not assemble in a level surface.

Panels

The panels may be obtained either from plywood or from solid stock. Plywood needs no other work done upon it than having the sides sanded so that they are smooth and the thickness is proper to fit the grooves, and having the sides and edges trimmed and squared to proper size.

The usual practice is to run the plywood panels through a double-end saw for trimming. A better way is to run them through a machine that also chamfers the edges so that the panels will enter the grooves of the stiles and rails easily.

Solid panel stock is first dressed on a planer and then sanded both sides on a drum sander. An endless-bed sander is ideal for this purpose.

If a single-end panel raiser is used, the panel stock must be accurately squared and sized first. One edge at a time is raised on this machine. Raising a panel consists of actually cutting away stock on the surfaces around the edges so as to leave a raised surface effect in the center.

From the step-off at the border of the raise the panel tapers down to near the edge, where the sides again become parallel for a distance at least as wide as the grooves in the rails and stiles are deep.

A double-end machine for this purpose cuts two sides at a time. Panels are first run through so that the ends are cut, and then a second time, when the sides are cut. This operation may also be done on a shaping machine. This is the machine that was formerly used exclusively for this job.

Dowels as Made for Doors

The dowels used in doors may be made of oak, maple, birch, or other hardwoods. Yellow pine and gum are sometimes used. They may be purchased from plants that specialize on dowels, turned items, etc. The larger door factories generally accumulate rippings of hardwood, and these are worked into dowel stock. Generally speaking, it is wasteful to cut stock lumber specifically for making dowels.

In doors $^3/_4$ in. thick, $^3/_8$-in. dowels work best; $1^1/_8$-in. and $1^3/_8$-in. doors may have $^1/_2$-in. dowels, and $1^3/_4$-in. and $2^1/_4$ in. doors may use $^5/_8$-in. dowels. In some plants the $^1/_2$-in. size is used for doors up to $1^3/_4$ in. thick. In others a $^5/_8$-in. dowel is used on $1^3/_8$-in. and thicker doors. Where softer woods are used, they should be of larger diameter.

They are usually 5 to $5^1/_2$ in. long, and the ends should be tapered or chamfered for easy entrance.

The stock for making dowels should all be well dried; at least it should be as dry as or drier than the door stock. For $^1/_2$-in. dowels the stock is ripped about $^5/_8$ in. by $^5/_8$ in., or in general about $^1/_8$ in. larger than the dowel size.

This stock is run through any one of several types of dowel-rod machines. In these machines the stock passes through the hollow shaft of a revolving head. Stock is kept from turning by in-and-out feed rolls, while knives on the head cut off the corners and produce a smooth, round rod. A spiral groove may be cut on the rod during this same operation. Feeds run from 50 to 75 ft per min.

Cutting and pointing of the dowels is done on a turret type of machine where the rods are set in vertically and are passed by cut-off and chamfering saws. Such a machine may cut and point over 1000 dowels per minute.

Dowels with necks cut near the ends are sometimes used. A spiral or a straight groove on the dowel assists greatly in allowing air to escape when the dowel is driven. It is not unusual to split a stile or rail in driving a tight-fitting dowel unless the entrapped air and glue have a means of escaping.

To provide dowels with notches and the like for the glue to obtain a better hold is of doubtful value, but it is important to have a place into which excess glue may flow.

A properly glued dowel should break under tension before the glue joint should break. Failure in a test on dowels shows that the softer wood around the dowel generally fails first.

A dowel must not be too tight or it will split the door parts. A dowel's holding power may be attributed in some measure to the inward bending of the end grain of the wood forming the dowel hole. When the dowel is pulled outwardly, it is gripped by a sort of toggle hold. This grip can of course be exerted only on fairly tight dowels, and it may even be annulled entirely by the shrinking of a dowel or by the glue setting the fibers around the dowel.

The advantages of doweled over mortise-and-tenon construction are many, some of them being as follows:

1 An amount of clear lumber the length of the tenons is saved in the length of each rail that is used.

2 The machining and assembling operations are simpler and faster.

3 The holding power of dowels is greater per unit of glue area. In an oblong mortise one cannot count upon permanent glue joint along the sides of the tenon and mortise. Shrink and swell are quite apt to break it lose. A dowel hole is round and small. The shrink and swell of parts is generally so little that the adjoining wood will yield enough to prevent rupture of glue joints.

4 Several dowels are less apt to split a stile or rail than a long continuous mortise because there is a tie or bridge between the holes.

Assembling

The assembling of the door may be performed by locating the stiles, rails, mullions and panels, etc. in relative positions while the door stands on edge or lies flat upon the clamping machine. If the door is assembled outside the clamp, rubber-headed mallets are used to drive the parts so that the dowels of the rails are started into the holes of the stiles. When assembled in the clamp, the mallet often is not needed.

Glue must be applied to the dowels before assembly of the door. This may be done by dipping the ends of the dowels that project from the rails, into which they have already been inserted.

A faster way and one used almost exclusively is to squirt glue into the holes in the stiles. A special gang glue squirter is used for this. Properly spaced nozzles enter the holes, and pumps force in the glue at the right instant and in the proper amount.

If one follows the method of laying the door parts in relative

positions in the door clamp, the process will be readily understood. One stile is laid against one jaw, and the dowels at one end of the rails are started into the proper holes. The panels are entered in the proper grooves, and the last stile is put in place so that closing of the clamp will squeeze the whole door together. Some clamps operate at an angle, others are level.

A squaring device is used along one jaw. This consists of an inwardly spaced bar that contacts the door and a series of rollers between it and the main jaw of the clamp. This permits the side of the door to move longitudinally along the jaw so that when the door comes solidly together the squared ends of the rails will be parallel and tightly against the stiles.

A certain amount of dexterity is required in operating one of these clamps. If all joints do not enter readily, the dowels or panels must be assisted by crowding or pushing. A mallet of proper size or the hands of the operator are used. It is no small trick to learn to keep one's fingers out of places where they may be pinched or even crushed.

The operator controls the closing of the clamp with a foot pedal. He must learn to work with caution, and be ready to stop instantly. Care must be exercised to stop in time to keep from crushing the door. The capacity of a door clamp is dependent upon the character of the door being assembled and the skill of the operator. It may range from 20 to 80 doors per hour.

A clamp driven by screws at each end of the jaws seems to give most satisfactory results. Air clamps are not so easily controlled. If one end squeezes up more easily, the jaws at that end will move up more readily. Parallel movement of the jaws is essential, as is also slow but positive movement. It is good practice to have the jaws set slightly closer at the end where there is the greatest resistance—namely, the bottom end of the door where the rail is wider.

In assembling doors of complicated design and where there are a large number of parts such as sash doors, a certain amount of experience is required to make the parts come up properly. End-clamping is often necessary in addition to side-clamping.

After assembly and clamping the doors are stood aside until the glue on the dowels can take its initial set. Hot animal glue is generally used on the dowels. It seems to work best with the machinery available. The dowels should fit tightly enough in the holes so that they will not readily come out even if not glued.

Sanding Operation and Repairing Defects

Sanding of the doors may be done within an hour after they are assembled. Drum sanders are used for this purpose. Machines with four drums sanding each side are growing in favor over the three-drum types. Roll-feed machines are used almost exclusively. Double-deck machines are growing in favor where capacity is an item. Such machines may consist of two machines set in tandem or a single machine having six or eight drums built to sand both sides at one pass.

Drum speeds formerly were about 1300 to 1400 rpm. Since motor drive direct on the drums is available, the speeds have increased to 1750 rpm. The rates of feed will range from about 15 ft per min to 25 ft per min. Doors should be run through at a slight angle for best results.

The grades of coarseness of paper will vary with the kind of wood and the evenness with which the parts fit. If the joints are not level, more stock has to be removed and coarser paper is required. No. 2 grit is about as coarse as should ever be used. If too coarse paper is used on the first drum, it produces scratches too deep to be removed by finer paper on the following drums. Paper may vary from No. 2 on the first drum to No. 1/2 or No. 0 on the last drum. Experience alone will tell what is the best combination for different woods, character of work, and rate of feed.

The doors should now be completed and ready to start on the way to the user. All doors after sanding are carefully inspected. Occasional small defects can be repaired on the bench. Such defects may be loose panels, an open-face joint, or a wood defect that previously was hidden. By skilful "slivering" minor defects can be repaired satisfactorily. Sometimes the door must be torn apart and a new stile or rail put in.

It is one of the functions of the assemblers to guard against use of any defective parts, but certain defects may show up after the door is sanded.

Other benchwork consists of putting in glass or nailing in moldings, stops, etc. depending upon the kind of door.

The process just described covers ordinary doors built up of solid materials. Veneered doors are put through exactly the same process just as though the parts were solid.

Building Up Veneered Stock

It will be necessary to deal now with the details and methods of building up veneered stiles and slab doors. The operation of manufacturing plywood will be omitted, since this is an industry in itself, and many door manufacturers buy plywood panel stock cut to size, sanded, and ready to use in the assembly of doors.

Stiles and rails of dimensions identical to solid are built up of core, edge strips, and face veneer.

In the process of developing cut stock, many short and narrow blocks are produced. Much of this is free of knots and fairly straight-grained. This is commonly known as core stock. When lumber is high in price, it is economically profitable to assemble these blocks with edge strips and to veneer them for use as solid stiles, but the real occasion for the built-up stiles and rails is where the face of the door is to be oak, birch, mahogany, walnut, or similar woods.

Many of these woods are too expensive or are otherwise impossible of manufacture except by the veneering process.

Edge strips are accumulated from rips of 4/4-in. lumber. They must be of a length equal to the stiles or rails in which they are to be used. One exception is that a joint may be made in the edge strip of a stile if it is so placed in the finished door that it is concealed by one of the rails. Generally, they run full length.

The processes of building up core are as varied in number as the shops that produce it. The core blocks must be ripped to uniform width. In some shops this is done on accurate straight-line saws and the sawed edges are glued directly as they come from the saw.

In other places the blocks after ripping are dressed accurately to thickness and then glued with their flat faces. Still other plants form tongue-and-groove joints on the blocks and edge strips.

A properly fitting flat-faced glue joint is as strong as one with tongue and groove. The real reason for use of tongue and groove is that it helps place the blocks in even-face alignment when they are assembled.

In some instances the blocks are machined and run into bins and subsequently used as needed. One difficulty with this method is that drying of blocks after they are in the bins may make them of uneven thickness before assembly. A better method is to dry all the blocks and dress them to thickness just before assembly. They may well be dried to as little as 4 or 5 per cent moisture content, because the application of glue will raise the moisture several per cent.

The usual method of assembling the core and edge strips is on some sort of pan, caul, or table and clamping them up edgewise to be held till the glue sets.

The time needed for setting depends on the kind of glue used.

It may be of the casein, vegetable, or animal variety. Casein and starch glues seem to have been preferred in recent years.

When the core and edge strips are removed from the clamps, they must be surfaced to receive the face veneer. The wood of the core and the strips will be swollen next to the glued joints, and if not dried before being run through the planer it will dry out afterward and leave a depressed surface along the glue lines. For this reason the assembled core should be carefully dried before running it through a planer. Perhaps some of the newer glues may eventually change this.

Face veneer may be produced by sawing thin pieces from the logs or cants or it may be sliced off with knives. It also may be rotary cut by shaving it from around the log.

For the sawed veneer there is little choice as to which side should be outward. Sliced or rotary-cut veneer should have the same side out when glued as was out before it was cut. The reason is obvious, because in the slicing the veneer will be ruptured slightly due to bending. Such ruptured side should be next to the glue.

For door construction $^1/_8$-in.-thick veneer is generally used on stiles and rails. Thicker veneers have been proved by tests to be more durable in resisting exposure to weather. This is contrary to the common belief that thinner veneer will come and go with less danger of rupturing a glue joint. For slab-door construction, where the veneer is to be grooved as for plank effect, a thickness of $^1/_4$ to $^3/_8$ in. is needed.

Application of veneer to the core is generally performed by running the core through a glue spreader that applies glue to both surfaces. The core is then laid between the two face veneers like the meat in a sandwich. Successive assemblies of this kind are stacked up from three to six in height. Stiffener plates or cauls are inserted at intervals until the stacks of core and veneer are built up to the height capacity of the press. Generally this assembly is completed outside the press, and the unit is then rolled into the press, with suitable plank cauls and steel retainer beams above and below the stock to be veneered.

The entire stock is then compressed with a unit pressure of about 100 lb per sq in. of glue surface. Retaining clamps are applied, and the unit may be removed and set aside for the glue to dry.

Hydraulic presses are common for veneering purposes. There are many who favor screw-driven presses. A hydraulic press without an accumulator operates more slowly. A leaky pump also may make it uncertain as to exact pressure at the time the retaining clamps are applied. A screw press will maintain its pressure during clamping or overnight if necessary. Both types are in common use. For larger installations the hydraulic press with an accumulator may operate more rapidly. A paper by Mr. Francis on glue presses should be read in this connection.[5]

After removal from the retaining clamps the veneered stiles should be piled on stickers and run through a drying box to remove excess moisture added in the veneering operation.

The ends can now be trimmed and chamfered and any overhanging veneer be trimmed off, and the stiles and rails are then ready for making into a door in exactly the same manner as a solid piece of wood.

Slab doors are built up by much the same processes as for making veneered stiles and rails. Core and edge strips are built up in the same way. In fact, identical stile and rail core before veneering may be run through the sticker and tenoner.

The usual practice is to cut a groove on the inner edge of each stile and to form a tongue on the rails at the ends. Dowel holes are bored and a complete door is built up with rails solid one against another the full length of the stiles.

[5] "Hydraulic Presses for Plywood," by Harry G. Francis, Trans. A.S.M.E., 1931, paper WDI-53-12.

This assembly, without any veneer, is squeezed up in the regular door clamp. In this way a built-up core is obtained for the slab door that has exceptional strength and is fairly free from shrinking and swelling. Since planers are not generally available for this size, this core is usually run through a sanding machine to level all the joints to prepare it for the veneer application.

Cross-banding is applied on this core. It consists of $^1/_{16}$-in. veneer run crosswise of the door. Over this cross-banding the face veneer is applied at right angles or lengthwise of the door. It may be from $^1/_8$ to $^3/_8$ in. thick.

The remainder of the operation is to place this door under the press, and when the glue is set and dried, run it through the sander and trim the edges.

In applying face veneers of widths needed on a slab door, if of more than one piece, the edges are taped or glued to hold the joints securely.

Subsequent operations of grooving and cutting out and installing of glass are largely bench operations. For these operations portable power saws, routers, and sanders are used extensively.

Special Designs of Doors

The methods described cover the most usual types of doors. There are doors of special designs that need to be handled in exceedingly special ways.

A door has been marketed recently where the outside appearance is that of a number of planks with a groove at the joints between boards. The facing boards are cut on the back side with dadoes having angling sides to form a dovetail joint with rails which have a coacting rib threaded through them. The side stiles are then applied. They are doweled to the ends of the rails, and on the front they resemble in effect one of the facing boards. Such doors are not level-faced on the back and are used for garages, etc. To build these doors some very special machinery is required.

Mention has been made of the one-panel doors with an inserted frame surrounding the panel. The usual method of making these frames is to miter the corners and assemble them with clamp nails driven into saw kerfs. This is a much faster method and generally more satisfactory than the older form of splined or tongue-and-groove joint.

Another innovation is in the design of the lower edge of panels on exterior doors. In the usual construction the panel is slid into a groove in the rails. This groove aids water to run down the panel and get into the very heart of the door, where it may loosen glued joints and dowels and may even cause rotting unless the door is always kept properly painted.

The new joint involves a groove in the lower end of the panel which straddles a rib on the top of the rail, so that water is effectively directed outwardly.

For hand-trimming of doors there are a number of small machines available. In cutting doorstops, foot-power miter-cutting machines are used extensively. Other forms of miter cutters are provided with power-driven saws and generally produce more accurate and smoother work.

For cutting out openings, especially in slab doors, such as needed for lights of glass, portable motor-driven saws guided on suitable tracks clamped to the doors have proved to be great time savers. These saws can be set in place on the door and the saw let down to cut through the door and then moved forward on the track as desired.

These saws when fitted with an angle-faced grooving saw are very handy for cutting the vertical grooves of the modern and fashionable slab door.

For rounding the ends of circle-top and Gothic-top doors a modern router can be used to advantage. A form is placed on the

door, and the router bit cuts the door as the router is guided around the form.

Another machine that proves itself handy is the small portable belt sander which is run over the door like a flatiron. It is very useful and efficient in cleaning up special doors, repaired spots, or for touching up spots missed by the regular door sander.

A small power-driven hand jointer is convenient for use in trimming and repair of doors.

An operation commonly known as "slivering" is frequently resorted to when surface defects show up on doors after sanding. Rather than de-grade the doors, repairs can be made to overcome the bad effects of surface checks, pitch pockets, etc.

The tool used consists of a small mill-type file, ground at an angle and sharpened at one end. This tool is run with the grain along the crack or defect and forms a V-shaped slit. Into this is driven a sliver to which glue has been applied. The sliver is wedge-shaped about like the cross-section of a jackknife blade. Slivers are ripped by a saw from clear straight-grained lumber. Pieces are cut the length desired and fitted and driven into the slit. After the glue has set, the sliver is cut off even with the surface and sanded smooth. Such a repair is permanent and is impossible of detection if properly done and if the grain and color of the wood are matched.

In glazing doors the glass is ordinarily held in place by stops mitered at the corners and nailed in with brads. Such doors for exterior use should have the glass bedded in putty.

Grading rules for doors are quite general in their scope. Such a list of rules was prepared by the National Door Manufacturers Association and the Wholesale Sash and Door Association in 1930.

Handling to Avoid Damage

The handling of doors needs to be done with care to prevent damage. There are a few precautions that will help. Chamfering the edges of the stiles helps to prevent slivering if they are bumped. As a rule doors should be lifted or slid carefully on the edges upon a smooth floor or surface as the faces are easily marred.

In sliding a door on its ends it is very easy to split off part of the stiles. Chamfering the ends of the stiles is desirable. On veneered doors it is a necessary precaution. The stiles at both top and bottom usually are allowed to project about $^1/_2$ in. as a protection. These horns are to be cut off when the door is hung.

Slab doors should have a cleat or strip nailed on the ends and extending the full width of the door. If this is not done, veneer is apt to be damaged or torn off.

In storing doors in a warehouse there are three ways of arranging them. They may be stood on end, sloping slightly to lean against a post or wall. Care should be taken to see that about equal numbers of doors lean against opposite sides of a post, otherwise considerable side push is created that may cause a building to collapse. Where large quantities of doors are stored, they may be piled flatwise on top of each other. Strips should be laid down on the floor under each pile. Such piles should be only of a height for which the floor is safe. Where a large variety of doors of many sizes and kinds are stored, it is probably most convenient to build suitable racks, with either adjustable or permanent cross-members, on which to lay the doors. Space for 10 doors of a kind between the cross-members is a convenient size.

In all of these methods of storing it is of utmost importance to keep the top or exposed doors covered. This can be done very well by using old doors or fiberboard covers made for the purpose. This will keep the doors clean.

It is also important to keep excess light and especially direct sunshine from the doors, as this will discolor the doors quickly. Then, too, it is obvious that there should be a tight roof overhead.

Another good practice, when new doors are added to the stacks, is that they should be placed in new piles or underneath the older ones of the same size and kind. This will keep the doors moving and will prevent an ultimate collection of old and shop-worn stock.

The suggestions regarding storage of cut stock apply to doors in warehouses also, and much more so. Proper door-storage rooms should be as dustproof as possible. Floors should be sprinkled or, better yet, covered with wet sawdust before sweeping. There should be good ventilation, and the temperature should be controlled against extremes. It should not go below about 40 F in the winter time. In some storage houses the space just below the roof becomes abnormally hot in the summer time, and this is not a good door-storage place.

While humidity should be as constant as possible, this is not generally easily controlled. It is therefore important to provide ventilation and to guard against extremes in temperature.

It has been explained how low temperatures tend to increase the moisture content of wood. High temperatures will tend to produce excessive dryness. Anything that causes extremes in moisture content is harmful to doors. Aside from injuring the joints, it also may weaken the glue used in the door.

Molds and rot are not apt to be present in a warehouse that is kept dry. It requires from 15 to 20 per cent moisture content in wood to support fungus growth. Such extremes would occur only under a leaky roof or where doors are piled on dirt or on damp concrete floors.

Another enemy that needs watching is insects. The termite, sometimes called the white ant, is becoming an increasing pest in the more southern districts and is said to be working northward. By keeping door piles up from the floor they will generally be safe. These "ants" build a dried mud tunnel or tube from the ground up to the wood in which they bore. They must have this tube leading to the ground to obtain a proper water supply. They may bore up through the wood blocks or strips on which the doors are piled.

Powder post beetles are also a pest. There seems to be much to learn about them. It is not uncommon after a door has been hung and finished to find a pile of fine sawdust on the floor and small round holes in the finished faces of the doors. The holes may vary from $^1/_{16}$ to $^1/_8$ in., and they look as though bored by a high-speed drill. It is claimed by some that these beetles develop from eggs laid in the core of plywood and in veneered doors. It also is said that they originate in hardwood cores such as oak or chestnut. Attempts to prevent trouble along this line consist of putting a germicide in the glue, which should kill them as they attempt to eat their way out. The high temperatures of the re-driers used in plywood factories are also counted upon to kill the eggs or larvae of this bug.

In preparing doors for shipment much care is required to protect them from damage by the none-too-gentle truck drivers and freight handlers.

Crating of doors requires covering of both faces with thin lumber or sheets of fiberboard. Where crating is used, the only place where nails can be driven is at the edges, preferably at the top and bottom, and then only in the ends of the stiles.

An improved method is to use prepared fiberboard cartons that completely surround the doors and are held in place by tightly drawn steel taping. By this method no nails are driven into the doors.

In loading cars care must be taken to remove all nails from the car that might deface the door. Strips of board are laid down on which to pile the doors. Sheets of paper are used generously to cover the piles of doors. A recent practice is to line the inside of the box car with paper. Special paper covers are now made up for the entire under side of the car roof. It is highly important

to keep the cinders and dirt incident to freight traffic away from the doors in transit.

Another important thing is to pack the car full from end to end or to put in bracing or bulkheads, so that the doors cannot shift within the car. The usual method employed in freight-train switching or at the "hump" in the yards is responsible for many damage claims on shipments of doors.

The use of hooks for handling crates or bundles of doors is prohibited, and yet one may sympathize with the man that has to handle a bundle of doors as they are unwieldy.

The precautions concerning storage and handling apply from the time the door leaves the factory until it arrives at the place where it is to be installed. It is highly important that the same diligent care be exercised all the way to the house. The final truck driver should not attempt to deliver doors in bad weather without properly protecting them.

Precautions in Installing Doors

The builder or mechanic on the job has his responsibilities too. Doors should not be delivered until the house is completely dried out after plastering and is properly closed up to keep out the weather.

Installing a door is a well-known practice, yet there are a number of things that are often overlooked. The doors must be trimmed top and bottom, and the sides will need dressing for proper clearances. As already pointed out, it is possible for a door having two 5-in. stiles to shrink and swell a total of $^{5}/_{8}$ in. No such amount needs to be allowed for in practice. It may be assumed that a door will be hung when with about 10 per cent moisture and that this may vary about 5 per cent either way. This would mean that about $^{5}/_{32}$-in. clearance would care for most conditions of swelling. If the door frame is still swollen when the door is hung, this may be reduced. It is also best practice to bevel the edge of the door opposite the hinges to give swinging clearance for the outside edge of the stile.

The door should be "sighted" to determine if it has a bowed edge. If possible, such edge should be placed at the hinge side, and three hinges should be used. If the lock side has a bow in it, the hollow side should close toward the doorstop. All these precautions will help to hold the door in proper shape.

Clearance to swing over the floor should always be such that the door will not rub or strike.

A door should be properly protected against weather by proper finishing. If paint is used, nothing is better than an undercoating of good flake aluminum paint. This to be covered by paint to give the proper finish and color. The tops and bottoms of the door should be painted. In fact, it may be more important to protect the top and bottom edges than any other part of the door.

The use of stain only in finishing a door may bring dissatisfaction. Stains do not protect the wood surface from moisture changes and surface checking.

The use of stain filler and varnish is good practice and is to be recommended.

Recently there have appeared dozens of new paints, dopes, preservatives, and what-nots that are claimed to make any surface waterproof. Misunderstanding may be cleared up if one will distinguish between water in the form of liquid and water in the form of vapor. In samples of wood treated with these dopes the water runs off or stands in beads on the surface. But if these same samples are placed alongside an untreated control block and are exposed to dry and to humid air conditions, most of them will absorb or give off moisture as readily as the untreated sample. There may be a slight lag, but after a very few days generally all the samples are found to become dry or wet just as though no treatment was applied.

Experiments indicate that absorption of moisture by a door is most effectively prevented by two coats of properly applied flake aluminum paint carried by suitable vehicle, two or three coats of good paint, or three coats of good varnish. The value of the newer materials as an agent to prevent moisture change and reduce shrink and swell of wood, especially doors, needs to be better established. Some of these materials may have other desirable properties such as durability, preservation, quality of finish, etc.

The home owner also has his responsibilities. He can guard against the various forms of physical abuse. A sticking or binding door should be properly refitted. The door should be kept properly painted or finished. Doors exposed to weather and sun are necessary evils in modern architectural designs which are considered good. A front door without any sort of protection such as a canopy, stoop, or porch is in for a hard time, and will need frequent help from the painter.

Weather-stripping of doors has increased in vogue. It is unwise to say what kind of strip is most to be preferred. Surely a type that crowds against the door or opposes its closing should be avoided. It will prevent the door from latching properly and may even tend to warp the door. Types pressing against the edges of the door are most in favor. Felt or rubberized strips are effective, although they may not look so well.

Use of double doors in winter is always preferable. Weather-stripping a single door does not attain quite as effective results as with the double door.

Humidity in the home, too much or too little, is injurious to woodwork in general. Humidity may be as low as 15 or 20 per cent in some homes. This will shrink the woodwork and open up cracks. With the arrival of summer, and 50 per cent relative humidity, the cracks will tend to close again, but leave broken, dark-looking, ugly joints. Such conditions are common and doors suffer as a result.

In houses kept at 40 to 50 per cent relative humdity in cold weather, frost will form on single doors and windows. Storm doors and storm sash are the best remedy. Frosted doors are sure to suffer from swelling.

The house owner has his problem to know how wet or how dry to keep his house, but most of them are much too dry in the winter; 35 to 40 per cent is a good range.

The wrong type or kind of door is often used. For inside purposes almost any kind of good construction will be satisfactory. Veneered doors built up on core have a tendency to stay straighter and are preferred for this reason.

Exterior doors probably cause the door maker more grief than any other. They are subject to heat and cold, sun and rain, and many forms of abuse. All the causes are present to effect shrink and swell, warp and twist, rot and decay, paint and glue failure, and loosened joints. A door in such a place should be given a fair chance for its life. The modern door is the best ever made, but poor judgment is often exercised in its use.

The subject of doors is an extensive one, but many of the phases of discussion properly belong under other headings. Testing of doors, strength, durability, shrink and swell, fire resistance, etc., are subjects for the laboratory and not properly a part of the manufacture. The door has been followed from the sawmill to the finished home, but in a necessarily limited manner. It is hoped that enough of the ground has been covered to stimulate further study on this century-old industry. As we progress, there will most assuredly be changes that will still further improve the modern door.

The woods used in modern door construction are listed by the U. S. Department of Agriculture in bulletin No. 158, which gives the average comparative properties of the clear wood of species grown in the United States.

BIBLIOGRAPHY

Catalog of sash, doors, blinds, and moldings, 1891, Curtis Brothers & Company, Clinton, Iowa. This shows four-panel door with raised panels; section of construction at stile and panel joint; five-panel door with mold nailed on; ornamental glass door; door with raised ornaments; fancy door when "gingerbread" decoration was in style.

Catalog of doors, glazed sash, and blinds, 1903, Huttig Manufacturing Company, Muscatine, Iowa. This shows five-cross-panel plain-face door with raised panels; two-panel door using plywood for panels; one-panel door with plywood for panels; a fashionable front door of the early 1900's.

Catalog of architectural woodwork, 1932, Curtis Companies, Inc., Clinton, Iowa. This shows a modern front door with possibly the limit of present-day decoration; an English design with many panels; circle top or groove door; modern glass door; favorite outside door; two-paneled door with veneered stiles and plywood panels; English design of raised-panel door; one-panel door with molded insert frame around panel; pair of French sash doors; smooth-faced slab door.

[The illustrations of the doors included in these three catalogs, and referred to in the paper, are halftones and therefore incapable of clear reproduction. This limitation to reproduction also applies to the illustrations of the various machines described in the paper. It is assumed that those interested in the paper know the principles and appearance of these woodworking machines generally.]

Discussion

F. L. CROOKS.[6] We wish to take exception to statements as to the superiority of the dowel door over the mortise-and-tenon door. The author referred to hand-made doors in buildings of the Revolutionary days, made mortise and tenon. Could a better argument be used for the merits of the mortise-and-tenon door than these early American doors?

The author states that the dowel door is far superior to the mortise-and-tenon door. We are manufacturers of both doors, and feel that the dowel door has its place. The principal argument is that it can be manufactured at less cost than the mortise-and-tenon door, and in certain types it is just as good a door, will serve the purpose just as well, and will last just as long as if made mortise and tenon.

Competition demanded that we install dowel-door machinery to reduce our costs of manufacture, and when this dowel equipment was installed it was naturally supposed that we would have little use for mortise-and-tenon machinery. But we found that when we made a one-panel dowel door with 5-in. stiles and top rail and the door was molded with a $1^1/_4$-in. flush or raised mold, in a great many cases when springing the molding in to get tight miters, it forced the door apart at the top rail. On examination, we found that the dowels would be properly glued, as the fibers of the wood in the core would still be perfectly tight to the dowel, but had been fractured, allowing the dowel to pull out of the end of the rail. We have also had the same experience with two-panel dowel doors, especially where they were molded with a heavy flush mold, and in bradding in the mold, blows from the hammer on the nails would drive off the stile, which apparently had been weakened when the molding was sprung in place. This necessitated putting clamps over the door at the rails to stop this breakage while doors were being molded.

After several experiences of this kind with the dowel construction, and never having encountered this trouble with the mortise and tenon, the management was convinced that it was a mistake to make all types of doors of dowel construction. Our experience teaches that certain types of doors should be made mortise and tenon.

The one-panel door is finished with a flush mold and not solid mold, as we would not care to take a chance of making a large lot of these doors running up to 3 ft 6 in. wide, and have to depend on two dowels in the top rail carrying the weight of this door over the years. The constant slamming of the door would have a tendency to weaken the dowel construction, and we would expect to be called on to replace or repair doors made this way.

The six-panel door is another design which we feel should be made mortise and tenon. On doors of this type, the mullions are mortised into the rail with a tenon $1^1/_2$ in. long. If this door was made dowel construction, it would have to be a slip tenon $^1/_2$ in. long. If this type of door is made dowel construction, very accurate workmanship is necessary, or there will be a strain on the dowels in the top rail, and when assembling the door, in a great many cases the dowels are bent and break off when door is being assembled. Mullions mortised and tenoned in the rail make a very much stronger and more durable door than if put in with a $^1/_2$-in. slip tenon. If the door is mortised and tenoned, it can be driven together and clamped at both ends and sideways, and tight joints are assured.

The same conditions as described for the six-panel door apply to the ten- and fifteen-light doors. It is practically impossible to make this door of dowel construction and not bend the dowels in the top rail. This, in a great many cases, causes loose bars and mullions. If this door is made mortise and tenon, it allows the top and bottom rails to be drawn tight on the mullions, insuring much more rigid bars than if the door is made dowel construction.

Where the mortise-and-tenon door is more practical than the dowel door is on special doors, accordion doors as large as 3 ft 6 in. wide and 20 ft high, 3 in. thick, special paneled doors paneled differently each side, paneled doors 10 or 15 panels flush molding one side, one flush panel the other side, circle head, special small paneled two-side doors with one diamond light in center, solid doors of different designs and different kinds of wood from $1^3/_4$ to 4 in. thick, and many other types of special-design doors which are practically impossible to make of dowel construction and have them stand up over the years.

CHAIRMAN ARTHUR D. SMITH, JR. (president, Geo. W. Smith Woodworking Company, Philadelphia, Pa.): Our experience has been that mortise-and-tenon door construction is better in special-door manufacture, where the door is being built to architect's details. Unquestionably the dowel door is just as good and cheaper, and therefore more desirable for the stock doors that are made in Mr. Madsen's plant. I also hold with Mr. Crooks that the mortise-and-tenon door is the more practical one for a special-order proposition. We recently had a job in Philadelphia for 61 doors on one floor of a building, every door being different. It was a difficult job using the mortise-and-tenon construction, and it would have been even more so with the dowel construction.

Mr. Crooks said that where the door is a molded door rather than solid sticking, it is the practice to spring that molding in and set it in one corner, and then bend it and set it down in the other corner. He said that he had known where springing that molding in has caused an expansion that broke the glue joint of the doweled door. If a door was properly made, I cannot conceive of breaking the door apart by springing the molding.

P. J. SCHLOMER (Wilkin-Challoner Company, Oshkosh, Wis.): Mr. Madsen's paper was mostly on stock doors. Mr. Crooks, on the other hand, turns out special doors mainly, and I believe his statements are also correct. So far as the small molding having a tendency to break apart the glue joints, I do not believe that, because when the glue is squirted in, there is always sufficient glue left on the door, and that has a tendency to make a tight joint. So far as open joints developing, I do not believe that is the result of the boring of the holes in the doors. That

[6] President, W. D. Crooks & Sons, Williamsport, Pa.

would be more likely to come in the tenoning operation where the drill does not cut square.

V. J. Reed (Mattison Greenlee Company): If the machine operation is accurate enough so that no flaw can be found from the machine operating the bore, there is very little difference between the dowel and the tenon.

Chairman: Do you find that the dowel construction is more prevalent?

Mr. Reed: Yes; that is true in the West, but not in the East. It is a little easier to machine on the tenon than on the dowel. The tenoner can be set up very readily; and in the boring, if the machine is not accurately built, you are going to expand that part of the hole that is out of line. I would not say that my preference would be for a mortise-and-tenon on an order that had very few of a kind or size. Sometimes it would not be profitable to set it up for a few doors.

Mr. Kurkjian: Sometimes the Eastern designers of furniture for a hotel or an apartment use their own ideas of what is effective and strong, and will put in mortise-and-tenon joints; and I know of one manufacturer who took the order on the furniture and had it written in the order that they would not be responsible for the mortise-and-tenon joints holding after the fixtures were in. Their reason was the extreme dryness of rooms in a hotel and the moisture in the air from opened windows, so that this sudden variation affected the mortise-and-tenon joint. The dowel would have been guaranteed. In the Grand Rapids district the dowel construction of joints of furniture is general. On the other hand, in the Carroll district, I believe the mortise-and-tenon is used almost exclusively. An Eastern architect specifies mortise-and-tenon joints because most of those men are brought up under the old-school influence, and they still are of the opinion that the man who made the door by hand with a mortise and tenon, and had the tools to do that, was right. Now we have special machines to bore straight and hold the stock down. If the matter of the strength is brought in, I believe those doweled doors are certainly just as strong as any mortise-and-tenon doors were.

Chairman: The author states that it would be of interest and service if each type of door could be tested to destruction, to prove which is the most serviceable. In the East the building code provides for fireproof construction in certain buildings. The code will permit wooden doors as being fireproof, provided that the door will pass certain tests. I have witnessed one of these tests, and the door that withstood that test had mortise-and-tenon construction. At the same time, doors were tested in the same furnace with dowel construction, and some of them passed. It is my recollection that the average of the mortise-and tenon door was much higher than that of the dowel door.

C. Lindbeck (United Lumber and Supply Company, Jamestown, N. Y.): I think a mortise-and-tenon is ahead of the dowel construction, as it stands up better. In a building it does not make much difference, but in an ordinary test the mortise-and-tenon door will stand more. It depends on how they were put together at first.

William H. Gunlocke (Wayland, N. Y.): After many years of furniture manufacturing, particularly chair manufacturing, we have come to know something about the dowel construction of chairs. In most instances it is superior to mortise-and-tenon. I cannot picture a door constructed with the dowel permitting of the molding pushing the door or spreading the stiles. There was something wrong in that instance; either the dowels did not fit and were not glued or the man who was cutting the molding did not understand his business. We do not use a doweling machine, because we have no faith in such a machine. There are too many failures in a machine that glues and drives dowels. If you are boring a hole in a piece of wood, side or end grain, and take a glue stick and glue that hole and drive that dowel, and then with a pair of pliers extract that dowel, you will be surprised to learn what a small percentage of film or coverage you have on that dowel. Few people appreciate that a $^1/_2$-in. dowel has $1^1/_2$ in. of width that must be covered if it is going to hold. The dowel is longitudinal grain; you have $1^1/_2$ in. there; there is the same amount of area in the end wood. That is 3 in. of wood that must be covered with glue to give this a joint to do a good job. We have a large hot-air box, and when the dowels come in, we never think of taking the moisture-content reading. There are screens in this hot box, and those dowels are put on trays of this mesh wire. Over the front of the box is a hanging canvas.

When we drive those dowels in, they are absolutely bone dry—so dry that the moisture will expand the dowel after it is driven. As to the mullions in a mullion door not fitting, that is only poor work. No one calling himself a mechanic would do that kind of work. If the holes were bored as they should be and properly framed, this would not happen. As to doors taking on moisture, if the door is finished, there is not much chance of its taking on much. One of the worst problems in the furniture industry is the manufacture of a wood-seat chair, and it is almost incredible that wood-seat chairs 18 or 20 in. wide will expand $^1/_4$ in.; that they just pushed the back rails and slats apart. One of the things that we are most particular about is the coating of the seats around the outer side. You can do this better with a brush.

C. B. Norris (Haskellite Manufacturing Company, Grand Rapids, Mich.): The matter of the fire test interested me. We are making fireproof panels that might be used in door construction. These fireproof panels do not have any fireproof wood in them. However, they would stand up well in the test described. We have tried them with bunsen burners, and they compare very well with panels made up with fireproof lumber. They are made in the ordinary way, except that underneath the cross-banding we have glued a layer of asbestos millboard that has been impregnated with phenol formaldehyde. This will give the board strength so that it will not spread afterward. We have had rather good success in these panels, because after all no wood is fireproof.

Author's Closure

The discussion on the manufacture of doors centers upon the relative merits of dowel and tenon construction. When we consider special or odd doors we sometimes find constructions where only mortise-and-tenon joints are practical because of limitations in space, etc. In making odd doors, a few of a kind, which are identical to stock doors except for size, it is just as easy to machine the parts and bore them accurately for dowel construction as for mortise and tenon.

A modern door factory, using proper methods, gages, and equipped with proper and adequate machinery, has no difficulty in machining parts properly and boring holes accurately spaced for the dowels. Dowel construction can be made just as readily and economically as mortise-and-tenon construction when applied to the stock type of doors.

To call it an advantage of tenon construction that the tenon may be cut under-width to permit side movement to absorb inaccuracies is questionable. It looks more like toleration of inaccurate work.

To question the possibility of boring doweled holes accurately enough is to question the soundness of the method by which possibly 95 per cent of all stock doors are manufactured in the United States.

As to gluing dowels, some tests have proved that squirting glue in the holes is more satisfactory than dipping the dowels

before driving. Putting glue in the hole applies the glue to the walls. Glue applied to the dowel is largely scraped off the dowel by the square shoulder edges of the holes. A slightly pointed dowel tends to ride over glue on the walls of the hole. A combination of the two would be better yet. Perhaps counterboring the holes on a bevel would improve the holding of the dowels, but this is impractical where the dowels enter on a surface that is molded other than flat.

The real answer is to make some tests on the two constructions and determine the relative holding power of each method.

WDI-55-3

Laminating With Phenolic Resins

Some Practical and Theoretical Considerations Involved

By ERICSSON H. MERRITT,[1] LOCKPORT, N. Y.

Phenolic resins as wood adhesives have qualities that have been long known, but commercial application has been retarded because of the cost. The method of manufacturing plywood is said to be revolutionary in the manner of applying the adhesive. The paper describes four ways in which these resins may be applied as an adhesive between two or more plies of wood or other material, these being as a varnish, as a film, as a dry powder, and as a colloidal solution. The author concludes that, despite objections raised against the high temperatures employed in laminating with resins, they constitute an ideal adhesive for thin panels.

PHENOLIC resins, so called, are synthetic products derived from the condensation and polymerization of phenol (carbolic acid) and formaldehyde or, in special cases, other aldehydes. The resulting resinous products may vary in their physical characteristics over wide limits, depending upon the proportions of phenol and formaldehyde as well as upon the procedure employed and the type and amount of catalyst used. The present commercial development and application of phenolic resins started with the inventions and discoveries of Dr. Baekeland about 1909, though the reaction of formaldehyde and phenol had been known for many years previously. In several of his early patents Dr. Baekeland disclosed that phenolic resins could be used as adhesives for wood. However, until comparatively recently, there had been no commercial developments along this line, though patents had been taken out in this country and abroad from time to time covering specific processes involving phenolic resins as wood adhesives. Commercial development has been primarily retarded, at least in the plywood field, by a cost consideration, and it is still the cost item that prevents their widespread use today.

There are several ways in which resins may be applied as an adhesive between two or more plies of wood or other material, some of which involve features that are patented or have patents pending on them. They are:

(1) *As a varnish.* The resin being soluble in alcohol, acetone, and other similar solvents, it may be made into a varnish and applied to the plies by brushing, dipping, or rolling. When this method is employed, it is next necessary to pass the coated plies through a kiln or oven to drive off the volatile solvent prior to hot pressing.

(2) *As a film.* In place of applying the varnish directly to the surface of one or more of the plies, a thin sheet of paper is impregnated with the varnish, the solvent is driven off, and the resulting dry film used as the adhesive by placing a sheet of it between each pair of plies and hot-pressing the resulting assembly.

(3) *As a dry powder.* The dry resin is ground into a fine powder which will pass at least an 80-mesh screen, and this dry powder is applied by special equipment to the surface of the plies, which are then assembled and hot-pressed.

(4) *As a colloidal solution.* The resin is not soluble in water, but it is possible to suspend it in water with the aid of a protective colloid, thus securing a stable solution that can be applied the same as the varnish. After the application of this colloid, it is necessary, just as with the varnish, to dry out most of the water prior to hot-pressing.

Because there is no apparent commercial future to method (1), on account of its involving the loss of relatively expensive solvents, it will not be discussed in detail. The other three methods will be taken up in detail later.

While there are several differences and variations in the various laminating processes involving phenolic resins, due to the different methods of application of the resin, they have characteristics in common, many of which vary from conventional glue methods.

In the first place, phenolic resins, in their reactive state, are thermo-plastic. By thermo-plastic is meant that they become plastic when heat alone is applied, without the necessity of a liquid being present. The usual glues are not, or are at least only partially, thermo-plastic. Animal glue and casein will melt or become plastic when heated in the presence of a very small amount of water, while with reactive phenolic resins no liquid is necessary to secure plasticity. Therefore, this characteristic theoretically permits a perfect dry-gluing process.

Second, phenolic resins are thermo-setting. They set or polymerize with the addition of heat, in contrast with the usual setting of glue by the evaporation of water or the setting of cement by combination of the water chemically with the cement itself. The setting or polymerization of the resin is somewhat similar to the setting or coagulation of a blood glue.

Since phenolic resins are both thermo-plastic and thermo-setting, they must be used with heat and pressure to make the bond, which means that a hot-plate press must be a part of the equipment in laminating veneer with resin. It is obvious that in laminating sheets of veneer that are not perfectly flat and that are rigidly deformed or buckled, pressure must be applied to bring them into contact. However, in making a bond with phenolic resins, pressure is also necessary to develop the proper bonding qualities of the resin. When, by the application of heat, a phenolic resin polymerizes and changes from its reactive state to its insoluble and infusible state, a multitude of small blisters is formed. In other words, the resin seems to bubble or boil. To prevent this and to secure a perfect bonding film between the plies, it is necessary to apply a combination of heat and pressure. Consequently, the hot plate press must apply both uniformly.

It is evident that these resins constitute an adhesive which, in its primary form, is dry and can remain dry on the surface of the assembled but unpressed plies. Moreover, they will become plastic and flow without the addition of any liquid, simply by the

[1] President, Merritt Engineering & Sales Company, Inc., and General Manager of Plywood Engineering and Process Company. Mr. Merritt was graduated in 1916 from the College of Engineering of the University of Michigan, and was employed for one year as mechanical engineer by the Cadillac Motor Car Company. Since 1917 Mr. Merritt has been associated with the Merritt Engineering and Sales Company, being the third generation of his family in direct charge of the company. He has been president of that company since 1926 and General Manager of the Plywood Engineering and Process Company since its inception two years ago.

Presented at the meeting of the Wood Industries Division of The American Society of Mechanical Engineers, Jamestown, N. Y., November 15 and 16, 1932.

Note: Statements and opinions advanced in papers are to be understood as individual expressions of their authors, and not those of the Society.

application of heat and pressure, and they will then change into an insoluble and infusible form, making a complete and permanent bond between the plies. Thus we have an adhesive that theoretically is 100 per cent dry and is not dependent upon the presence of any liquid. This, obviously, is a big step forward in the adhesive art, since the swelling of the wood upon the application of wet adhesives, combined with the consequent shrinkage when the excess liquid is driven off, accounts for many of the problems and failures encountered in conventional gluing processes.

But beyond this, the resin, when polymerized or "set" by the heat and pressure to form the bond, is not only water-resistant, but is totally insoluble in water, and if the polymerization is complete, is insoluble in most other solvents, except concentrated alkalis. Also, it is infusible and is not further changed by heat until it begins to break down and char at temperatures in excess of 500 F. It is not susceptible to attack by fungi and bacteria. In fact, it is surprisingly inert.

There are problems of application, but before discussing them, let us examine the necessary requirements of pressure, heat, temperature, and time.

Pressure

When using phenolic resins, there are no requirements concerning the application of pressure that are not always present in the lamination of wood plies by any process. Since heat must be applied along with the pressure, some new factors are introduced, although they are common to all hot-press operations. The principal one is that, since there is only a thin body of material to be pressed between each pair of plates, there is very little cushion to take up press deflection, whereas in conventional cold pressing, the thick bundle of material will in a measure compensate for press deflection. Any hot press, in order to produce even passable results, must have rigidity far beyond that required in a cold press working on a bundle of stock. Therefore, the cost of the bare press must necessarily be higher than the cold press used with cold wet glues. It is not practical to convert a typical cold press into a hot press by the simple addition of some hot plates.

Since the pressing of any glue that is practically dry at the time of pressing involves no "squeeze out" problem, maximum pressures permitted by the wood may be employed, and since better bonds and more homogeneous panels result from the use of maximum pressures, it is usual to employ pressures from 150 to 300 lb per sq in. when laminating with resins. Due to the relative inertness of resins applied as film, it is necessary to employ higher pressure with films than with resin applied in other forms, other conditions being similar.

Heat

This thermo-plastic material requires a definite time-temperature cycle to produce polymerization, and therefore a definite heat input requirement, since it is necessary to maintain a minimum temperature for a definite time. There are two factors that determine the total Btu input required; one is the type of resin and extent of polymerization at the moment of heat and pressure application, and the other is the mass of the panel. Thickness of ply—that is, the distance of the glue line from the hot plate—affects the time of heat application, but the total mass of the panel being pressed also influences the total heat input, since it is obvious that the greater the mass, the greater the number of Btu required to develop a given temperature at the glue line. For example, if three plies of $^1/_{20}$th veneer are subjected to a pressure of 200 lb per sq in. between two plates having a temperature of 320 F, a bond can be secured in 50 sec with the proper resin applied as a dry powder, but if the $^1/_{20}$th center ply is replaced by a lumber core $^3/_4$ in. thick and the same two $^1/_{20}$th-face plies are applied to it, 120 sec will be required under the same pressure and temperature to effect a bond, since the mass of the core absorbs the heat and prevents development of the required temperature at the glue line until the temperature of the mass of the core has reached the point at which further transfer of heat practically ceases. The fact that it is necessary, in a short time, to heat up a lumber core to a minimum temperature of 250 F by pressure contact with hot plates, in order to secure the necessary temperature conditions at the glue line, constitutes one factor wherein phenolic resins fall short of the ideal adhesive. This rapid heating of a mass of substantially dry wood, like a lumber core, to a relatively high temperature, and holding it at the temperature long enough to cure even the most advanced resin, introduces stresses that cannot be other than detrimental. High temperatures may be safely applied to wood surfaces by the application of hot plates as long as evaporation is taking place. Time of contact is not a disturbing factor until evaporation ceases, but at that point rapid deterioration of the wood begins.

Temperature

Phenolic resins, in the reactive state, are not completely stable. Slow polymerization is constantly taking place. But in considering such resins as adhesives, this factor does not particularly enter. Temperatures at which plasticization and polymerization take place in producing plywood are what count. It is obvious that temperatures must be employed at the glue line that will, in combination with the pressure, be high enough to cause the resin to become plastic. However, it has been found that the melting point of a given resin must be materially exceeded if the proper rate of polymerization is secured to produce a good bond. The minimum temperature which will result in the necessary rate of cure or polymerization depends upon the particular resin used. The minimum temperatures for phenolic resins, in general, are given by a number of authorities on the subject at 290 F. The author has found, from testing a large number of phenolic resins for wood-bonding properties, that glue-line temperatures below 300 F result in material loss of strength. These tests include resins applied as varnishes, films, dry powders, and as colloidal solutions. On the other hand, some recommend plate temperatures as low as 266 F, which would result in even lower glue-line temperatures, as will be shown later. Since apparently the employment of increased pressures will permit of the use of slightly decreased temperatures, this difference of opinion as to permissible minimum temperatures may be due, in some measure, to differences in the amount of pressure used. Temperatures up to 350 F apparently have no detrimental effect upon the curing of the resin. At any of these temperatures the critical factor in the problem is, after all, the wood itself, rather than the resin, and the critical point with respect to the wood is complicated by the time element and the moisture content of the wood. The essential point to be brought out is that the use of phenolic resins as adhesives necessitates the application to the wood of temperatures at least above 260 F. Thus it is evident that such resins again fall short of the ideal adhesive. While it is possible, under certain conditions, to employ such temperatures for the required length of time, without the slightest detrimental effect on the wood structure, the ideal adhesive should not require temperatures above 212 F, thus eliminating all chance of blister from the formation of steam in the interior of the assembly.

Time

Time enters the problem from several angles, and it in turn is influenced by nearly every other factor. The time required to complete the bond has a vital bearing on the total cost of laminating. It affects the cost of the equipment, since the press

capacity required for a given daily production is in direct proportion to the time required in the press. It affects the labor cost, the floor space required, the inventory, and the carrying charges. It determines the service that it is posisble to render the customer. Duration of temperature and pressure is by far a greater factor in the effect produced on the wood than either temperature or pressure.

The time required to make a complete bond with phenolic resins is influenced and determined by numerous other factors, which will be covered later. With veneers containing 5 per cent or less of moisture, a plate temperature of 320 F, and a pressure of 200 lb per sq in., panels of three equal plies can be completely bonded with a suitable phenolic resin applied as a dry powder in the following times: $^{3}/_{64}$ in., $^{1}/_{2}$ min; $^{3}/_{20}$ in. 1 min; $^{3}/_{16}$ in., $1^{1}/_{2}$ min; $^{3}/_{8}$ in., 3 min.

When a similar resin is applied as a colloidal solution, these times are increased approximately 50 per cent, even if sufficient water has been removed prior to the pressing operation to bring the coated surfaces to a proper dry condition.

Published data on the time required with a certain resin film glue are as follows: "Thickness of the outer veneers up to $^{1}/_{16}$ in., gluing time 6 to 8 min; thickness of from $^{1}/_{16}$ to $^{5}/_{64}$ in., 10 min. Thickness of from $^{5}/_{64}$ to $^{5}/_{32}$ in., 12 to 15 min."

These figures convey a general idea of the speed possible with phenolic-resin adhesives applied to thin panels. The most obvious factor affecting the time required to secure a given result in any hot-pressing operation is the thickness of material interposed between the hot-plate surface and the glue line; that is, the thickness of the outer plies. To determine the effect of the thickness of the plies, it is necessary to determine the rate of heat transfer through wood under the particular conditions prevailing at the glue line. Fig. 1 shows this rate of heat transfer for $^{1}/_{64}$-in. and $^{1}/_{16}$-in. dry birch. Fig. 2 shows the rate of heat transfer through $^{1}/_{8}$-in. aluminum cauls. These tests were all made with veneers containing less than 5 per cent moisture. While the rate of heat transfer is influenced materially by the moisture content of the wood, it will not be considered here, since veneers containing over 10 per cent of moisture cannot be used successfully with resin in any form.

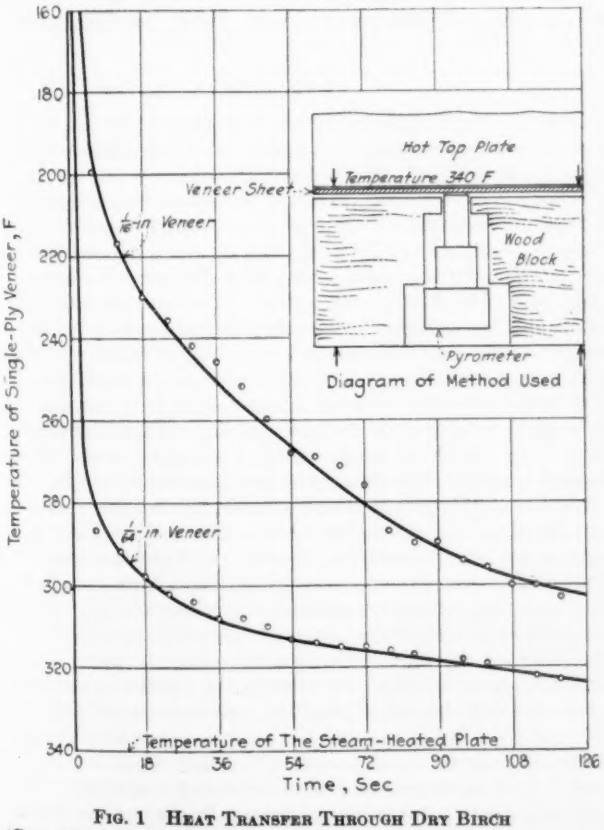

FIG. 1 HEAT TRANSFER THROUGH DRY BIRCH

(Curve showing rate of heat transfer from a steam-heated platen through a single-ply veneer sheet when held in contact by a pressure of 150 lb per sq in.)

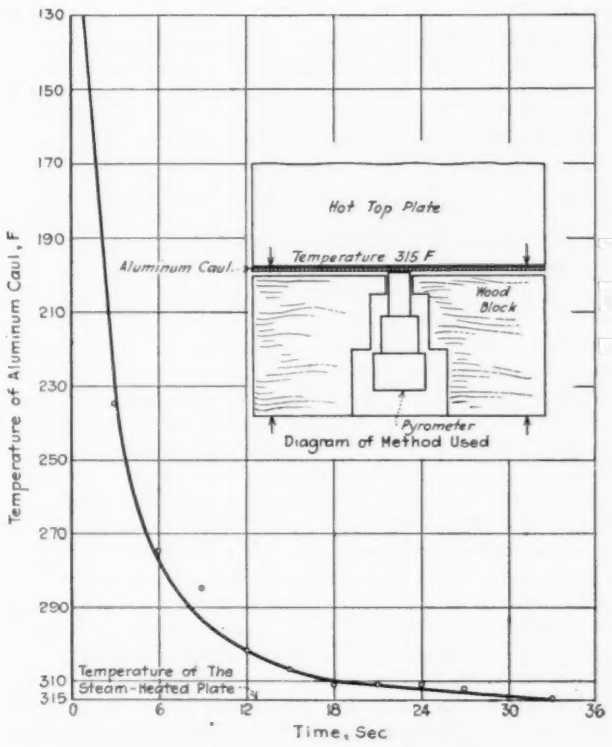

FIG. 2 HEAT TRANSFER THROUGH ALUMINUM CAUL

(Curve showing rate of heat transfer from a steam-heated platen through a $^{1}/_{8}$-in. thick rolled aluminum caul when held in contact by a pressure of 150 lb per sq in.)

Another important factor affecting the press time required to secure a complete bond is the character and condition of the resin at the time heat and pressure are applied. First, there is the fundamental fact that the time-temperature curve of all phenolic resins is not the same. Second, due to the method of applying the resin or to the influence of other prior operations, the extent to which the resin may have been partially cured or polymerized will vary over wide limits. Since the aim in any hot-gluing process is to achieve a minimum time of application of heat and pressure, the ideal resin is the one that has the fastest rate of cure. This is a problem of the resin manufacturer who secures rapidity of cure by the addition of various accelerators, just as in the rubber industry speed of vulcanization is increased by the addition of chemical accelerators. After the particular resin to be used has been selected, it must be determined how far the cure may be safely carried during its manufacture and still allow sufficient range, not only in the resin itself, but in its application as an adhesive. Allowance must be made for possible further cure during shipment and storage, and during closing of the press where heat is present and may reach the glue line before the application of the pressure. The latter is a very vital consideration, especially in a multiple-opening press where, with manual loading, there may exist a considerable time element between the insertion of the first assembled panel between a pair of hot plates and the moment of application of full pressure on

the completely loaded press. If due to contact of the panel assembly with the hot plates or to other causes the cure or polymerization of the resin progresses too far before the full pressure is applied, no bond will result. While there is no disturbing "assembly time" factor entering into the laminating of plywood with resin, there is this important factor of time of press loading and closing, even if protective measures in the form of metal or wood cauls are used. The whole matter of premature cure of the resin between the plies in the hot press may be best understood by comparing it with the making of steam in a boiler. If cold water is put into the boiler, it is necessary to apply heat for a considerable time in order to bring the water to boiling temperature, but if water at, say, 200 F is put into the boiler, very little heat and very little time are required to develop boiling temperatures. In the same way if resin, with a low cure, is applied to the veneer, it is necessary to apply considerable heat for a relatively long time to bring the resin up to the point at which final and complete polymerization takes place, but if the resin, when it is applied to the plies, has been "advanced" nearly to its "end point," very little heat and time are required to reach this "end point." Of course, the degree of advancement of a resin will in some measure influence its cost, just as hot water is worth more to a steam plant than cold water. Due, however, to the action of heat and pressure on the veneer and the cost of hot-pressing equipment, it is usually much cheaper in the long run to pay a premium for a highly reactive resin that is sufficiently advanced to give minimum pressing times.

Time required in the press is also vitally influenced by temperature. If we apply to the plies hot plates that have a temperature of 320 to 330 F, not only will the transfer of the heat through the plies be faster, but the cure of the resin will also be faster than if plates of a temperature of 260 to 270 F are employed.

Time of cure of a resin is also influenced by the amount of free liquid present. A given amount of resin in solution or in suspension will not, under identical conditions, completely polymerize in the same time as will the same amount of dry resin. Therefore, the greater the moisture content of the assembled panel prior to pressing, the slower the cure, and, conversely, the longer the time required under heat and pressure. It is immaterial whether this moisture content of the assembled plies be due to moisture carried in the veneers themselves or whether it is water or other liquid added to the assembly during the process of applying the resin. Due to this factor and also to the fact that the total moisture content of the assembly must be low, in order that blisters will not result from the hot-pressing operation, any method of application of the resin in solution or suspension must be followed by a drying operation to remove the liquid vehicle. Such a drying operation must be under careful temperature and time control to prevent excessive curing of the resin during this operation. If the cure is carried too far in this drying operation, no bond will result, largely because there will be no stage during the hot-pressing at which the resin will be in a plastic state. It is obvious of course that any method of applying the resin in a liquid vehicle introduces the same old problems of swelling and shrinking the wood present in all wet glue processes, irrespective of whether the bulk of the liquid vehicle is removed prior to the hot-pressing operation. It must be borne in mind that the introduction of any appreciable amount of water or other liquid that swells the cells of the wood is a serious detriment, and only introduces problems that otherwise might be avoided.

The amount of moisture present in the unpressed assembly at the time it is inserted in the press not only affects the time of cure of the resin in the hot press, but it also has a vital influence in other ways. At the temperatures and pressures employed any moisture present will be transformed into steam, and if this steam does not entirely escape from the panel being pressed, an internal pressure will be developed in the panel. This internal pressure is counteracted by the external pressure exerted by the press, but as soon as the external pressure is removed, upon opening the press, the internal pressure must relieve itself, and blisters form between the plies. In extreme cases the wood itself is ruptured. The formation of such blisters can be combated by reducing the moisture present, by providing means for it to escape or by reducing the temperature of the pressed panel below 212 F before the removal of the external pressure. The latter method is a remedy for a bad condition, while the elimination of excess moisture removes the cause. A heating and cooling cycle with the usual solid drilled steel hot plates is a slow and costly process, due to the large mass of metal involved. However, new types of hot plates have been developed which permit a heating and cooling cycle in less than 1 min, with a minimum requirement of steam and cold water. However, their use with resin adhesives does not completely give immunity to the use of high-moisture-content veneer. This arises from the fact that, while it is perfectly possible to completely cure a phenolic resin in the presence of considerable moisture, the resin so cured does not make a good bond with the wood plies. For example, if three sheets of $^1/_{10}$th veneer, containing 20 per cent moisture, are assembled with resin in any form and hot-pressed, and then cooled before the external pressure is removed, in order to avoid the formation of blisters, it will be found that the bond is only superficial. Apparently there is a definite limitation on the allowable moisture that may be present when laminating with phenolic resins. There is also some evidence to show that the maximum allowable moisture will vary with different species of wood, with gum requiring a lower moisture content than several other species.

Four methods of applying resins have been enumerated, each method having definite characteristics due to the method employed.

Film

In the film method, certain problems incident to the use of the varnish or colloidal method are assumed by the film maker. The laminater is furnished with a uniform product, in which the resin has been cured to a definite point, and in which there is a constant and definite resin content. In using a resin film, the spread of the adhesive is uniform and it is constant. Under some conditions, the fact that the laminater cannot vary the amount of spread might be a distinct disadvantage, since it is quite generally admitted that the minimum amount of adhesive to secure a maximum bond will vary with the thickness of the plies and with the different species of wood. It is reported that the resin content of one well-known resin glue film is such that 11 lb of actual resin are applied on each 1000 sq ft of glue line. This corresponds very closely with the average spread of actual dry resin, when the resin is applied either as a dry powder or as a colloidal solution.

While phenolic resins are thermo-plastic, it is necessary, in the manufacture of a resin film glue, to use a high-melting-point resin and one that is not too reactive, in order to minimize the tendency of the film to react and become sticky in the roll when stored and used under the extreme temperature conditions that are met in the Southern parts of this country. Therefore, to aid in the plasticizing of the resin in the film, advantage is taken of the small amount of moisture contained in the veneers to be laminated, and it is important that this moisture be sufficient to effect plasticization of the resin. Also, it is important that the amount of moisture is not excessive, for otherwise no bond will result. This requirement of a rather definite minimum and maximum limit to the moisture present in the veneers to be laminated with the film places this method in the realm of an exact technical process. The description of one such film defines

these moisture limits as follows: "(1) Cores should not exceed 5 to 6 per cent moisture content. (2) Crossbanding veneers, outer veneers, and fancy veneers require a moisture content of approximately 6 to 10 per cent. This is the moisture content that is found in veneers which have been stored for some time in workshops with normal temperature and moisture content, i.e., a room temperature of 70 F and atmospheric moisture of 60 to 70 per cent."

Since, in using a film, it is necessary that a definite amount of moisture be present, it is impossible to progressively press long panels in a short press, because the wood adjacent to the press during the first pressing dries out to such an extent for a short distance beyond the press that no bond will result over this distance when the next pressing is made. Therefore it is necessary to use a hot press having a platen area equal to the maximum size panel that it is desired to make.

In using a film-resin glue it is claimed there is no difficulty in making five-ply or seven-ply panels in a single pressing, though naturally the time in the press must be increased to compensate for the total thickness of plies lying outside of the inner glue lines.

Powder

When the resin is applied in the form of a dry powder, the laminater is furnished with a uniform product having a definite degree of cure, which may be well toward the "end point" of the resin, and a very reactive resin may be employed, due to the fact that the resin can be maintained in powdered form even under severe temperature conditions by the addition of special agents. Due to the high reactivity and advanced degree of precure of the resins applied as dry powders, extremely short times in the press will produce the complete bond. However, it is desirable with these resins to further speed up their cure by employing somewhat higher temperatures than are recommended for use with the film. Due again to the high reactivity of the resins applied in powdered form, the presence of a liquid is not required to secure the required plasticity under the action of the heat and pressure; consequently, there is no minimum requirement as to the moisture content of the veneers. Thus it is possible to progressively press long panels in a short press. This is an important factor, since it permits the laminater to purchase a press of the size of his average length panel and still be able, by progressive pressings, to make the small percentage of panels longer than his average.

While it is possible to insert a dry glue film between plies of veneer and have it maintain its position in relation to the plies during the various handling operations incident to assembly and loading of the press, this is not true of a dry powder. Therefore when the resin is applied in this form, it is necessary to provide some means to hold the powder in the same even layer in which it is deposited. The usual means of accomplishing this is to spray on the surface of the ply a minute amount of liquid, so that the dry powdered resin is applied to a slightly moistened surface. If a heavy spread of the dry resin is applied, it is also of advantage to spray a similar amount of the liquid on the deposited layer of the powdered resin. The preferred procedure involves the use of a liquid having a boiling temperature above the maximum temperature reached in the hot press and one that will combine chemically with the resin itself, so that no vapor is liberated to develop internal pressure and the consequent blisters from the action of the heat and pressure in the press.

Another factor arising from the use of a highly reactive resin in dry powdered form is that the character of the bond is influenced by the rate of cure. This makes it extremely difficult to make five-ply and seven-ply panels in a single pressing, unless the plies are $^1/_{16}$ in. or less in thickness.

Colloid

As previously pointed out, the application of any adhesive in a wet state is open to adverse criticism. While the problems arising from pressing a wet adhesive can be eliminated by drying out the liquid used as a vehicle prior to pressing, in the case of a resin adhesive this operation must be carefully controlled. However, when a resin has been applied as a colloidal solution and the drying operation has been properly conducted, the resulting film of dry resin on the surface of the coated plies is uniform and the resin itself may be in a highly reactive state and develop complete bonds in a relatively short time in the press. The recommended temperatures correspond with those with the powdered resin. It is also possible to progressively press with the resin applied in this manner.

In conclusion, it would appear that despite any objections that might be raised against the high temperatures employed in laminating with resins, they, on the whole, constitute an ideal adhesive for thin panels. Whether they or any other hot-press adhesive employing the same amount of relatively high temperature input be successfully and economically employed with very thick plies is still an open question.

Discussion

Charles B. Norris.[2] We have been doing some work lately on phenolic resins in connection with the design of a large hydraulic press for the mass production of panels 10 ft square and about $^3/_4$ in. thick. We also have adapted this method of laminating to the hot-plate presses with which our plant is equipped. We have been chiefly concerned with the resins as colloids dispersed in water. We have done some work with the varnishes, but very little with the powder. We have concentrated upon the colloid because it seemed to be the most easily handled of the three. The results of our experimental work seem to justify our choice. The author indicates that he has found it very difficult to use the colloid. In fact, he gives quite a list of rather serious obstacles in the way of its successful use. We are using it successfully in our plant at the present time.

The author says that gluing with the colloid "introduces the same old problems of swelling and shrinking of wood." Let us see of what these problems consist. In a section through a three-ply panel at one of its edges, the grain of the two faces runs parallel to the plane of the paper. The grain of the core is perpendicular to the plane of the paper. If the panel has taken on moisture since it was glued, the core would have swollen and bulged out beyond the edge of the panel. The faces have not swollen in proportion because wood swells very little with the grain due to increase of moisture content. The core grain was of course straight at the time the panel was glued. A compression stress is built up in the core due to the swelling of the wood. The swelling of the core is restrained by the faces, and hence the faces are in tension. The compression in the core is transferred by shear in the glue line, to the faces where it balances the tension. The shear stress is local to the edges of the panel. It is very high at the edge and decreases rapidly toward the interior of the panel. It is directly proportional to the compression in the core of the panel due to the swelling or shrinking, other factors being kept constant. There will be a certain moisture content of the panel at which the stresses within the panel are zero. This moisture content will be that which obtained in the panel at the moment the various plies were bonded together. Variations from this moisture content will give rise to the stresses described. Computation of the shear stresses involved is rather difficult,

[2] Mechanical Engineer, Haskelite Mfg. Corp., Chicago, Ill. Mem. A.S.M.E.

but the compressive stress in the core is very easy to evaluate. The shrinkages we can expect in different woods have been tabulated by the Forest Products Laboratory.[3]

We find that yellow poplar, for example, will shrink or swell about 0.28 per cent for a change of moisture content of 1 per cent. We may assume that the faces hold the core so that this swelling does not take place, since the shrinking and swelling of wood with the grain is negligible. If the longitudinal shrinkage of wood is computed from the volumetric tangential and radial shrinkages given in Technical Bulletin No. 174, a value of about 0.08 per cent for a moisture change of 1 per cent is obtained. However, the values given are not accurate enough for this use. The Forest Products Laboratory has found a value of 0.01 per cent to be about correct.[4]

The amount the faces stretch because of the tensile stress to which they are subjected is very small. Young's modulus for wood with the grain is about 20 times its value across the grain. (See "Report on Materials Used in Aircraft, 1920, by C. F. Jenkin, British Aeronautical Research Committee, His Majesty's Stationery Office, London, 1920.) Therefore if we assume that the faces are as thick as the core the extension of the faces is about one-fortieth of the amount that the core wishes to swell, or about 0.007 per cent for a moisture change of 1 per cent. The Young's modulus of poplar across the grain is about 80,000. The Forest Products Laboratory in Bulletin 556 of the Dept. of Agriculture, gives a value of about 1,600,000 with the grain; hence the value given above.

The stress, then, for a 1 per cent change in moisture content is about $0.0028 \times 80{,}000 = 224$ lb per sq in. It is evident that this stress may become quite high if the panel is allowed to assume a moisture content very different from the moisture content it had at the moment it was bonded together. The average moisture content of wood placed out of doors is about 12 per cent; therefore plywood which is to be used out of doors should be glued up at this moisture content if internal stresses are to be avoided. In the light of this fact it is not seen that the use of a dry glue overcomes the difficulties implied in the paper.

The author warns that the high temperatures used in making plywood with phenolic resins will cause serious internal stresses, particularly in thick panels. We have made successfully panels composed of nine plies of $^1/_7$-in. poplar veneer. The stresses set up by changes in temperature are similar to those set up by changes in moisture content. Coefficients of thermal expansion are given by Otis F. Hendershot,[5] and by the Forest Products Laboratory (project 134–8).

We find that when yellow poplar cools from 300 F to 70 F it will shrink about 0.354 per cent across the grain and about 0.023 per cent with the grain. The deformation in the core due to the cooling is then about 0.33 per cent. The stresses set up are, therefore, a little greater than those due to a change in moisture content of 1 per cent. It is evident that these stresses do not present a serious obstacle to the gluing of thick panels.

The author points out the danger that panels glued at high temperatures will blister when the press is opened because of the presence of moisture. This is a real difficulty. If water is held at a higher pressure than 67 lb per sq in. abs and heated to 300 F, the water will remain in the liquid form; however, if the pressure is reduced below 67 lb per sq in., steam will be formed and the temperature of the water will be reduced. Various pressures and corresponding boiling temperatures are given in standard tables of the properties of saturated steam. Exactly the same thing will happen to the water in a wooden panel during the hot-pressing process at the same corresponding temperatures and pressures. This can be shown by embedding a fine wire thermocouple in the panel and noting the temperature as the pressure is slowly reduced. The temperature will remain constant until the pressure is reduced far enough to allow steam to form. The formation of the steam reduces the temperature of the panel; thus the exact pressure at which steam forms can be determined. Experiments show that these pressures and temperatures check the values given for saturated steam exactly.

This fact suggests a method of opening the press so that blisters will not form. The pressure can be reduced rapidly to the critical pressure, and then reduced very slowly to atmospheric pressure. When the critical pressure is reached, steam will be formed at a rate depending upon the rate of reduction of the pressure. If the steam is formed slowly enough, it will force the press plates very slightly apart, and escape slowly without damage to the panel. This method completely solves the problem with respect to water. However, when panels are made with phenolic-resin glues, other gases than water vapor are formed, notably formaldehyde. We have not been able to find any data upon the pressure-temperature relations which obtain in the forming of these gases. We have found that we can open the press without blistering the panels if the pressure is decreased uniformly from its highest value (150 to 350 lb per sq in., depending upon the species of wood) to atmospheric pressure in a five-minute period. A more rapid rate of pressure reduction would probably be satisfactory, but not quite so safe. This method is so effective that we have made good panels without drying the colloid prior to the pressing operation.

The author states that it is safe to apply high temperatures to wood surfaces by the application of hot plates so long as evaporation takes place. Reference to tables of the properties of saturated steam will show (in the light of the foregoing) that if the pressure applied to the panel is 300 lb per sq in., no evaporation of water will take place (except a small amount around the edges of the panel) unless the temperatures is over 417 F. Evidently the evaporation of moisture has little to do with the temperature to which wood can be subjected in a hydraulic press without damage. We have found that the temperature at which the destructive distillation of wood starts depends upon the pressure applied to the wood. We have made panels successfully at very high temperatures. In one experiment two panels were made of Western pine at a temperature of 400 F. One panel was glued at a pressure of 200 lb per sq in., and the other at 300 lb per sq in. The panel glued at the lower pressure was turned to a golden brown by the heat. The other panel was hardly discolored at all.

We find that drying the colloid on the veneers before the pressing process has certain manufacturing advantages. We do not agree with the statement that "such a drying operation must be under careful temperature and time control to prevent excessive curing of the resin during the operation." The resin will not excessively cure if it is exposed to room temperatures. Reasonably rapid drying can be obtained at room temperatures if high air velocities are used. T. K. Sherwood[6] reports some careful work on the "rate of drying very wet blocks of pressed sulphite paper pulp containing over 100 per cent water, dried in a small tunnel through which air was forced by a blower." He finds that the rate of drying increases with the air velocity in a very regular manner and that it is directly proportional to the wet-bulb depression. We have run some tests upon the rate of drying of blood-albumin glue and the phenolic resin colloid under conditions similar to Sherwood's tests. We find that so

long as the glue is at all wet to the touch, the rates of drying are equal to those found by Sherwood. The rates of drying at air velocities between 1000 and 2000 fpm are high enough for commercial application, and no danger of excessively curing the resin will be encountered. The heat-transfer curves given by the author are interesting. The problem of heat transfer in flat slabs is a very old one. It was first solved by Fourier and recorded in his classic paper on the subject. H. P. Gurney and J. Lurie[7] have plotted the results of Fourier's complicated equations to non-dimensional coordinates so that they can be readily applied to certain problems. They give a special series of curves which apply to flat slabs. We have run some experiments which show that the diffusivity of yellow poplar is about 0.00128 cgs in the radial direction and that there is no surface resistance to the flow of heat between the plates of a hot press and the wood between them.

With these data available the temperature distribution in a poplar panel being pressed in a hot-plate press can be computed. The temperature will vary with the thickness of the panel, the point within the panel at which the temperature is computed, and the time. The author does not give the dimensions of the apparatus which he used in determining his curves; however, one would guess from his sketches that the data were influenced by the apparatus to a great extent.

The warning that a hot press "must have rigidity far beyond that required in a cold press working on a bundle of stock" is timely. This fact is often overlooked by panel manufacturers. It is easy to show that the variation in pressure upon the panel is large for small variations in the distances between the plates. The variation in pressure is directly proportional to Young's modulus of the wood and the variation of the distance between the plates and inversely proportional to the thickness of the panel. If we assume a Young's modulus of 80,000 and a variation in the distance between the plates of 0.001 in., the variation in pressure upon a panel 1 in. thick is 80 lb per sq in. A $^1/_8$-in. panel would have a variation of pressure of 640 lb per sq in. These figures show that it would be impossible to have any success at all gluing thin panels in a hot-plate press were it not for the fact that wood becomes somewhat plastic under the influence of heat and moisture.

Wilbur L. Jones.[8] The use of phenolic resins in plywood manufacture requires technical control and exactitude in advance of woodworking practice up to this time. There is a growing realization, however, that in order to make good panels there must be planning and sound methods promptly executed. The effect of one or two manufacturers offering waterproof, check-free panels will be to incite their competitors to emulation. There will be a brushing up of techniques all around, and perhaps in the end the hot press will become standard equipment in the plywood factory, as it is to a large extent in parts of Europe.

On reading the paper one wonders if there is not, perhaps, a fifth method of applying phenolic resins—a modification of the film method. Instead of resin-impregnated paper, would it not be feasible to use actual cores and crossbands carrying the resin in a film or coating on their surfaces? According to this plan, the resin manufacturer would furnish coated sheets of veneer all ready for hot-pressing. These coated veneers could be cut, inserted in the regular assembly, and pressed to a panel. This would avoid the disadvantages of the processes that the author calls Nos. 1 and 4, these being somewhat objectionable because they add water or some other liquid to the wood. As to process 3, the dry-powder method, the writer has never seen it in operation. It seems that the use of resin-coated crossbands and cores, as suggested, would possibly be more convenient to the plywood maker.

The greatest advantage arising from the use of precoated laminations might be realized in the making of five-ply and other multi-ply panels. The point is that a highly reactive resin could be furnished on the plies that will go near the center of the panel, where the heat has difficulty in penetrating. A more sluggish resin could be used next the face. It is almost necessary that a comparatively unreactive resin should be used under thin faces, especially of porous wood, because the resin must under no circumstances strike through. Resins may not be alkaline like certain glues, but they should not come through anyway, because they might still be noticeable on the finished surface.

If center plies were provided with a coating of highly reactive resin and crossbands with a less reactive resin, it appears that press times could be shortened and superior panels produced. Furthermore, the difficulties mentioned in connection with successive pressings on long panels might be diminished if resin-precoated crossbands and cores were used.

Perhaps it would be best if the resin manufacturer were to assume the responsibility of coating the interior plies, furnishing them properly spread as to density and reactivity of the resin. This is just a thought; it is just possible, however, that it is worth a trial.

A. J. Norton.[9] The simplest picture of what a resin is and what it does when used as a glue is a straight line extending from a molecule of phenol and formaldehyde at the beginning to the insoluble, inert set-up mass at the other end of the line. Each point on the straight line represents the formation of new chemical compounds, and without control it is possible to form many thousands of different products in one resin. It requires eight or ten hours under vacuum and pressure to bring the resin to the point where it is brittle. At this point it is soluble only in alcohol and spirit solvents, and a period of five minutes longer converts the material into an inert mass. It is the inertness of the product, with the high finish when heated under pressure, that attracts the attention to synthetic resins. It is readily seen that this extremely violent reaction must be controlled very closely in order to get a product which will set in five minutes to give the tough, inert resin.

In applying these resins as glue we turn to varnishes first because of our experience in laminating paper, and we felt that this was the proper method to use in woodworking. We found, however, that the varnish penetrated too much and the resin would not stay on the glue line. By making a very viscose varnish we could spread that varnish and by preheating it, could get it into the stage where it would stay viscose and remain on the glue line. This gave good gluing, but the cost was excessive.

The next attempt was to make powdered resin advance to the point where it would set quickly when heat and pressure were applied to the wood. This powdered resin is the type that the author spreads.

Previous to this in making a resin for binding sand cores, we found that where 3 per cent of powdered resin was necessary to give a certain strength, only 1 per cent of resin was necessary if this could be dispersed in a colloidal form to a very thin film. The next step in wood gluing, therefore, was to disperse the powdered resin into a colloidal form, which gave two advantages. First, the resin remained in the glue line, and, second, it could be spread thin enough and give good enough bond to help meet the price of common glues.

The film method of applying synthetic resins does not appeal

[7] "Charts for Estimating Temperature Distributions in Heating or Cooling Solid Shapes," *Industrial and Engineering Chemistry*, vol. 15, no. 11, p. 1170.

[8] Madison, Wis.

[9] General Plastics, Inc., North Tonawanda, N. Y.

to us because we do not feel that it can be manufactured cheaply enough, and in addition the paper content of the film is high enough to hurt the bonding properties.

In wood gluing it is not necessary to get the strength of the glue line stronger than the wood itself, and for cheap woods the colloid could be spread in a very thin glue line at a very much reduced cost. The powdered resin is very suitable for standard type of panels where the lower glue spreads are not necessary and where the cost is not so vital a feature. We also furnish the film form of material if anybody desires it, although at the high price it has no particular advantage to offer.

Author's Closure

Mr. Norris' interpretation of some of the text does not coincide with the thought the author tried to express. For example, the author had no intention of indicating that he "found it very difficult to use the colloid." On the contrary, the equipment at the author's disposal was exceptionally adapted to using colloid, and no trouble was experienced in handling it, other than that inherent in this form of adhesive. To those who daily contend with these inherent difficulties of a wet adhesive, they perhaps are not looked upon as such, and it is only in comparison with other methods that these troubles become so apparent. It is admitted that, for certain types of laminated work, the application of the adhesive in a wet state causes no trouble; for example, in laminating multiple plies of $^1/_8$-in. veneer. But it is still contended that the application of 12 to 14 lb of water to 1000 sq ft of $^1/_{24}$-in. or thinner veneers, and especially face veneers, will cause difficulties, which can be overcome by eliminating the application of this water.

The application of this water to the veneer obviously "introduces the same old problems of swelling and shrinking of wood." This water is supposedly applied evenly to the sheets of single-ply veneer, but the veneer will not evenly absorb this water, due to the non-homogeneous structure of the wood. The sheet, therefore, swells unevenly. The next step is to drive out all or part of this water, prior to pressing. This is, essentially, a redrying operation. It has become standard practice to redry single-ply veneer between hot plates, because this method is the most efficient and produces the flattest stock. In drying the colloid, hot plates cannot be used, nor can any appreciable temperature be applied. As Mr. Norris states, the drying must be accomplished by means of high-velocity air. This is not an efficient method in reference to time and power input, and the general run of single-ply veneer will not dry as flat by this method as it will if dried between hot plates.

The crux of the whole argument is: Why carefully redry the veneer to a moisture content of 4 to 8 per cent, then apply 12 to 14 lb of water per 1000 sq ft to the same veneer for use with the glue material, and then introduce a second redrying operation to eliminate this water? The question is pertinent, in view of the fact that the limitations of the second redrying operation prevent the use of recognized efficient redrying methods.

The author did not intend to imply that where gluing is done without introducing water there remains no problem of shrinking and swelling of wood. Everywhere there is moisture in varying quantity, and its results must be reckoned with, but why voluntarily add to the trouble, if it can be avoided? The diagnosis runs somewhat as follows:

Any variation in moisture content of wood results in swelling or shrinking. In wet gluing, water in the glue is absorbed by the wood, an increase of moisture content occurs, and swelling takes place. The same thing happens with colloidal glue. In the dry process, water is not introduced by the gluing process per se, and nothing is added to the problem of swelling and shrinking that did not already exist.

Moisture in wood creates a problem in nearly all its applications in the art, but not to the same extent that it has in glued-up work. Now if the gluing of wood can be accomplished without introducing moisture, the remaining problems, due to varying moisture content, are no more than those met with in other wood utilities.

It should also be noted that the sudden application of water to a wood surface, as when wet glue is applied, is quite different from adding moisture by the slow process of absorption in the air, and especially in hot pressing, where the time is exceedingly short, as compared with cold gluing. The sudden addition of glue and water introduces the old problems of shrinking and swelling in a particularly disturbing manner.

Mr. Norris' explanation of the problem of tension and compression in plywood, due to variable moisture content, is as helpful as any theorizing can be, when applied to so tricky a material as wood, but after all it is practical experience that convinces the average woodworker. Data obtained from a wood as homogeneous and ductile as yellow poplar do not mean much when applied to birch, maple, beech, and gum. The author does not believe that we know very much about the strain existing in any given piece of wood that has been processed. In his example of a three-ply panel, Mr. Norris states that the two faces are in tension, while the core is in compression, due to the fact that wood grain does not appreciably shrink and swell lengthwise. But he has stated only half the problem. When the faces of a three-ply panel are under tension with the grain, they are under compression across the grain, and the core, while under compression across the grain, is also under tension with the grain. These strains are also not confined to a single plane, but they lie in three separate planes, and that introduces new complications. Since the grain in the most homogeneous wood is never theoretically straight and never free from tension inherent in its make-up, it is never safe to prophesy what will happen when a disturbing influence like moisture is introduced, and the safest way is to avoid, as far as possible, that which produces trouble.

It is no doubt possible to dry the colloid on the sheets of veneer at room temperature. It is merely a question of time, but that is something to reckon with, because time means money. To produce high air velocity also costs money, and when all is said and done the whole thing is avoided if the resin is put on dry in the first place. High air velocity must also present some difficulty with very thin sheets of veneer, which curl readily when dried on one surface only, and they do not easily remain in position on a conveyor.

The evaporation of water within a panel being hot pressed follows the pressures and corresponding boiling temperatures as given in standard tables of the properties of steam, provided the exact specified conditions are attained. The conditions upon which the steam tables are produced do not always occur in a wood panel. They would, if each cell were a perfectly closed, elastic pressure vessel. Many of the cells are ruptured. There are faults or defects in the veneers, and Mr. Norris has pointed out the great difference in pressure resulting from as small a variation of distance as 0.001 in. between plates. The same difference in pressure would also result from 0.001 in. variation in thickness of the veneers. All these things are factors which make it extremely uncertain as to whether all the water is enclosed in a cell and subjected to the required pressure to prevent evaporation, and also as to what pressure is actually developed within any part of the panel. Consequently, in practice, a general slow evaporation does take place, and often a rapid local evaporation depends upon the soundness of the veneer.

There are plants operating on cottonwood whose regular procedure is to hot press the wet veneer direct from the lathe and turn out a dry panel. The moisture content of the panel going

into the press averages over 80 per cent and the dry finished panel 8 per cent. The pressure applied often exceeds 70 lb per sq in., and the temperature of the plates averages 260 F. Theoretically, the panel would not dry, due to the reasons given by Mr. Norris, but actually this practice produces commercial panels in daily operation.

The work of the author with phenolic resin has had, as its objective, the development of an extremely rapid process in order that the press investment can be kept at a minimum and one which would have a universal application. On the other hand, the Haskelite Corporation specializes in various types of plywood and is equipped with a highly trained technical staff which can develop technical control of plant processes. This situation is entirely different from that of the average plywood producer. Consequently, a procedure which may be entirely feasible for the Haskelite Corporation might not be well adapted for use by the trade in general.

Mr. Jones offers a thought which might result in an ideal procedure for plywood manufacture if it were not for some of the characteristics of phenolic resins and the economics involved.

The reactive resins are not stable, and reactive resin spread on sheets of veneer subjected to the heat of a summer day and the pressure which would be imposed on the bottom sheets of a pile would quite rapidly polymerize and lose their reactivity. This would result in no bond being formed when the veneers were hot-pressed. The economic factors which would mitigate against such a procedure would be the immense sums tied up in inventories and the extra freight involved in shipping the veneer from the cutting plant to a coating plant and thence to a plywood manufacturer. If the coating were done by the single-ply manufacturer, there would be no gain, only a shifting of the burden of coating from the laminator to the single-ply producer.

Mr. Norton has given a clear explanation of the formation of a phenolic resin which helps in picturing the final result in the finished glue line. It appears to the author, however, that some misconception might arise from the last of Mr. Norton's remarks. On a pound basis of resin, the dry powder and the colloid are practically the same in price. As light a spread can be applied with the dry powder as with the colloid, at least in a practical range, since the powder can be applied uniformly as low as $3^1/_2$ lb per 1000 sq ft of surface. Therefore, the dry resin would be just as applicable to the manufacture of panels in the lower price range as the colloid, and in addition the cost of drying the water applied with the colloid is eliminated.

In conclusion, the author wishes to correct an impression he may have given as to the limitation of hot-plate pressing to thick material. There is no practical limit as to the thickness of the final plywood which can be produced effectively with phenolic resin. But, in the opinion of the author, the lamination of single plies over $^1/_4$ in. thick, and particularly the lamination of lumber core panels, is something the practicability of which is yet to be established.

Fundamentals of Knife-Cutting Veneers

By JOHN N. and JOHN R. ROBERTS,[1] NEW ALBANY, IND.

In the last 25 years the per capita consumption of veneer in the United States has increased nearly 500 per cent. The manufacturers of veneer and its subproduct, plywood, are constantly finding new uses, better processes, and improved equipment. The principal methods of veneer cutting are undergoing marked changes and developments, requiring a clear understanding of the fundamental principles.

WHEN the first knife-cut veneer was produced is not definitely known, but before 1850 there were practical devices for producing thin sheets of wood veneer with a knife. The first machines were clumsy and crude. The early slicers had a straight cut without provision to avoid tearing the delicate cross-grain wood figure. The shearing or angling cut was not devised until about 1885. The first lathes had the cap, knife bed, and frame made of wood (see Fig. 1), and it was not until the later 1860's that the lines of the present-day veneer-cutting lathe began to take form. A great advance in the wood-working industry occurred in the period between 1870 to 1900, when all types of veneer-cutting machines were greatly improved and refined.

It is not the purpose of this paper to give a history of veneer cutting, but only to utilize enough historic background to show the necessity for the development of the devices that added so much to the quality of veneer and to the efficiency of the present-day machines.

A glimpse into government records reveals the size of the veneer-producing industry in the United States. The quantity of logs cut into veneer, by log scale (not surface feet of veneer), is shown in Tables 1 and 2, both according to species and states.

VARIETIES OF KNIFE-CUT VENEER

The three kinds of knife-cut veneer are shown in Fig. 2 and are as follows:

Rotary veneer, producing some 90 per cent of all veneer cut
Half-round veneer, an intermittent segment-cutting operation, used especially for face veneers
Sliced veneer, a flat-cutting process, used principally for face veneers or for special requirements.

Rotary Veneer

Rotary-cut veneers (Fig. 2-*B*) are principally used for non-decorative purposes, since little opportunity is afforded to develop the best grain and character figure. Rotary cutting may be speeded up more than the other processes, an especial advantage in producing cheaper grades for packages, cross-bands, and other commercial products, and it produces the large sheets so desirable in making structural plywood. When manned with experienced crews, the quality of rotary cutting may be excellent and entirely comparable with the other processes.

Veneer Utilization. There is an interesting economic factor in the use of rotary veneer that is shown graphically in Fig. 3. When a log is sawed into boards, the saw-kerf and slab losses exceed 25 per cent, with an additional subsequent loss from the planing necessary to smooth off the saw marks and reduce the boards to standard thickness. On the other hand, when a log is rotary-cut into veneer, these saw-kerf and slab losses are avoided, and the veneer is so smooth as to require only a sanding before finishing, and the only losses are in the initial rounding up and the final core. The conversion costs are strongly in favor of veneer, and the subsequent gluing up of thin veneer into plywood leaves the latter product less costly than solid wood on an equal-strength basis, but makes it somewhat more costly for equal thicknesses. Plywood has marked advantages, however, that permit the use of artistic face veneers, that increase its strength over solid lumber, that make it non-splittable, and that permit it to be bent and curved.

The evidence of census statistics proves that the per capita consumption of veneer in the United States has increased nearly 500 per cent in the last 25 years, while that of solid lumber has decreased over 50 per cent in the same period.

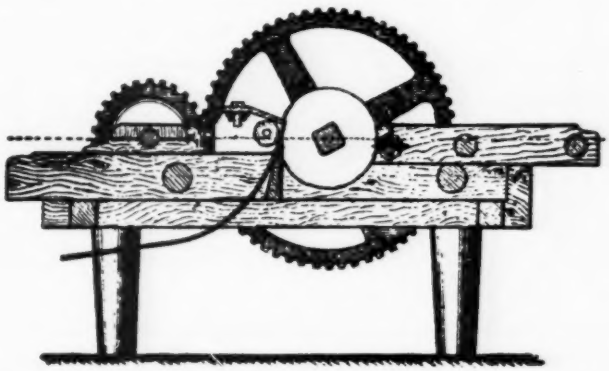

Fig. 1 Humphrey Lathe With Wood Frame

(Cutting pressure is exerted by roller, instead of bar. Face of knife is against log, as usual in early machines. Protruding top sections of table are pushed in as log diameter is reduced. Spur cutter for trimming veneer ends is opposite knife. Probably before 1860.)

Half-Round and Sliced Veneer

While rotary veneer is produced in large sheets, half-round veneer (Fig. 2-*C*) and sliced veneer (Fig. 2-*A*) are made in individual single sheets, each limited to the area of the flitch. These sheets are kept in consecutive order, and thus the almost identical character of two or four adjacent sheets permits artistic and mechanical combinations into beautiful face veneers, so much desired for cabinet, furniture, musical-instrument, and interior-finish design, a marked artistic advantage over solid wood.

Description of Processes. The half-round and rotary processes will be described together, as the two are produced on the same machine. While lathes are built primarily to cut rotary veneers, almost all lathes may be equipped with a stay-log attachment or

---

[1] John N. Roberts is a native of Indiana. One of his first tasks, in the late 70's and early 80's, was to operate the lathe shown in Fig. 4. He has been actively engaged in veneer manufacturing during these 50-odd years and has originated and aided in the development of many of its improvements. His son, John R. Roberts, was graduated from Purdue University in 1918, and is now President of the Roberts-Dulaney Veneer Corporation.

Presented at the meeting of the Wood Industries Division, Jamestown, N. Y., November 15 and 16, 1932, of The American Society of Mechanical Engineers.

Note: Statements and opinions advanced in papers are to be understood as individual expressions of their authors, and not those of the Society.

eccentric bar for holding flitches from which half-round veneer is to be cut.

The slicer is entirely different in design and operation, requiring a separate description.

ROTARY LATHE

A veneer lathe consists primarily of a rigid bedplate or frame, with sturdy fixed housings at either end. The housings are equipped with bearings for the main spindles. The log revolves on the spindles toward the knife, which is mounted on a movable assembly carrying the knife and pressure bar. This assembly moves in and out, at right angles to the spindle, on accurately machined and solidly mounted ways or slides built into the bedplate. The feed mechanism controls the rate of movement of this assembly, and consequently regulates the thickness of the veneer during cutting.

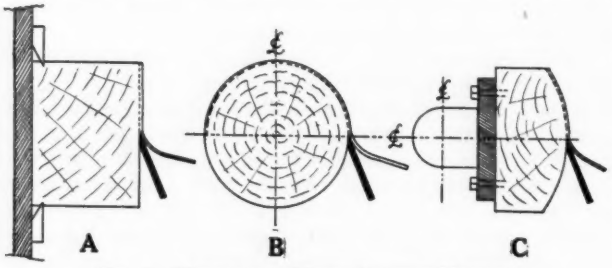

FIG. 2 METHODS OF KNIFE-CUTTING VENEER

(*A*, Sliced, flat shear-cut veneer. *B*, Rotary, continuous sheet from revolving log. *C*, Half-round, lathe cut when mounted eccentrically.)

The earlier wood-frame lathes (see Fig. 1) proved to be entirely too weak and yielding and were soon displaced by the all-metal lathe similar to those illustrated in Figs. 4, 5, and 6. These proved adequate for some years, but did not meet the exacting demands of later years. The major improvements for improved quality and increase of output were:

1 Additional strength and rigidity in the main parts of the machine
2 An efficient feed mechanism that would accurately control veneer thicknesses
3 Convenient and easily operated adjustments for the knife and pressure bar.

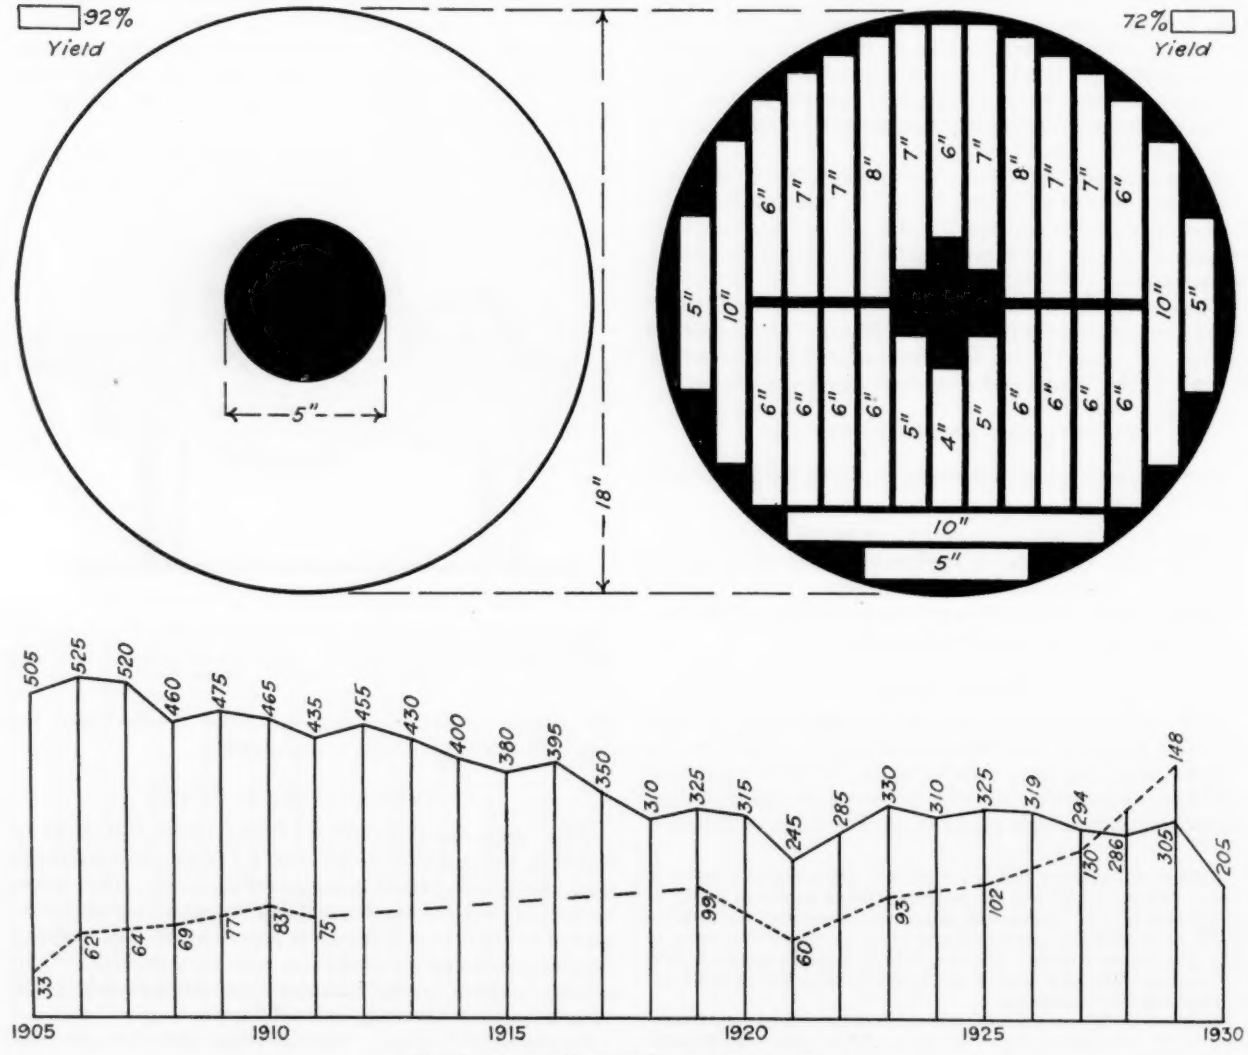

FIG. 3 CENSUS DATA ON VENEER PRODUCTION

(Above: Cross-sections of 18-in.-in-diameter cylinders showing the rotary veneer yield of 92 per cent of total area, compared with 72 per cent on sawn lumber. Unless lumbering operations are carefully managed, this lumber yield seldom exceeds 60 to 65 per cent. The standard Scribner-Doyle log scale allocates 58 per cent yield to such a log. Lower: Graphic chart of 25 years of lumber and veneer per-capita consumption in the United States. Lumber is given in log scale feet, which is practically board measure. Veneer is surface feet 1/16 in. thick, or log scale × 16.)

Strength Requirements

It is essential that a lathe be built on a sturdy and unyielding bedplate so as to give the machine rigidity. The bedplate carries the entire stress of mounting or chucking the logs. The housings at each end carry the main spindle bearings and are mounted on the bedplate. They must be heavy enough to withstand the tremendous torsional strains applied on the main bearings by the cutting stresses and leverage of the spindles.

Main Bearings. The main bearings on the early lathes were made of babbitt metal and were much smaller than those in use today. Even when the size of these bearings was substantially increased, the babbitt wore unevenly, broke out, and had to be frequently replaced. The bearings were next made of cast iron. This proved satisfactory, if they were given care and lubrication. One of the best bearings in use today is lined with fiber, which is less likely to score or wear the spindle shafts than cast iron and is easily renewable.

Knife Bed. The knife bed of an early lathe was probably the most rigidly built part. Much less importance was attached to the rigidity of the cap or pressure-bar holder, as its chief purpose at that time was to regulate the thickness of the veneer, without regard to its firmness and quality. These parts were made in various shapes of cast iron, superseding the earlier wood parts. On modern lathes the knife beds and caps have come to be very heavy castings designed to hold the pressure bar and knife in

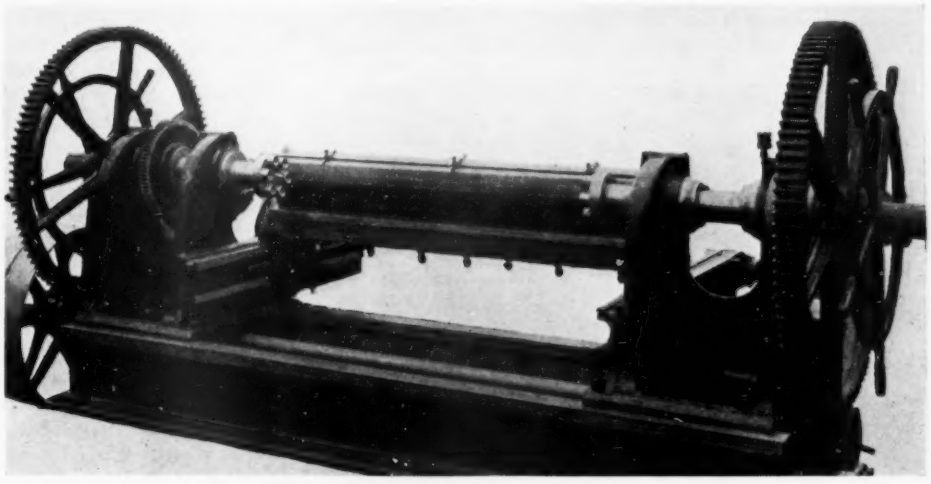

Fig. 4 Front View of an Early Lathe, Around 1870–1880

(Contrasting this with Figs. 8 and 12, notice the light bed plate, inadequate housings, and combination cast-iron and babbitt bearings; hand windlass wheels for end movement of spindle; bevel on knife against wood and pressure bar with practically no cap, and adjustments lacking except end screws; main bearings are split nearly vertical; feed screws are low with inadequate ways; spindle chucks have "vacuum" cups to prevent log twisting; ratchet and pawl feed is quite indistinct. This is the first lathe to establish the lines of modern design.)

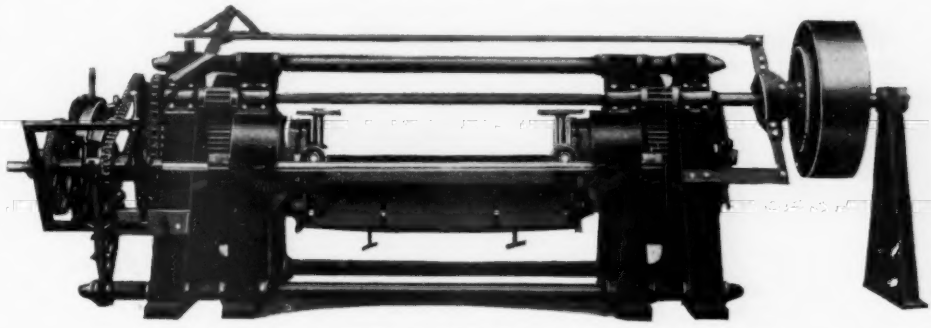

Fig. 5 Different Type of Mid-Period Lathe (1890–1900)

(Back view with feed mechanism at left, with sprockets and change gears. Cap, for pressure bar, is light. Knife bed very deep and heavy. Heavy rods or bars, two below and one above, substituted for heavy bed plate. Pressure screws are vertical rather than horizontal.)

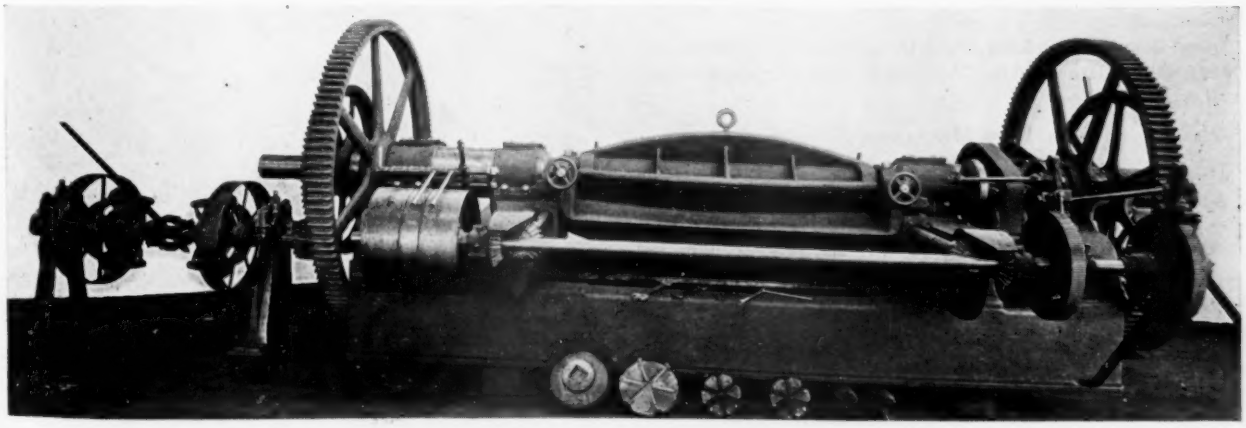

Fig. 6 Back View of a Lathe Developed in the 1880's

(Right: Double-ratchet feed mechanism, giving practically uniform feed. Center: Cross-shaft with bevel gears near each end connecting to feed screws with ratchet wheels at right end and double T & L pulley at left, with separate source of power to enter and withdraw knife from wood. Left: Another separate power source for chucking, with double clutch to move spindle in and out of logs. Note: Bearings split at approximately 45 deg. Knife bed and cap of sturdy modern design. Different size and shape of chucks shown below at center.)

alignment with each other and to be as nearly as possible free from spring or vibration.

Temperature Expansion. The heat from the log has some tendency to cause expansion in the knife bed and cap, particularly the cap, which may change the alignment between the pressure bar and the knife. The distribution of metal in these castings

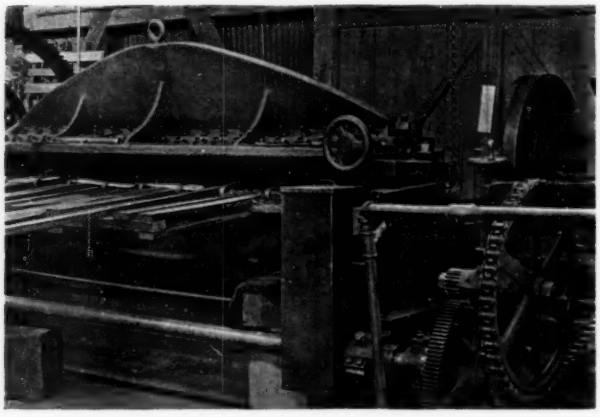

FIG. 7 COMBINATION GEAR AND CHAIN-FEED MECHANISM
(Back view of lathe, with sprocket wheel and gear train at right. Cross-shaft at lower left drives feed screws.)

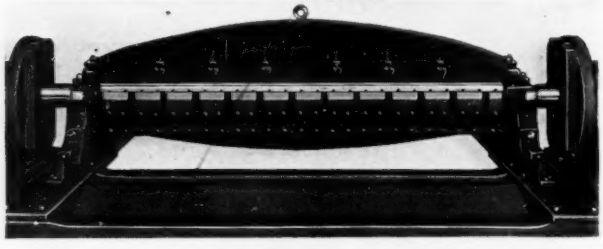

FIG. 8 MODERN STURDY LATHE
(Notice weight and rigidity of cap casting, above, of knife bed, behind knife, and massive bed plate, below. The sectional holding or clamping bar permits using narrow veneer knives, thus lengthening their useful service, as well as holding the knife more firmly than do the standard cap screws in knife slots.)

should be such as to prevent this as far as possible. In very long machines it is necessary to put a hog chain and adjusting screw on the cap, with which it can be sprung back into alignment with the knife bed.

There is nothing unusual about the strength requirements of other parts of a lathe, and they are designed according to standard engineering practice.

FEED MECHANISM

This device, controlling the "in and out" movement of the assembly carrying the knife and pressure bar, has undergone quite radical changes during the transition from the primitive wooden-frame lathe to the modern sturdy and nearly automatic veneer-cutting lathe. The principal types of past and present feed mechanisms are:

1 Hand control, a crude and early type requiring an experienced operator, but practically obsolete
2 Ratchet-and-pawl feed, originally an intermittent apparatus, but later practically continuous; seldom used on lathes, but standard on slicers
3 Combination gear-and-chain feed, continuous, and in general use on lathes
4 Gear-box feed, like the shift gearing of an automobile.

Hand Control. In the lathes built before 1870 the thickness of the veneer was regulated by the distance between the pressure bar, or pressure roller, and the knife. The feed on these machines was accomplished by a hand wheel, which operated feed screws to keep the pressure bar or roller pressed firmly against the log. In rounding up a log or in cutting half-round veneer, the wheel was marked, and the feed was advanced by hand for the thickness of the veneer, every revolution, while the knife was out of the cut. A hand-chain equipment, similar to those still in use on some veneer saws, was also used on half-round machines.

Ratchet and Pawl. On this earliest mechanical feed the screws that carried the knife against the log were operated by bevel gears from a cross-shaft. The cross-shaft was turned by a keyed ratchet wheel and was advanced by pawls, which in turn were operated by a crank geared to the spindle. The length of this crank was adjustable so that the number of teeth advanced by the pawls on each revolution of the crank could be varied in accordance with the thickness of the veneer to be cut. This is shown in Fig. 6. Of course, one pawl rocking back and forth gave an intermittent feed. A practically constant feed was gained by increasing the number of pawls that alternately engaged the ratchet wheel or wheels. The ratchet feed in its multiple form was satisfactory and had the advantage of making it possible to vary the feed and consequently the thickness of the veneer to any desired extent rather than to a limited number of set feeds, as is the case with the direct-geared or chain feeds in general use today.

While largely superseded on the lathe, this ratchet-and-pawl

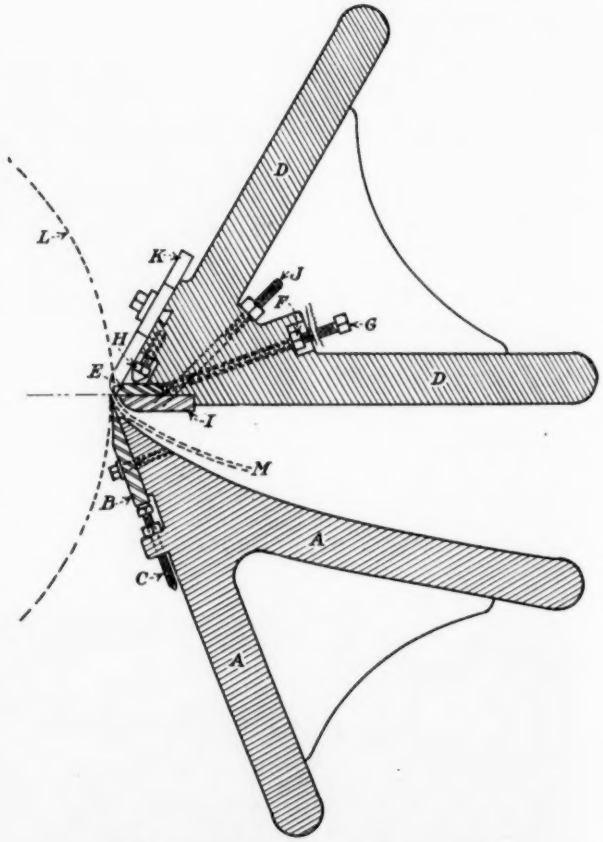

FIG. 9 DETAIL OF COMBINATION ASSEMBLY
(*A*, knife-bed casting; *B*, knife; *C*, knife-adjusting screws; *D*, cap or pressure-bar bed casting; *E*, pressure bar; *F*, pressure-bar adjusting bolts, in tension; *G*, pressure-bar adjusting screws, in compression—*F* and *G* alternate in cap casting; *H*, pressure-bar adjusting screws; *I*, pressure-bar auxiliary plate; *J*, pressure-bar auxiliary plate bolts; *K*, spurs, for trimming edges of veneer as cut; *L*, log; *M*, veneer.)

feed has become the approved method on slicers, where it meets the conditions, since the feed is on the back stroke when the knife is out of the wood.

Combination Gear-and-Chain Feed. This device was developed about the same time as the safety bicycle, which brought this power-transference method into many other mechanical applications. Sprocket wheels and gears (see Fig. 7) are changed for various speeds. Its full flexibility is limited by the number of available sprockets and the gear combinations, a limitation that sometimes prevents the desired accuracy in thickness. Its simplicity is in its favor.

Gear-Box Feed. This is a recent adaptation, and eliminates the delay and untidiness of gear changing, and can be entirely housed in an oil bath. While it gives great promise of surpassing the other feed mechanisms in convenience and flexibility, it has not been used long enough to become generally adopted. Such an enclosed feed mechanism has the advantage of permitting thicker initial cuts in rounding up the log, before setting the veneer thickness.

Separate Power for Withdrawing the Knife. In backing the knife away from the spindles with any of the feed mechanisms, the power connection is always disengaged and the feed screws are reversed and operated by some separate source of power (see Figs. 6 and 11-*D*).

Thickness Tolerances. In cutting veneer today for some purposes, it is desirable to be able to vary the thickness enough to take care of the shrinkage in drying, in order that the finished dry veneer may be of the required thickness. In view of the fact that the volume of this type of cutting is increasing, it would seem that there is an opportunity for the engineering profession to further develop lathe feeds that are both flexible in range and nearly automatic in operation.

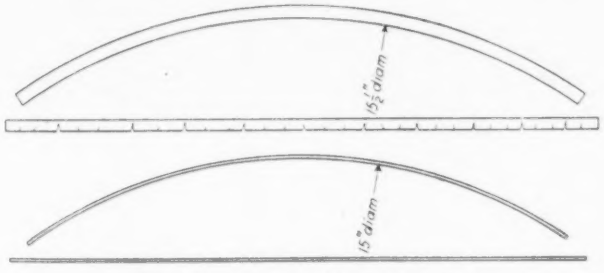

FIG. 10 TIGHT AND LOOSE CUTTING

(Above: Rotary veneer, 1/4 to 1/8 in. thick, with cutting checks due to inadequate pressure. These cannot be entirely eliminated, but in many grades of rotary veneer they are unobjectionable and cause the veneer to flatten better. Below: Rotary veneer, 1/28 in., standard thickness for face work. Proper pressure produces tight cut veneer and eliminates cutting checks, thus permitting both sides of the veneer to be used, as in matched faces.)

KNIFE AND PRESSURE BAR

Possibly the best idea of the development of this combination assembly—the knife, knife bed, cap, and pressure bar—can be gained by comparing the illustration of the early lathe (Figs. 4, 5, and 6) with that of a modern machine (Fig. 8). The details of this assembly are shown in Fig. 9. It would seem that the modern lathe builders have gone to extremes in putting so much metal in the knife bed and cap castings. As a matter of fact, while a much lighter machine will cut a log into veneer, it is possible on the heavy machines to increase the pressure to as high a point as the wood will stand without mashing. This pressure, properly applied, holds the wood fibers intact while the veneer is being cut from the log, and the result is a sheet of veneer that is not only smooth on both surfaces, but is internally sound and has its full strength value (see Fig. 10).

Knife-Bed Adjustments. Two castings, one at each end of the knife bed, rest on the feed slides and carry the knife-bed and cap assembly. There are two adjusting screws at each end, by means of which the assembly can be raised or lowered or tilted to bring the knife into cutting position. When the adjustment is made, the knife bed is held in position by tightening the center bolts, which hold it firmly to the carriage castings. These adjusting screws are shown in Fig. 11-*A*.

By raising or lowering the back screws, the knife can be tilted into or out of the wood. The angle of the beveled surface of the knife with a tangent to the surface of the log at the point of contact is called the "lead." "Applying more lead" or "putting in lead" means tilting the knife into the wood. Tilting it out of the wood is called "taking out lead."

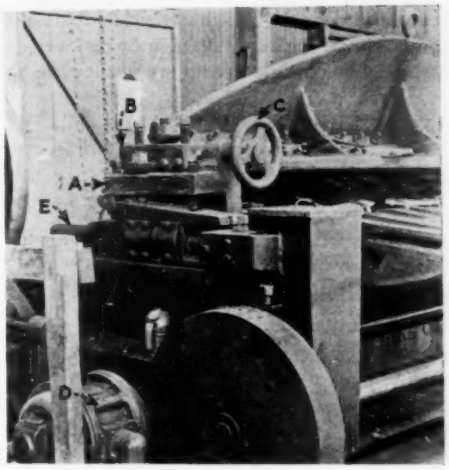

FIG. 11 KNIFE-BED AND CAP ADJUSTMENTS

(*A*, knife-bed casting, with two outside screws to adjust "lead" and center clamp bolt; *B*, cap casting, similarly adjustable: *C*, pressure screws to move cap toward knife; *D*, reversing motor to back combination assembly away from the log; *E*, feed screw, actuated by feed mechanism and advancing knife into the wood.)

Cap or Pressure-Bar Bed. The cap is mounted on top of the knife bed in the same manner as the knife bed is mounted on the carriage castings. The screws upon which it rests raise or lower the cap with respect to the knife bed (see Fig. 11-*B*). There are in addition, however, two "pressure screws" (Fig. 11-*C*), one at each end of the cap, which move the cap and pressure bar horizontally toward the knife and hold it in cutting position.

Feed Screws. The feed screws are operated by the feed mechanism and revolve in the carriage castings (see Fig. 11-*E*), moving the combined knife-bed and cap assembly forward or backward on the slides. The feed screws carry the full force of the pressure applied in cutting. It has been found best to locate these screws high enough to minimize the tendency of the knife bed and cap to rock back on the slides and spring away from the wood.

STAY LOG FOR HALF-ROUND VENEER

The stay log (see Fig. 12) is the adjustable bar mounted eccentrically between the spindles of a lathe on which flitches are held while being cut into veneer. Veneer cut in this manner is termed "half-round" (see Fig. 2-*C*). The purpose of this type of cutting is to produce a veneer with a more regular grain design than full rotary veneer, where the log is chucked centrally in the heart between the spindles and the knife follows the annular rings fairly closely as the log revolves. When half a log or flitch is attached to the stay log, the heart of the log is away from the center of the spindles, so that as the flitch is revolved, the path of the knife crosses the annular rings. The character of the half-round grain design can be varied by adjusting the stay log farther off center,

between the broad-grain design of the full rotary veneer and the striped-grain design of the sliced veneer.

It is possible to get the half-round grain effect without using a stay log, by chucking logs eccentrically or to one side of the heart. The main objection to this method is that a considerable part of the best wood cannot be cut into veneer and remains in the discarded core.

The design of the stay log must be such as to give it ample rigidity. This would not be difficult if there were no limit to its size, but the back of the bar must clear the knife at every revolution. Hence a reasonably light but rigid and compact stay-log attachment has taxed the ingenuity of lathe designers.

The flitches to be cut into veneer are fastened to the stay log

with lag screws. The threads on these screws should be shaped so that they clear themselves and do not clog up with wet wood when used repeatedly. This involves a fairly sharp angle of thread toward the head and a much flatter angle on the under side of each thread when compared with the axis of the screw.

Variable-Speed Lathe Drives

Obviously it would be highly desirable on many lathe operations to have a constant flow of veneer on the delivery table, but there are certain limiting conditions that must be considered. Economy in time requires that all preliminary cutting, or "round up," be done at as high a speed or as thick a cut as practicable, since it is waste.

The average spindle speed of most production lathes is around 30 rpm, except for face veneer, which often is 20 rpm. On an average of 30 rpm the delivery speed will vary from 188 fpm on a 24 in. in diameter log to 63 fpm when the log is reduced to 8 in. in

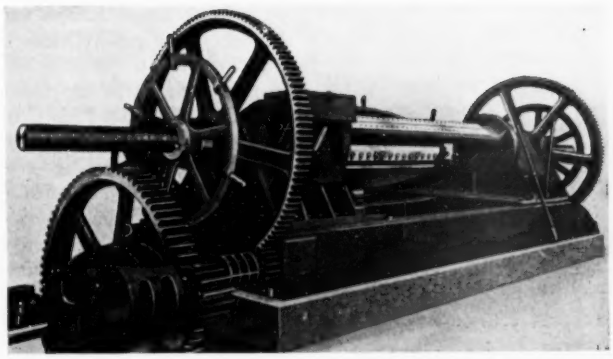

FIG. 12 MODERN LATHE WITH STAY LOG AND DIRECT MOTOR DRIVE

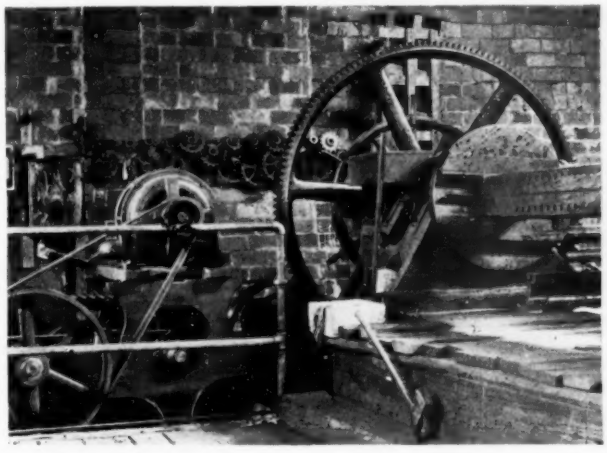

FIG. 13 VARIABLE-SPEED DRIVE FOR LATHE
(Motor above, connected to drive pulley on variable-speed device by V-belt. Variable-speed device, connected to main gear on lathe spindle, is not shown. Notice change gears for feed mechanism against the brick wall.)

diameter. It is difficult to arrange delivery clipper equipment and to man a crew to work efficiently over such a wide range. Various plans have been devised, none of them wholly satisfactory, to meet this condition. It is further complicated by the fact that $^1/_{20}$-in. veneer is light and easily handled but more fragile than thicker veneer, while $^1/_4$-in. veneer is hard to handle and must be cut more slowly, due to power demands. The species or character of log also has a bearing on speed; i.e., basswood can be cut faster than hard maple.

Hence the ideal arrangement would be three or four constant delivery speeds—at 100, 125, 150, and possibly 200 fpm. The speed requirements of such a program are outlined in Table 3. Such an arrangement should have the main drive connected with the feed-screw mechanism so that the operator would have no further concern about speed regulation after once starting the production cut subsequent to the round-up. This could be accomplished mechanically by certain variable-speed transmissions, although few such installations are yet in operation. It is also believed possible to devise electrical equipment to serve the same purpose.

Some veneer mills utilize a series of fixed speeds, such as 24, 30, 36, and 48 rpm, and set these speeds (by change gears or belts) for each log, or in the case of large logs, interrupt the operation to change speeds. The result of such a plan is shown in Table 4.

Variable-speed motors have been adopted for such a program with fair success, but many types of motors will race unless under approximately full load. Such racing is objectionable when entering or leaving a cut. The variation in power demand between $^1/_{20}$ in. and $^1/_4$ in. thicknesses also causes racing and is a handicap to a variable-speed motor. Frequency changers are preferable to a variable-speed motor, giving greater flexibility and more constand speeds under varying loads.

In the case of face-veneer operations or stay-log work, the speed-control problems are of a different nature, since wood characteristics must be considered. Delivery speeds, although still important, must be subordinate to veneer quality. On stay-log work the constant-delivery speed is scarcely a factor, since the total thickness of the flitch is rarely a large part of the total cutting diameter.

The problems of either variable speeds on the lathe spindle or constant veneer delivery speed offer an excellent opportunity for engineers to serve the veneer-cutting industry. The problems are almost entirely mechanical and demand adequate solution. Veneer operators are schooled and experienced in their ever-present problems of wood artistry and need the cooperation of engineers in the mechanical phases of their equipment.

One illustration of a variable-speed drive on a lathe is shown in Fig. 13.

SLICER

It is generally conceded that the highest quality of knife-cut veneer can be produced on a slicer. However, a preference for a sliced veneer (Fig. 2-*A*) is generally due to a desire for either the "across the heart grain effect" or "straight stripe grain effect" or for longer veneer. Due to the center support to the flitch table

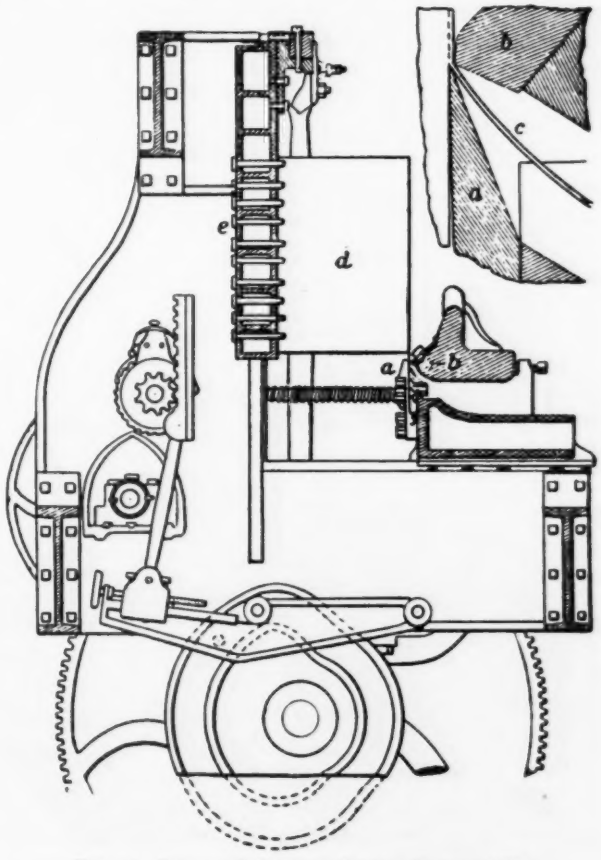

FIG. 14 PARKER & SLEEPER SLICER, BEFORE 1875
(*a*, knife, mounted with face against wood; *b*, pressure bar; *c*, sliced veneer; *d*, log. Ratchet-and-pawl feed mechanism, actuated by rack and pinion, shown against main casting. Feed screw shown below log.)

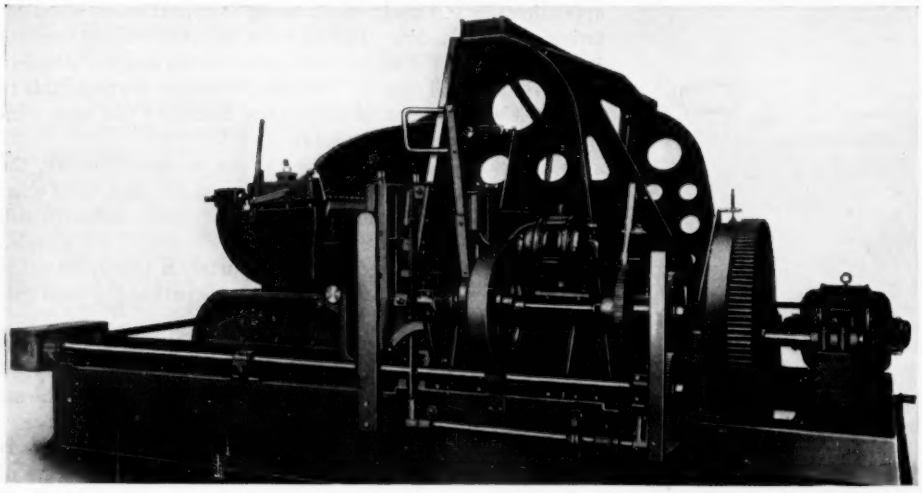

FIG. 15 VERTICAL-TYPE VENEER SLICER

(Knife bed and cap assembly at left above. Operating motor at right, and reversing motor against machine at center. Threaded feed screw at lower left. Three angling ways, for carriage travel, extend to cross-head across top of machine.)

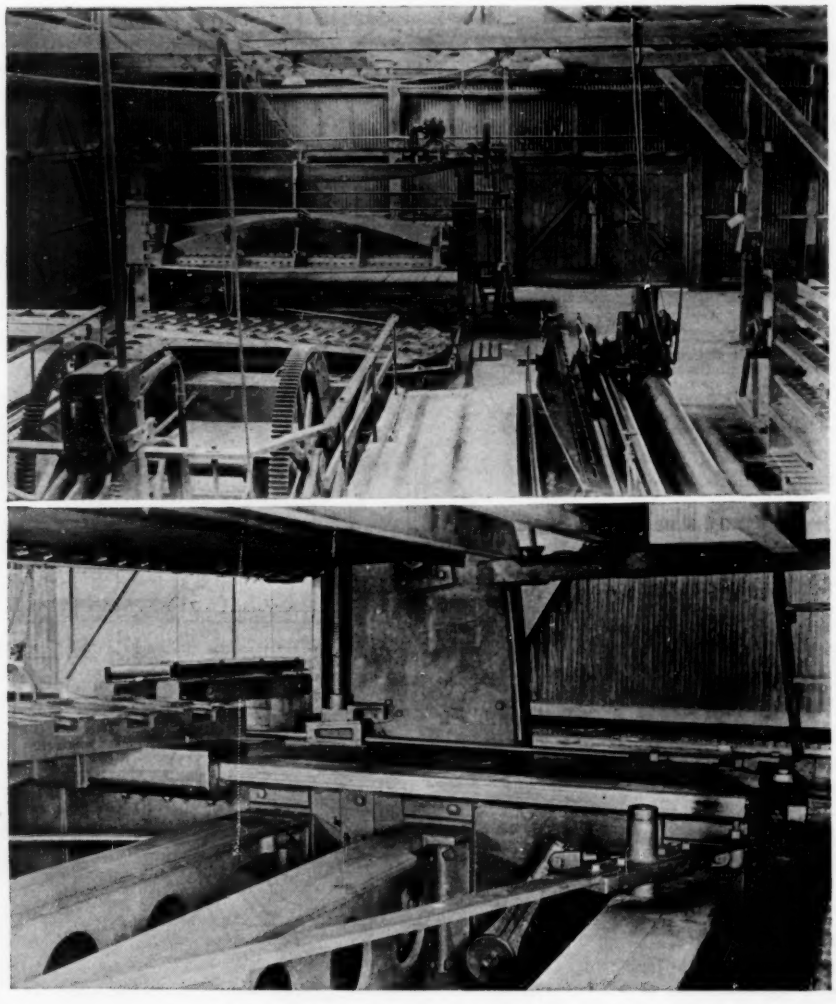

FIG. 16 HORIZONTAL-TYPE VENEER SLICER

(Upper: Front view, with angling flitch table in center, knife bed and cap assembly above. Driving gears at lower left, and end of knife grinder at lower right. Lower: Looking horizontally between the log carriage and knife, at upper left. Offset, tapered block, at center below vertical feed screw.)

on a slicer, longer flitches can be held more rigidly than is practical on a lathe. The length of slicers in use today generally runs from 12 to 17 ft, whereas lathes seldom exceed 10 ft in length.

The first slicer was probably little more than an elaborate splitting machine, possibly combined with a gigantic plane, cutting off somewhat irregular sheets for overlaying on solid wood.

One of the earliest known examples is the Parker & Sleeper slicer shown in Fig. 14, which had an all-metal frame, with a vertically reciprocating log carriage and a stationary knife, mounted with face toward the wood. The knife made a straight cut, without shear or draw, and represents quite a crude state of slicer construction.

VERTICAL AND HORIZONTAL SLICERS

Slicers have been built of various designs. They can be divided into two distinct types, vertical and horizontal. In the vertical type the flitch table or knife bed moves up and down. In the horizontal type the flitch table or knife bed moves horizontally.

There are machines of both types in use today, but in practically all cases in this country the flitch table moves and the knife-bed and cap assembly is stationary except for the feed and offset motion.

Vertical Type. The vertical machines built in this country follow the general principles of the Williams slicer, patented 40 to 50 years ago, and are the slicers in general use today.

Although the travel of the flitch on a slicer is reciprocating rather than rotating, as in the case of the lathe, the principles of veneer cutting are in both cases the same, and the construction of the knife-bed and cap assembly are similar.

The same requirements of weight and rigidity are applicable to the slicer as to the lathe.

The cutting stroke has a vertical motion of about 3 ft and a draw or lateral motion of about $1^1/_2$ ft. The draw gives a shear that eases cutting action and helps to prevent the flitch from breaking out at the back edge. The flitch table is mounted on three heavily built angling slides (see Fig. 15). The weight of the flitch table is counterbalanced by weights on the drive gears, which are connected with the flitch table by two pitmans.

The cutting occurs on the down stroke, and the feed takes place on the return, or up, stroke. The feed is of the single ratchet-and-pawl type and is capable of accurate adjustment to any desired thickness from zero to over $^1/_4$ in., which is above the practical usefulness of knife-cut veneer. As the feed takes place on the return stroke, an offset operates on the knife-bed and cap assembly that rocks it back to clear the flitch at the bottom of the stroke and returns it into cutting position at the top of the stroke. Regardless of how the offset operates, it is essential that the knife-bed and cap assembly be held rigid while the knife is in the wood.

Horizontal Type. The horizontal slicer has no draw cut and takes up more floor space than the vertical machine, but it has some features that are to its advantage (see Fig. 16).

The stroke is 8 ft long. The flitch table is pivoted at the center on a carriage in such a manner that the flitch can be turned in either direction to angles not exceeding 30 deg with the knife, to take advantage of the grain. This results in a flexible angling cut that will often be more favorable to wood grain than a fixed angle and results in smoother and sounder cutting. The offset raises the knife-bed and cap assembly directly on the feed slides so that the strain when cutting comes directly on the feed slides and not on the offset mechanism.

TOOLS AND TECHNIQUE

While marked differences have been indicated between veneer lathes and slicers in the frames, log (or flitch) mountings, and wood travel, yet there is a singular similarity in the knife and pressure-bar mechanisms. In fact, the similarity is so striking that the same crew, the same sharpening devices, and most of the adjustment principles can be used interchangeably on either type of veneer-cutting machine. Their descriptions will therefore be combined and their differences denoted.

Veneer Knives

For many years veneer knives have been made by the generally approved method of welding a strip of carbon tool steel on a soft iron or steel back, as shown in Fig. 17-*A*. All slots and holes for fastening to the knife bed are put in the soft back.

Knife Splicing. It is now possible to obtain a one-piece knife in almost any length desired, but ordinarily a jointed knife is satisfactory, and the extra expense of a single-piece knife is uncalled for. Most pieced knives are now welded so perfectly that it is practically impossible to locate the weld. Until this weld was developed, most makers put knives together with a dovetail key and threaded dowel pins, as shown in Fig. 17-*B*. Continued service is apt to cause this type of joint to become loose. This can be remedied by removing the dovetail key, filing the ends to give them clearance, and drawing the joint tight by replacing the key and peening the tapering sides of the dovetail.

Knife Mounting. In the early machines the knife was mounted with the bevel side toward the knife bed and away from the wood (see Fig. 17-*C*). This had three disadvantages: It was necessary to set the knife high enough for the bevel to be above the knife bed, which gave the knife insufficient bearing on the knife bed; it was imperative to clear the heads of clamping screws; and it permitted the cutting wear to come on the face side of the knife where it was difficult to grind off. On the other hand, the thrust of cutting came directly on the adjusting screws, with less strain on the clamping screws. The clearance was not so serious on lathes as on slicers, where the flitch passed the knife in a straight line parallel to the face and there was no curvature to the log to clear the bolt heads. This made it necessary to countersink the heads below the surface of the knife, which increased the difficulties of mounting the knife firmly.

Practically all modern veneer-cutting machines (both lathes and slicers) provide for mounting the knives with the bevel vertical (see Fig. 17-*D*) and against the log or flitch. This provides more rigid support for the cutting edge against the knife-bed casting and also supplies more adequate clearances for clamping and adjusting bolts. In the case of whetting or honing, if such becomes necessary, this method of mounting permits whetting the bevel rather than the face, which is the approved method.

There are now on the market several sectional knife-holding devices of the type shown in Fig. 8 that are designed to hold the knife more rigidly against the knife bed than is possible with the standard knife bolts. When properly installed and adjusted, these knife holders lessen the troubles caused by spring in the knife. The use of these sectional knife holders or clamps will also lengthen the life of a knife beyond the point where it can be held rigidly by standard clamping bolts.

Knife Temper and Hardness. Modern manufacturing methods

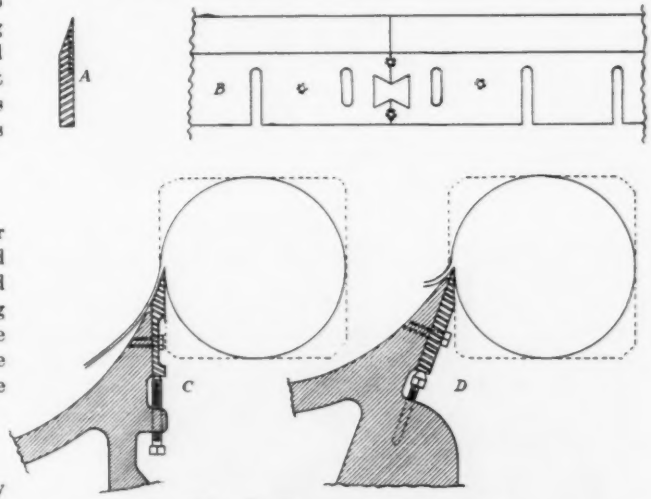

Fig. 17 Veneer-Knife Details

(*A*, showing hard-steel cutting edge welded to soft-steel back; *B*, method of splicing long knives; *C*, face of knife mounted vertically, with limited clearances, point of adjusting screw against knife; *D*, bevel of knife mounted vertically, with ample clearances, head of adjusting screw against knife. Relation of knife mounting in slicers shown by dotted line.)

and new alloy steels have permitted knives of more uniform temper and of tougher steel. It is possible to secure knives of almost any desired degree of hardness. The right temper depends on the kind of cutting and the wood to be cut. For face veneer, a hard knife should be used. If the operator uses care, a hard knife holds a straighter edge, which helps materially in keeping alignment of the knife with the pressure bar.

In cutting pine and similar woods, a softer knife must be used. The hard limb knots in the wood will cause a hard knife to break out. There is quite a difference of opinion as to the proper temper of knives, but the knife makers, with years of experience and contact with knife users, can be relied upon to furnish the proper knife.

Grinding and Whetting the Knife

Grinding machinery has been perfected to such a degree that the grinding of a knife is a simple matter. Originally the devices used in grinding were mostly contrivances developed by the various plants for their own use, some of them good, but all of them slow and requiring skilful handling to do a good job. This made grinding an unpleasant event and one that was as a rule put off until the last minute. In order to use the knife as long as possible, it was obvious that unsound practices, such as filing out nicks and using soft fast-cutting whetstones, would be tolerated. These practices are to some extent in vogue, but are disappearing

and will probably be forgotten in the next generation. A straight, thin edge is required to do good cutting, and to accomplish this, it is necessary to grind often and only to whet enough to keep the edge smooth.

Grinding. All modern grinders are equipped with a stationary knife bar and a moving abrasive wheel, mounted on a carriage that travels back and forth on slides (see Fig. 18). There are some grinders built so that the knife travels, but most of the grinders in use today are built with the wheel mounted on a reciprocating carriage, especially grinders for long knives.

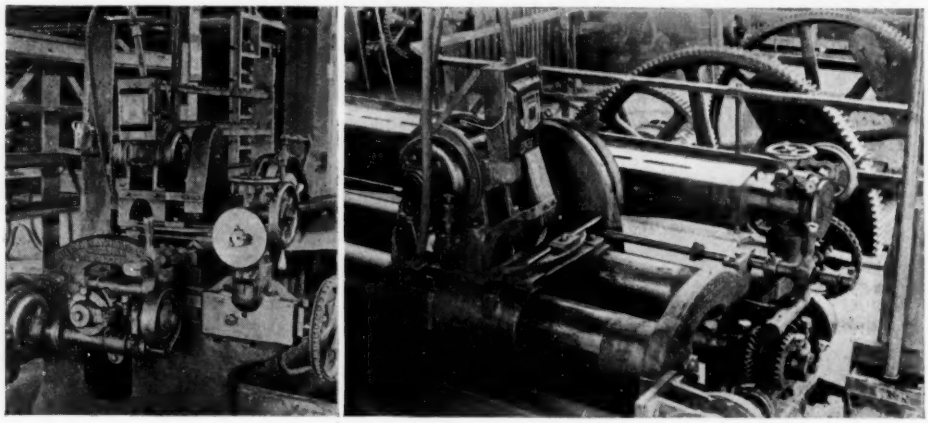

FIG. 18 VENEER-KNIFE GRINDER

(Left: End view of grinder, with abrasive wheel inside of guard. Right: Showing grinder-wheel carriage traveling on cylindrical ways. Knife bed with slotted boltholes in rear, with adjustments to control bevel.)

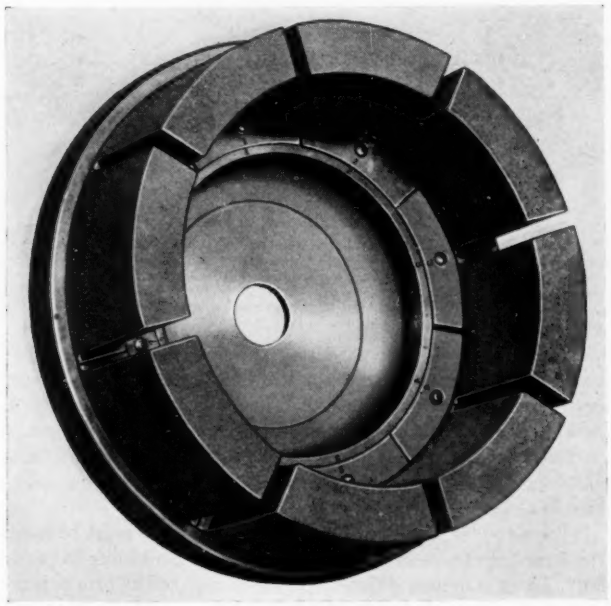

FIG. 19 SEGMENTAL GRINDING WHEEL

(Segments of abrasive wheel, mounted in holder, with approximately 1/2 in. clearance between blocks. Designed as a self-cleaning wheel with a minimum of glazing.)

The knife is bolted on the knife bar, the edges projecting about 1/2 in. above the bar. The bar is then brought up to the wheel and set so as to grind a 2-in. bevel on a rotary knife or a 2 1/2-in. bevel for a slicer knife. The wheel is then adjusted to grind not over 1/64 in. concave on a rotary knife and not over 1/100 in. concave on a slicer knife. The figures given are to be used on a standard knife 3/4 in. thick. It is not advisable to use more of a bevel or concave as there is danger of having the edge too thin.

The wheel used is usually a cylinder or cup wheel 14 in. to 16 in. in diameter and should run not over 650 rpm for a 16-in. wheel. The wheel should be kept burred off and not allowed to glaze. If a wheel is not cutting freely, there is danger of burning the knife.

A holder has recently been developed for segmental abrasive blocks, leaving 1/2 in. space between each segment (see Fig. 19). This is a great improvement over the solid wheel, for the reason that spaces between the segments allow the wheel to clear itself and thus prevent glazing.

Whetting. The wire edges should be taken off the knife before the knife is removed from the grinder. This is done by rubbing the whetstone lightly and squarely on the edge of the knife, removing all the wire edge down to the solid metal. Then the knife should be honed on the bevel side to an edge, being careful not to use the hone too much.

PRESSURE BAR

Most pressure bars (see Fig. 9-*E*) are made of mild steel, machined to fit in the cap, and drilled and tapped for the retaining and adjusting studs. The wear on a pressure bar is considerable, and it must be ground as often as the edge becomes rounded. Some cutters use a rounded bar on soft wood and a sharp bar on hard woods. It is the authors' belief that as sharp a bar as the wood will stand is better in all cases. In cutting soft wood, the angle of the bevel of the bar should be less acute to give the bar more bearing on the wood. This will prevent the bar from scraping the surface, equally as well as a more rounding edge, and the pressure will be much more sensitive, as it will be applied closer to the point of contact with the knife edge.

Tempered tool-steel pressure bars can be obtained today, at considerably higher cost. They require less frequent grinding and consequently are longer lived. It is a matter of opinion as to which bar is the most economical to use.

SETTING THE KNIFE AND PRESSURE BAR

Bolt the knife securely to the knife bed (the edge of the knife 1 1/2 in. or less above the knife bed). The best way to mount a knife is to adjust the setscrews on which the knife rests to about the proper height before putting the knife on the machine. Care should be used to have the bearing surface and the knife wiped clean so as to be sure that nothing interferes with having perfect contact of the knife with the knife bed.

Some of the older lathes were built with the back of the knife to the log and the bevel side to the knife bed, in which case the edge of the knife must be 2 in. above the knife bed.

The cap should now be placed in position, and the edge of the pressure bar and the edge of the knife should be in alignment vertically. This is done by means of the screws (see Fig. 9-*C*) on which the knife rests and the pressure-bar adjustments. The knife can be aligned to some degree by means of the setscrews, but short, low places will have to be taken out with the adjustments on the pressure bar. Some machines are built without a vertical adjustment in the pressure bar. In this case it is necessary to use shims to spring the bar up or down, as the case requires.

With the modern grinders and with proper care in handling the knife and pressure bar, the alignment of the knife and bar is a comparatively simple matter.

After the vertical alignment is accomplished, the horizontal alignment is necessary, which must be perfect and can be accomplished by the touch much closer than by any other means. After the knife is put on the machine and the pressure bar is adjusted, the knife bed should be leveled and the edge of the knife be brought to $^1/_{16}$ in. above the center of the spindles.

The same rules apply in setting the knife and pressure bar on a slicer as on a rotary with the exception of the height of knife edge above the knife bed. On slicers, the knife is carried higher than on a lathe, in some cases as much as $1^3/_4$ in.

There is no advantage in carrying a high knife, but it is important that the knife be afforded all the support possible.

Preparing the Wood for Cutting

There are few species of wood and not many conditions where logs can be cut into veneer cold—i.e., as they come from the stump without preparation. While it is admitted that cooking or steaming a log is a softening and toughening process that facilitates firm cutting, yet the processes of cooking or steaming have long been a controversial subject among veneer cutters, and the advocates of several different procedures seem to be successful, so far as veneer quality is concerned. The problem is one of heating the log through and making the fiber cuttable, without continuing the cooking to a point where the veneer fibers shred or separate. Some authorities advocate considering it a twofold problem of the temperature factor and the duration of preparation, believing this clarifies the issue. There are two principal methods:

1 Hot-water cooking vats, principally for hard woods
2 Steaming boxes, particularly for soft woods.

Hot-Water Cooking Vats. These are usually sub-floor tanks (generally covered with loose coverboards) of laminated wood or concrete, some 6 ft deep, as wide as lathe-log length, and from 20 to 40 ft long. Since duration of cooking is usually advantageous, these vats are generally in batteries, with conveyor chain overhead for removing the logs and transferring them to the lathe platforms. Live steam is discharged at one or more points below the water level, and often is under thermostatic control. Vats are exceedingly hazardous to workmen and need adequate guard rails and protective features.

Steaming Boxes. These are of wood or concrete, usually aboveground, where logs can be rolled in and removed by conveyor grabhooks. They are much easier to load and unload than are vats, and can be kept cleaner. The steaming process is usually more intense and shorter in time than cooking, so that fewer units are required, but the violence of rapid heating is hazardous on some species and rather ineffective on others. Doors to steam boxes, with in fact the entire structure, are subject to rapid deterioration from frequent and abrupt temperature and moisture changes.

General Preparatory Measures. The authors know of few veneer plants with an adequate supply of steaming boxes and cooking vats, and hence most operators are obliged to maneuver their scanty equipment and frequently to skimp on the best preparatory measures. The outline following is rather ideal, beyond full accomplishment in most plants, and will find many advocates, as well as some sincere objectors. Nevertheless, satisfactory work will result from adherence to the recommendations made. Heat should be applied slowly at first and increased toward the end of the cooking.

Poplar, basswood, and cottonwood, for utilitarian purposes, are often cut cold, if reasonably fresh from the stump. Soaking in log ponds is always advantageous. Gum is preferably cooked overnight at from 150 to 200 F. Coniferous woods, such as fir, pine, and spruce, are usually steamed 4 to 6 hours and sometimes longer. Oak, ash, and similar woods require boiling, usually from 12 hours up. Walnut, mahogany, and similar face woods cut best after cooking overnight, and sometimes longer, at temperatures from 125 to 200 F. Judgment should be used according to age and individual log characteristics. Too much heat is dangerous. Maple and birch should have similar treatment, but more rapidly to prevent discoloration, with temperatures up to 200 F. Stumps and crotches benefit usually by long soaking (several days) in warm (around 100 F) rather than hot water.

The important factors are to heat the log through and to find the happy medium between under-prepared or rough (sometimes fractured) cutting and over-preparation or fuzzy (shredded) cutting. The thicker the veneer to be cut, the higher the temperature required to reduce fracturing hazard. It is not at all unusual to remove a log from the flitch table to cool off or to recook it. Sometimes a flitch that cuts badly in one direction can be reversed and remounted so that it will cut satisfactorily. In general, long soaking at low temperatures, even in cold water in log ponds, is beneficial, and heat must always penetrate thoroughly but not too rapidly for the particular species or texture.

Operation

Operation, in the general sense of the term, is an individual problem in each veneer mill, and a procedure that might give the best results in one plant could be entirely inappropriate in another.

There are, however, a few fundamental rules that apply to veneer cutting in general. With the fit-up of the knife and pressure bar made as described, the cap should be raised to bring the edge of the pressure bar about $^1/_{32}$ in. above the edge of the knife; the cap should be pulled back so that a piece of dry veneer of the thickness to be cut can be slipped between the knife and bar. The lead should be flat; that is, the angle of the lead, as explained previously, should be at 0 deg.

With a flitch or log in the machine, it is ready to start cutting, with the principal adjustments in known positions. It is fairly certain that lead will need to be added, that the cap will have to be either raised or lowered, and that the pressure will have to be increased. After starting the machine and while taking off the first few sheets, adjustments should be made, such as putting in enough lead to hold the knife in the wood and adding pressure to preserve the texture of the wood (too much pressure will cause raised spots on the log). If the fit-up is not perfect, this can be relieved by pulling the pressure bar back at these points. If the cap is too high, adding pressure will not bring proper results. If the cap is too low, adding pressure will crowd the veneer too much in going between the knife and the bar, and cause a chatter, or washboard. This adjustment is very sensitive, and great care should be used not to change it too much. Since too much or too little lead will also cause chattering, it is well to get the lead set correctly before attempting to lower the cap.

On a lathe, the lead should be changed with the back screws so as not to raise or lower the height of the knife edge. The height of the cap is regulated with the front screws.

The back screws on the cap are used only to change the angle at which the pressure bar is presented to the log.

If changing the adjustments does not bring the expected results, it may be necessary to start all over. It is a good plan to mark the screws with chalk so that the amount the adjustments have been changed is always visible.

There are many other operating problems, subordinate to the fundamentals outlined, but their solution usually depends on the skill and experience of the operator and varies with the purpose for which the veneer is to be cut, the thickness of the sheet, the kind of wood, and the type of equipment available.

An idea of a typical lathe layout and crew may be secured from Fig. 20.

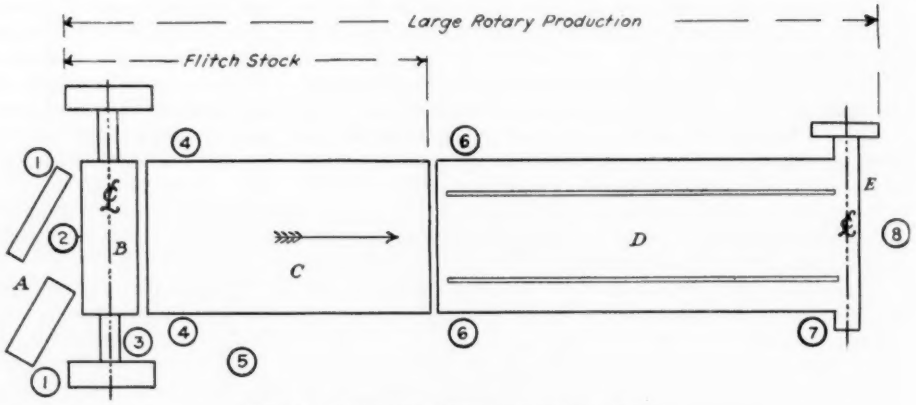

FIG. 20 STANDARD LATHE LAYOUT AND CREW

(*A*, log deck at floor level; *B*, rotary lathe; *C*, delivery table, sloping up to clipper chain; *D*, conveyor chain to clipper; *E*, clipper for trimming veneer. The standard crew, totaling 11 workmen, is as follows: (1) 2 log peelers, varies with lathes in service; (2) 1 log hanger; (3) 1 lathe operator and crew foreman; (4) 2 off bearers or breakers; (5) 1 waste collector; (6) 2 off bearers, for large production; (7) 1 clipper operator; (8) 1 clipper off bearer. A stay-log crew or rotary flitch stock usually eliminates the last four workmen.)

CONCLUSION

The dropping of sheets of beautiful veneer on the delivery table has a rare fascination for the artizan who can visualize the ultimate beauty of the wood in a handsome table or cabinet. The variations in color, shade, and figure are elusive and unending. Two trees never yet grew alike, and nature's artistry has never been equaled by man.

The modern American penchant for standardization has little place in the artistic value of veneer utilization. Beauty results from the intelligent use of color, grain, contrast, combination, and symmetry, and knife-cut veneer supplies a wonderful range for such artistic expression.

The full natural beauties of the forest products can be revealed only when the experience and artistry of the workmen combine the skilful flitching of the log with the intelligent cutting of each sheet of veneer from the flitch.

ACKNOWLEDGMENTS

The historic lathe and slicer illustrations, Figs. 1 and 14, were taken from "Knight's American Mechanical Dictionary." The photograph for Fig. 4 is from the archives of Sinker-Davis Company, Indianapolis, which has not built lathes since 1890; that for Fig. 5 was supplied by the Coe Manufacturing Company, of Painesville, Ohio; those for Figs. 6, 8, 12, 15, and 19 by the Capital Machine Company, Indianapolis.

Much credit is due to William Williams, of New York City, for his original idea for draw cutting on a slicer; to William Schwegman, of Indianapolis, for originating the pressure-bar adjustments that are in use today; to Louis Koss, of the Capital Machine Company, Indianapolis, for visualizing the need for sturdy construction and consistently working to that end; to H. H. Coe, of Painesville, for recognizing the advantage of placing the feed screws on the knife line, as well as for other original developments; and to I. E. Merritt, of the Merritt Engineering and Sales Company, Lockport, N. Y., for many of the refinements of modern lathe construction.

This paper has been prepared with the assistance and cooperation of Thomas D. Perry, the author of several plywood papers for A.S.M.E. Transactions.

Discussion

ARTHUR ANDERSON, Chautauqua Plywood Co., Jamestown: Referring to what Mr. Roberts said in regard to the necessity of having a perfect adjustment of the pressure bar and knife, I have seen poor cutting done on curly maple. He said that as long as these adjustments are right a machine should cut good veneer. But is it not true that the logs should first be properly conditioned for cutting—and what is the proper way?

MR. ROBERTS: To get the best results in cutting veneer the wood must be in the proper condition. An operation preliminary to the cutting operation is in most cases necessary to obtain this condition. There are two common methods of conditioning logs: First, by soaking them in water of the proper temperature; second, by heating them with a direct application of low-pressure steam. In the case of hard maple the logs should be soaked for about 24 hours in water at a temperature of about 200 F. If too much heat is applied, the veneer will show heat marks and the log should be removed from the machine and allowed to cool before further cutting is attempted. A very keen, smooth-edged knife will help prevent heat marks. If poor cutting other than heat marks is experienced, the cause will probably be found in adjustment of the knife and pressure bar.

PAUL SETTER, Setter Brothers, Cattaraugus, N. Y.: Mr. Roberts spoke of the knife bearing against the log; at what angle is it set?

MR. ROBERTS: The angle referred to is the lead, as defined under the heading of "Knife-Bed Adjustments." It is best to start cutting with this angle at 0 deg and to add just enough lead to hold the knife in the wood and maintain even thickness. It is necessary to carry more lead in cutting thin veneers.

CHAIRMAN: Speaking of overcooking, is there some easy method of telling how to cook a log?

ANSWER: Our practice is not to get the wood too hot. You can, by additional pressure, get good results with the wood a little cool.

AUTHORS' CLOSURE

The questions reveal a decided interest in log preparation, a process that is admittedly far from standardized. The reason is obvious, since no set rules have ever been found to bring uniform results. Trees of the same species will require different treatment according to age, texture, growing conditions, and the season in which they are cut. Hence the cooking operation must in the last analysis be accomplished according to the results of observation and experience.

WDI-55-5

The Electric Molder and Its Efficiency

By ANTON VONNEGUT,[1] INDIANAPOLIS, IND.

The great variety of molder work, involving different methods of operation and various types of cutter-head equipment to meet requirements in all branches of the woodworking industry, accounting for a wide range of expectations regarding molder performances, has caused the development of diversified points of view for appraising molder efficiency. This paper attempts to analyze basic molder design requirements, as determined by fundamental molder functions and principles of molder cutting actions, with the hope of developing a more general understanding of reasons and requirements for electric molder efficiency.

ONE might define a woodworking molder as "a machine with a series of fixed and adjustable devices to guide lumber into relation with plane or formed knives of rotating cutter heads that are removably attached to a multiple number of spindles having lateral and logitudinal adjustment for the purposes of surfacing or forming and dimensioning various sides of lumber simultaneously, as it is pushed through the machine by means of its power-driven feeding mechanism." The qualification of "multiple number of spindles" excludes single-spindle machines. It includes two-head molders and says nothing about the relation of one head to another. Therefore it applies alike to the European type of molder, in which the first cut is made with the bottom head, as well as to the standard American spindle arrangement, in which the first cut is generally made with the top head. The definition also covers "flooring machines" and "planer-matchers," because they are single-purpose and semi-single-purpose molders. Some of them are made with infeeding and outfeeding mechanisms, and they are generally much heavier than standard molders. They are less flexible in the range and variety of their adjustments than the more widely used type of general-purpose molder.

The range and flexibility of adjustments and the accessibility and convenience for making and locking adjustments are the distinguishing characteristics of general-purpose molders. They must be designed to handle a wide range of work from smallest patterns of fragile stock up to dimensions of their maximum capacity. They are used to cut all varieties and conditions of lumber and in every branch of the woodworking industry. Sometimes molder work is a preliminary operation to other machine work, sometimes a finishing operation following preliminary work on other machines, and sometimes the molder is called upon to make a finished pattern from rough lumber. In one instance the main objective may be speed and maximum production without primary consideration of quality, and in another it may be that smooth surfaces and accuracy of pattern are considered far more essential than the amount of work produced. More often the requirements include a good balance between quality and quantity of molder work.

In spite of all the need for flexible adaptability, some molder service may call for long runs of a limited number of patterns. On the other hand, many short runs and great variety of patterns often create the necessity of using more time for making set-up changes than for feeding the stock through the molder. Relatively satisfactory efficiency for the extreme services are available with the same machine on account of interchangeability of a variety of special and universal types of molder cutter heads. The utility of heads is also augmented by attachments, and this has developed two distinct systems of molder operation to supply the different requirements of different molder services.

Though there are well-defined extremes of requirements and services in different woodworking plants, there are also mixtures of those conditions and requirements in most plants; and there is generally a slightly different blending in the mixtures of requirements and expectations associated with each molder installation. There is no definite standard to measure quality and quantity of molder work. The maximum output of a detail mill might seem ridiculous by comparison with the minimum output of a production mill, and a standard of excellent quality of work in one plant would not pass the most lenient inspection of another. Such differences do not only exist as between different branches of the woodworking industry, but also within the same field of manufacturing. For example, there may be more differences of opinion regarding the proper way of using a molder and the results that ought to be expected as viewed by two manufacturers of furniture than between a mill man and the manager of a toy factory. That condition helps to point out the danger of misunderstandings, for lack of an established point of view, in any discussion of electric molders. In fact, there is even very little agreement on the subject as between different manufacturers of identical types of molders.

A Common Point of View of Efficiency

There can therefore be no doubt of the desirability for first finding some basic or common point of view before proceeding with any discussion of electric molder efficiency. Each of us may be interested in a different detail or a different phase of molder design, operation, or efficiency, but whatever that interest may happen to be, it has some relation to the three fundamental molder functions of feeding, guiding, and cutting the stock. Fortunately, that applies absolutely alike to all styles, types, and makes of molders—belt-driven as well as electric—and it does not take any stretch of imagination to claim that the functions of feeding and guiding are a means to an end. That end, namely, cutting, therefore suggests itself as the most important function. It is the basic factor of all molder efficiency.

Of course, it is needless to say that an inefficient feeding mechanism or an inadequate guiding device destroys the value of satisfactory requirements for cutting and that feeding and guiding must be considered in determining molder efficiency under all conditions, but it is equally needless to defend the greater importance of the cutting requirements. Incidentally, it should be said that there have been some most interesting electric-molder feed-works developments during the last few years. Nearly all electric molders are now available with traveling feed beds in addition to roll feeds. One make of molder

---

[1] Vonnegut Molder Corporation. Anton Vonnegut was born in Indianapolis, Ind. He is a graduate of Manual Training High School, 1901. He gained the M.E. degree at Cornell, 1905. Was engaged in machine shop and drafting work, 1905–1908. He was with the Vonnegut Hardware Company, Indianapolis, 1908–1910; president, Vonnegut Machinery Company, 1908–1930; president, Vonnegut Molder Corporation, since 1930.

Presented at the meeting of the Wood Industries Division of The American Society of Mechanical Engineers, Jamestown, N. Y., November 15 and 16, 1932.

Note: Statements and opinions advanced in papers are to be understood as individual expressions of their authors, and not those of the Society.

offers the three choices of roll feed, chain feed, and rolling chain feed.

There have been many improvements in guiding devices, particularly by way of increasing conveniences and speed for making quick set-up changes. It is also a temptation to mention materials and other refinements of electric-molder construction, but besides the limitations of time for those details, there is the very significant fact that none of those developments was a factor in the greater efficiency of the first electric molders by comparison with belt-driven machines.

The electric molder is therefore being discussed from the broad point of view that it is the same as a belt-driven molder except for a new means of applying spindle power and transmitting that power into the cut. That viewpoint is very well supported by the fact that several manufacturers are offering electric and belt-driven molders under the same catalog numbers, with no difference of specifications except as pertains to spindle drives. Furthermore, the relatively greater importance of power and spindle details is more or less self-evident as one becomes familiar with early experiences of electric-molder development.

Incentive for Designing the First Electric Molder

Paradoxical as it may seem, the incentive for designing the first motor-driven molder was the expectation of economical power consumption of a machine for an industry that had been notoriously indifferent to power economies, because it developed power from wood waste and refuse. Many woodworkers even took the attitude that power and the steam used for dry kilns, glue rooms, etc., cost nothing, because some form of burner and the expense of its operation would have to be maintained for refuse disposal. It must, however, be remembered that there was a rapid expansion of American industries between 1915 and 1920. Dry-kiln and power requirements soon exceeded boiler and engine capacities of many woodworking plants, and since power had generally been a matter of secondary consideration, those shortages were not often anticipated, and they frequently developed dangerously overloaded power plants before the facts were recognized. Such conditions naturally forced quick action in the purchase of motors to drive old line-shaft installations from public-utility power connections. Practically nothing had been done to correct the inefficiency of the old transmission facilities, and there were very unpleasant reactions against the monthly power bills, because the industry had learned to think of power as a low-priced by-product.

During the investigations resulting from that condition, attention was called to the larger power consumption of molders compared with other woodworking machines. Individual motors, coupled to countershafts, gave little relief, because of the many bearings and belts in connection with a long countershaft, a feed works, and four spindles of each molder. That data encouraged R. D. Eaglesfield, of the Vonnegut Machinery Company, Indianapolis, to undertake the design of the first electric molder early in 1916. It was installed in the plant of the Prest-O-Lite Company, near Indianapolis, with the gratifying result that it effected over 40 per cent saving of the power required by a new belt-driven molder of similar capacity, cutting the same amount of the same kind of lumber, at the same rate of feed. Considering the objective of the venture, the experimental machine was therefore a complete success.

Early Electric Molder Experiences

Subsequent tests have shown from about 40 to 60 per cent power savings for ball-bearing electric molders in comparison with babbitted-bearing belt-driven machines, and such evidence seems to justify the generality that the modern electric molder uses only about one-half the power required by old-style belted machines, while doing the same amount of work. The facts suggested that 25 to 30 hp, divided among four spindles and a feed works, would be more than sufficient for a fairly large-sized universal type of electric molder, because belt-driven molders were being driven by motors coupled to countershafts ranging from 10 to 25 hp, with only an occasional 50-hp installation for the heaviest service. Furthermore, the selection of motor sizes had been shown to be satisfactory by performances of twenty or more electric molders, when there came the startling report of insufficient spindle power in connection with one of those machines.

To understand that anomaly, one must remember the qualifying phrase, "at the same rate of feed," in the foregoing statements of power comparisons. Eliminating consideration of initial friction, windage, and electrical losses, molder power consumption increases in direct proportion to the rate of feed, and in the instance referred to, the purchaser was attempting to feed the electric molder approximately four times as fast as he had been feeding belted machines to do the same class of work. Thus the electric molder was forced to draw about four times as much power as would have been required if it has been fed at the same rate of feed at which the work had been done with belted machines and presumably about twice as much power as had been required to do the work with the old molders at one-fourth the rate of feed.

The work was being done in an automobile-body plant, and all of the patterns were to be covered in the completed product. The work had to be true to pattern, but there were no definite restrictions on the knife-mark spacings so long as the edges of the work were free from splinters and the surfaces free of torn places. Both types of machines were operated at spindle speeds of about 3600 rpm, because that was in the days before high-frequency molder operation. The work coming from the faster feed of the electric molder therefore had much wider knife-mark spacing than the work from the old machines, but it was acceptable—first, because there was more regularity in depth and spacing of those knife marks and, second, because there were fewer splintered and torn places in spite of the faster feed. The experience was the first conclusive demonstration that electric-molder efficiency included possibilities of increased production of greater proportions than the power economy for which the machine had been designed originally.

It had also been demonstrated, during early stages of electric-molder development, that the greater regularity in depth and spacing of knife marks produced a much better quality of work than was being obtained from belt-driven machines, and the electric molder therefore offered the threefold advantage of more economical operation, greater production, and better quality of work. All three divisions of efficiency had become a matter of fairly common knowledge even before the days of high-frequency molder operation and were evidently developed by smoother and firmer spindle rotation. Possibly that can be illustrated by comparison with another cutting action. We all know the contrast between stroking a pocket-knife blade or any form of edged hand tool firmly and quickly through a piece of wood and of shifting or twisting the blade hesitatingly before completing the cut. The one produces a smooth finish; the other a torn or splintered surface. It seems reasonable to assume that similar results would obtain with powered cutting tools and that the least lateral or longitudinal deviation in the line of cutter travel would account for torn and roughed molder cuts. Furthermore, even when the character of the wood is so favorable or the disturbed motion of the cutter is so slight as not to cause a torn surface, it is evident that the disturbance will affect the perfect regularity in the depth of each successive cut so as to destroy the effect of a perfectly finished surface.

Basic Reason for Electric-Molder Efficiency

The more nearly perfect spindle rotation of the electric molder was due to the three facts: (1) that the spindles were mounted in closely fitting ball bearings in contrast to spindles that floated on a film of oil, as is the case with friction bearings; (2) that ball bearings also restricted spindle end play; (3) that those spindles were being turned by balanced magnetic forces of the direct motor drive without being subjected to the pull and pound of high-speed belts. Those facts were evident, but they involved more than mere substitution. For example, the original electric molder incorporated substantially the same type of removable outboard spindle-bearing design as had been used with babbitted-bearing belted molders, but a friction bearing fits loosely and the spindle turns within the bearing, whereas the inside race of a ball bearing must be fitted to the spindle and turn with the spindle. With the old design there was the choice of fitting the ball race too closely for convenient removal and replacement or too loosely to provide firm spindle support. In one instance an operator gave evidence of the annoyance of replacing closely fitted bearings by deliberately filing down the spindle end diameters, thereby destroying the main advantage of ball-bearing spindles. At best, however, natural wear from bearing removal and replacement developed a sloppy fit that accounted for poor top and bottom head work after a few years, and in some cases after only a few months of service.

Subsequently, the problem was augmented by greater centrifugal cutter-head forces of high-frequency operation, but the fundamental requirements remained the same, and there followed the conclusion that the superiority of one electric molder over another electric molder depends primarily on its more nearly perfect cutter-head rotation coming from better spindle design and better means for applying the power to the spindles, just as the first electric molders had proved their superiority on account of a smoother spindle rotation than had been obtained from "floating" spindles that were subject to the pulling and pounding effect of heavy belts. Maximum molder efficiency depends upon the best solution of that problem.

Molder spindle design must provide for firm rigidity of the supporting parts that supply longitudinal, lateral, and angular spindle adjustments in combination with convenient accessibility for making and locking those adjustments. Then, besides answers to engineering questions pertaining to bearings, bearing housing, spindle shaft, motor, motor mounting, lubrication, ventilation, and the proper relation of all those spindle parts to one another, the problem also involved establishing standards and manufacturing methods to assist in obtaining the greatest possible accuracy of dimensions. An interesting sidelight on that point is that ball-bearing manufacturers hesitated to make any recommendations of tolerance allowances for fitting bearings in the first electric molder, because they knew nothing about molders and molder service. Those tolerances had to be worked out by molder manufacturers, and they have gradually been restricted, until present-day standards call for less than one-tenth of the allowances specified for the first electric molders. The desired results must provide the closest possible fittings in combination with uniform interchangeability of all the spindle parts.

It would be most interesting to go into the details that have been worked out in answer to those problems of design in the quest for maximum molder efficiency, because they have been the subject of so many claims and counterclaims among representatives of half a dozen molder manufacturers, but space forbids. The results derived from those designs must be examined instead of the details of the designs, and it is hoped that the foregoing generalities have served their purpose of emphasizing the importance of all that pertains to spindles in considering the following information regarding those results.

Molder Operating Methods

In spite of what has been said about the great variety of molder uses and the resulting diversity of opinions and points of view, there seems to be the prevailing interest, indicated by the frequency of the question, "How fast will it feed?" Theoretically, the correct answer would be, "As fast as the stock and finished work can be brought to and taken from the machine." However, the generality must be qualified by conditions. For example, there is greater possibility of crushing or breaking small patterns of fragile woods under the greater strains of higher rates of feed. That is only one of many other qualifications that, unfortunately, must also be omitted for lack of time; but beyond these, the rate of feed depends primarily upon the quality of work desired, and it is influenced by the method or system under which the molder is to be operated.

Two molder operating methods are determined by the two practices of "jointing" and "not jointing" the knives, or "multiple-knife finish" and "one-knife finish." The word "finish" is used because the term "one-knife" might suggest a single knife, and there must always be a balancing knife. There may be two, four, six, or even more knives per head, and all knives may be cutting, but if one knife projects only a fraction of a thousandth of an inch beyond the others, it wipes out the cutting marks made by the other knives, and the finished work shows only one knife mark for each cutter-head revolution, accounting for the term "one-knife finish." Jointed knives are attached to heads in substantially the same way as unjointed knives, but more care and time are taken to obtain approximately equal projection of all the knives. Then a firmly guided whetstone or emery stone is applied lightly to the knife edges, while the spindle is in operation, to equalize the knives, so that each edge projects exactly the same as the others, thereby effecting a distinctly separate cut and forming an individual mark for each cut; for example, four knife marks for each revolution of a four-knife head. That is comparatively simple for surfacing operations, because the jointing stone is drawn and guided along the length of a straight bar positioned parallel to the spindle. The same principle is sometimes attempted for formed work by guiding the stone along a jointer templet. More commonly a stone is conformed to the shape of the knives and then guided straight into the knives at right angles to the spindle. In either case the jointing of formed knives involves the preliminary time of making templets or forming the stones.

Theoretically, there is far greater production with jointed knives. At the same spindle speed, two, four, and six jointed knives will effect the same knife mark spacing as the one-knife-finish system, but at two, four, and six times the rate of feed, respectively. Practically, however, the theory must be tempered by the facts that the attainment usually involves more time for setting the knives besides the jointing time and that the amount of time is fairly well dependent upon the individual skill of each operator; that even a thoroughly skilled operator does not always joint the knives with uniform accuracy; that any slight difference of knife tempers may cause unequal wear and destroy the joint; that the gritty surface of an occasional piece of undersized stock cuts the knife edges and destroys the joint; and that jointing forms a "heel" or flat surface behind the knife edge, of which all parts are equidistant from the spindle center and which must therefore slide against and tend to glaze the surface fiber of the finished work.

The last point would suggest that since the object of jointing is knife-edge equalization it means that the process resolves itself into generating different widths of heels on different

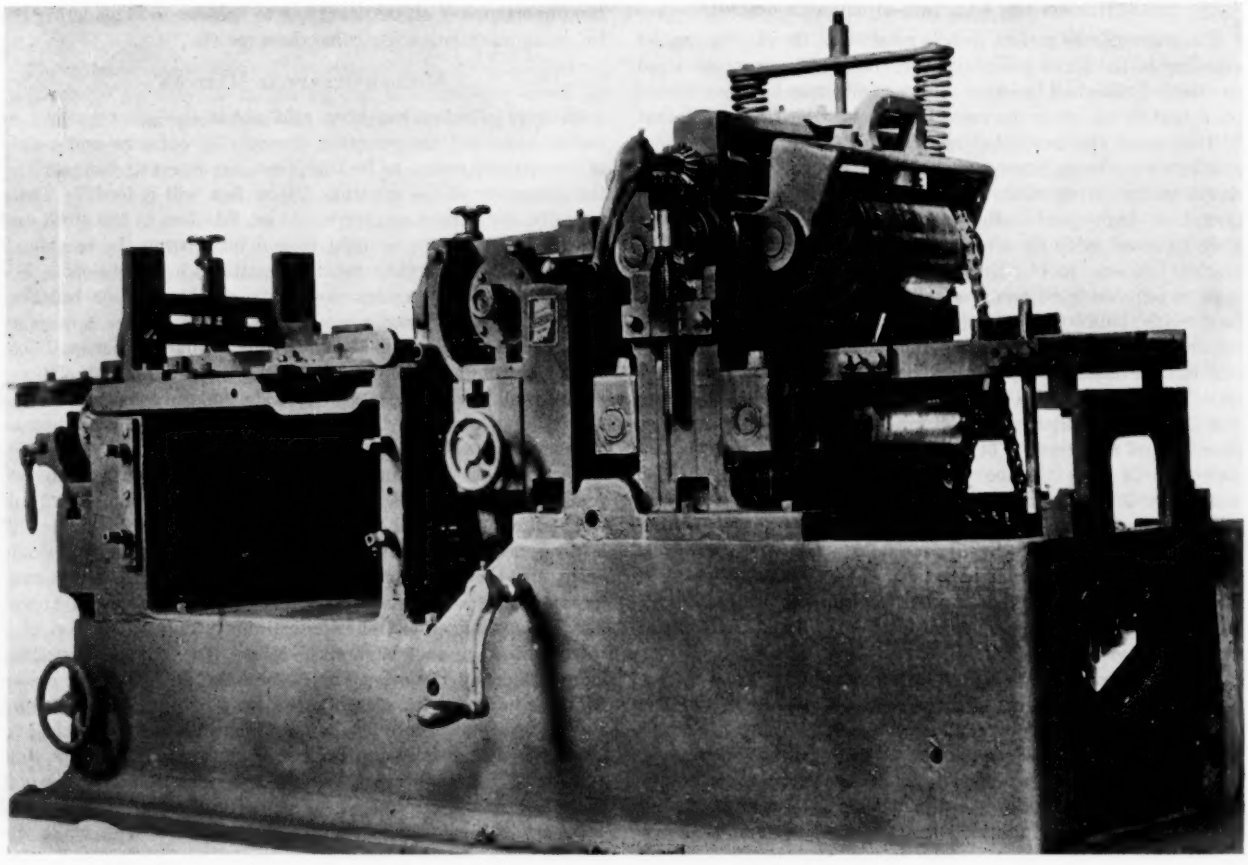

FIG. 1 FRONT VIEW OF THE FIRST ELECTRIC MOLDER

knives, depending upon their relative projection, and that the finished surface is therefore a series of slightly varying widths of heel marks. Possibly that sounds somewhat of the nature of hairsplitting, but the theory is supported by practice, because the desire for the very best quality of jointed work is fulfilled by generating the heels and then applying a grinder to the knife bevel to remove the excessive heels, without touching the edges. It takes time at best and is prohibitive for any except the most skilled and experienced molder operators. The system is commonly referred to as "fast-feed molder operation."

HIGH-FREQUENCY OPERATION

The feeding rates of one-knife finish are obviously slower for the same spindle speeds, but the standard 3600 rpm of earlier electric molders, operated from 60-cycle current, has been raised to speeds of from 6000 to 9000 rpm with 100- to 150-cycle power circuits developed through frequency changers from the primary lines or generated by alternators from almost any source of power. Assuming an average of 7200 rpm, the increased rates of feeds available with earlier electric molders have therefore been doubled. Higher spindle speeds, causing greater knife velocity, also account for cleaner cuts, and when the one-knife finish is used, the cuts are made with keen-edged knives that leave no heel mark. That system, in combination with the desired quality of spindle rotation, therefore makes each cut an exact reproduction of every other cut along that surface. The character of finish on all sides of the pattern is also similar, and the method offers much greater possibilities of maintaining a uniform standard of work at all times than a method that depends upon similarity of cuts made by different knives and upon the vigilance of the operator to maintain that similarity.

Besides the most uniform quality of work, the combination of identical repetitions of a keen-edged cut at high velocity, as occurs with one-knife-finish high-frequency electric-molder operation, self-evidently permits a higher percentage of running time, because it eliminates all lost time for jointing and preparation for jointing, and one is led to wonder whether it would not be better for the average woodworker to ask, "How much *good* work, according to my particular standards of quality, will my molder produce per hour, per day, and per month?" rather than, "How fast will it feed?"

CONFLICTING OPINIONS AND RECOMMENDATIONS

There is common consent to the opinion that no interior trim contract mill, small furniture factory, nor in fact any woodworking plant that intends to make a reasonable variety of patterns with one or a limited number of molders, can afford the time required for jointing and that high-frequency operation is to be preferred. Even in automobile body plants, where maximum output is paramount and where some machines, in batteries of a half-dozen to more than a dozen molders, could be kept busy on a single pattern or two, all molder work is being done with one-knife-finish high-frequency operation. Yet enthusiasts for the jointed-knife system are inclined to foster it with the argument that it is the means for faster feeds without the necessity of additional investment in a frequency changer (generally about 20 per cent of the molder price). In some instances that thought is even carried to the detail mill man by suggesting that high spindle speeds are dangerous with long knife projections; that all deep cuts must be made with spindles

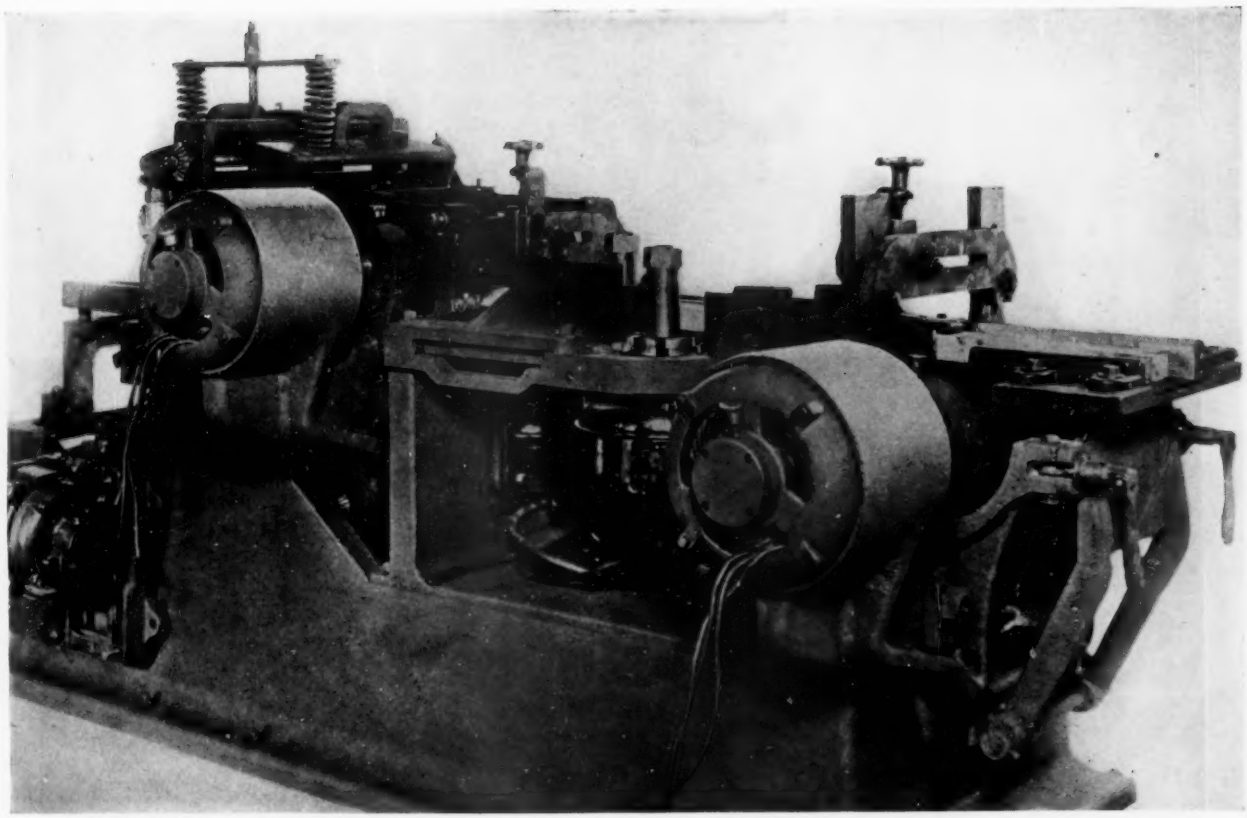

FIG. 2 REAR VIEW OF THE FIRST ELECTRIC MOLDER

turning at 3600 rpm; and that, since high spindle speed cannot be used at all times, the price of the frequency changer may be eliminated. The sponsors of such recommendations generally also maintain that knives cannot be jointed at 6000 and 7200 rpm.

There are intermediate opinions, but other molder manufacturers insist that maximum efficiency can be obtained only with high-frequency operation, because it is the means for making keen-edged knife cuts at from 50 to over 100 per cent faster rates of feed; that there is no more danger of throwing and breaking knives, with the smoother rotation of present-day cutter-head equipment, than existed at slower spindle speeds with inferior equipment of a few years ago; that speed enthusiasts can obtain maximum rates of feed by jointing knives with spindles revolving at 6000 to 7200 rpm; and that those expectations are being fulfilled at rates of feed approximating 200 fpm in both hard and soft wood operations. They do not overlook the fact that higher spindle speeds tend to accentuate difficulties of attaining and maintaining uniformity of multiple-knife finish, requiring the service of the more skilled operators, but claim that the success of that operation, like other phases of molder efficiency, is primarily dependent upon rigidity of spindle support and smoothness of spindle rotation.

It would therefore seem that conflicting recommendations regarding best operating methods for obtaining maximum efficiency resolve themselves back to the controversies about engineering problems and manufacturing methods relating to motor applications and spindle designs for obtaining the smoothest cutter-head rotation.

ILLUSTRATIONS OF SAMPLE WORK

Visibility of molder-knife marks depends partly upon the wood on which they are made, but mainly upon the angle at which the wood is held in relation to the light and the eyes but it is impossible to reproduce the knife marks at those angles photographically without showing distorted foreshortening, which would destroy the effect of the true relations of the marks. The accompanying reproductions were therefore photographed at right angles to the wood surface. All marks are therefore not distinctly visible, but since the photographs were taken under exactly the same conditions, they serve their purpose of showing comparative effects. Figs. 3 and 4 are samples of gum to show the similarity of cutting effect on a hard wood with the redwood of the other samples, which was used because it happened to be conveniently available when the work was ordered. Fig. 3 was made with a strong sidelight to show the curved character of the individual cuts, which is not noticeable with closer knife-mark spacing. All other photos were taken with the light coming from the vicinity of the camera.

It should be understood that some of the samples are not intended to illustrate results of normal practices. The conditions are deliberately exaggerated for the purpose of showing effects that are not ordinarily visible, but that nevertheless generally exist in some degree. For example, Figs. 3, 4, and 5 show one-knife finish, 7200 rpm, 190 fpm, with greater knife-mark spacing than would be desired for any practical purposes, but the uniformity of depth, spacing, straightness, and parallelism of clean cuts, with untorn surfaces, are a good means of demonstrating the effect of smooth spindle rotation, which accounts for perfect work with closer spacing of the same character of cuts, at slower rates of feeds.

One heel of four knives that produced the multiple-knife finish of Fig. 6 was deliberately emphasized to illustrate the effect of heel marks that always exist, though seldom so noticeably. In fact, that mark happens to show up more plainly

FIGS. 3 TO 11 (*See preceding page and this page*)

FIG. 3 GUM, ONE-KNIFE FINISH, 7200 RPM, 190 FPM, WITH HORIZONTAL ILLUMINATION. FIG. 4 SAME AS FIG. 3, GUM, 7200 RPM, 190 FPM, WITH NORMAL LIGHT. FIG. 5 REDWOOD, ONE-KNIFE FINISH, 7200 RPM, 190 FPM. FIG. 6 REDWOOD, FOUR KNIVES JOINTED WITH ONE EXTRA-HEAVY HEEL, 3600 RPM, 95 FPM. FIG. 7 SAME AS FIG. 6, BUT FED AT 190 FPM. FIG. 8 REDWOOD, FOUR PROPERLY JOINTED KNIVES, 3600 RPM, 190 FPM. FIG. 9 REDWOOD, FOUR PROPERLY JOINTED KNIVES, 3600 RPM, 140 FPM. FIG. 10 REDWOOD, SAME KNIVES AS FIGS. 8 AND 9, BUT AT 6000 RPM, 190 FPM. FIG. 11 REDWOOD, SAME AS FIG. 10, 6000 RPM, 190 FPM, QUARTER-SAWN

in the reproduction than was expected by the appearance of the original sample, and the work shown in Fig. 7 was immediately made under exactly the same conditions, but at twice the rate of feed, before realizing that the glazed heel mark would show up as plainly as it does in Fig. 6.

Fig. 8 shows work that was done at the same spindle speed and same rate of feed as Fig. 7 and with the same four knives, but with knives properly jointed. If the intermediate knife marks of Fig. 7 were as plain in the halftone as they were in the sample work, it would be seen that the knife spacing of Figs. 7 and 8 are equal, despite the great differences of the two effects.

Fig. 9 shows multiple-knife finish, 3600 rpm, like Fig. 8,

but at 140 fpm instead of 190. Work shown in Figs. 10 and 11 was also fed at 190 fpm and with the same jointed knives as shown in the two preceding figures, but with spindles turning at 6000 instead of at 3600 rpm. The contrast of Figs. 10 and 11, with no knife marks showing in the latter, is because the direction of grain in the quarter-sawn board of Fig. 11 favored the finished appearance of that work. The contrast is an excellent illustration of the many variables that enter into the difficulties of establishing definite means for measuring molder efficiency.

Other Considerations for Efficiency

After all, however, the final analysis of efficiency must include investigations that begin ahead of and end beyond the molder. It involves questions of how much work must be done before the stock goes to the molder and of how much sanding and how many other subsequent operations will have to be required, with consideration of losses due to inspection rejections. There is no intention of considering those phases of molder efficiency, and the following three examples are offered merely by way of illustrating the suggestion that molder efficiency involves even more than economy of power and quality and quantity of work.

Fig. 12 Seven-Sectioned Desk Seat

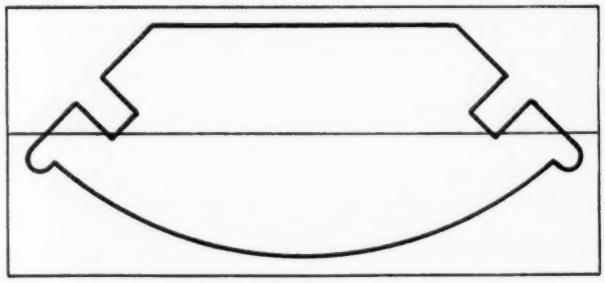

Fig. 13 Corner Cabinet Post

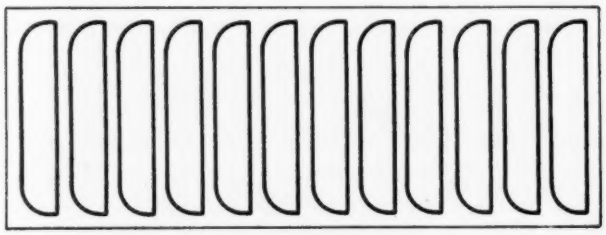

Fig. 14 Thirteen Roof Slats

Fig. 12 is a school desk seat in which the tongue, grooves, and slightly angular edges of seven pieces of stock are matched and glued to make the pattern. Before the days of electric molders, the seats required several operations for surfacing and thicknessing the top and bottom sides of each piece of stock, then glue jointing each edge separately, and running the glued-up seat pattern through a special machine having a formed cutter and formed feeding rolls before attempting the final sanding. With an electric molder it is possible to surface and thickness the top and bottom sides and glue-joint both edges of each piece so accurately in one operation that the pattern is ready for sanding as soon as it comes from the glue carrier. Of course, there is a substantial reduction of machining operations to account for considerable saving, but a far greater earning is effected by eliminating the finish-forming operation, because that accounted for much breakage, with resultant loss of labor, material, and salvaging expenses. The molder method also produces a more uniformly satisfactory product.

Fig. 13 shows a cabinet corner post. The two grooves must be of uniform width along their entire length, at 90 deg to each other, and the two surfaces into which they are cut must of course form a similar angle and must be perfectly straight along their entire length to provide for the mechanical requirements of construction. The large curved surface calls for a substantial removal of material requiring about an inch of knife projection to cut the two rather delicate border beads, which must be done without any splintering or tearing. The least blemish of the three curved surfaces would fail to pass inspection.

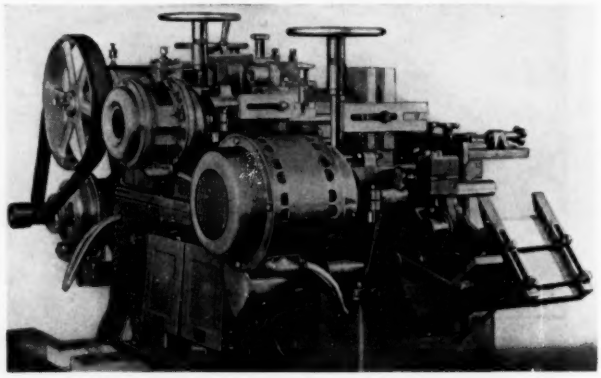

Fig. 15 30-Hp Motor, Developing Approximately 50 Hp at 6000 Rpm, on Bottom Spindle of a 6-In. Electric Molder

The pattern is made of built-up walnut. Thus loss on account of rejections would include the labor of gluing and of surfacing stock to prepare for gluing, besides the labor of molding and the cost of a comparatively high-priced lumber. Furthermore, the finish requirement dictates the best possible quality of work, because excessive sanding, to correct imperfect machining, would tend to change the contour of the two beads and thereby destroy the effect intended by the designer in the finished product. The example illustrates that good quality of molder work is also rewarded by less lumber waste and savings in preliminary and subsequent machining operations, as well as the better appearance of the finished product.

Fig. 14 shows a cross-section of stock, about 2 in. by 5 in., to be ripped into 12 automobile body roof slats of about $^{5}/_{16}$ in. by $1^{3}/_{4}$ in. Each has a quarter-round edge made with 12 cutters between 13 saws, on top and also on bottom spindles. It was known that the saw friction would require much power, and a 6-in. molder was originally equipped with oversize 20-hp top and bottom head motors, each developing approximately 33 hp at 6000 rpm when operated from a 100-cycle circuit, but even that was not sufficient to permit the desired rate of feed. The top-head load was relieved by throwing more of the slotting cut on the bottom spindle, and the latter was then equipped with a 30-hp motor which developed almost 50 hp at 6000 rpm. That provided the necessary power to feed 75 fpm, which was the maximum permitted by facilities for inspecting and handling the finished work. It illustrates one advantage of the greater power available with electric molders. Imagine belt sizes, belt speeds, and the pull and pound on the spindle to transmit 50 hp to one spindle and the resultant effect on the accuracy of making the 13 saw cuts with a belt drive! It is admittedly an extreme example, but exactly the same principles prevail, only in lesser degrees, with belt drives of smaller capacity.

Discussion

WARREN RICKETTS (Curtis Machine Corporation, Jamestown, N. Y.): In our experience, based on selling molders, there are just three fundamentals—feeding, guiding, and cutting. There is just one question that is put to me, especially when trying to sell an electric molder to a man who has a belt-driven molder. He will say that with our direct-motor-driven molder we have 10 hp on the top head, 10 hp on the bottom head, 5 hp on each of the side heads, and a 3 hp for feeding, and that nevertheless it is asserted that he will save power by having his machine with a total of 33 hp when he is driving his present machine with a 15-hp motor.

ANSWER (by the author:) This brings out an interesting part of the history of the electric molder. I did not stress, as I should have done, that perfect spindle rotation is the important thing of any molder. The big difference between an electric molder and a belt-driven molder is mainly a matter of better condition due to a better means of power transmission. In a belt drive, we have a belt pull on a pulley and on a spindle. It is driven at a very high rate of speed; there is a disturbing action there. In an electric molder, you have a self-centering, invisible magnetic force surrounding the motor and turning it with a self-centering action. There is a big advantage for truer spindle rotation. I cannot speak specifically on the power consumption of a ball-bearing, belt-driven molder and of an electric molder, because I have never made the test. The first suggestion of building an electric molder was with the idea of saving power. The first test required 40 to 60 per cent of the power required to do the work with the belt-driven molder. The electric molder will require about 50 per cent of the power required by a belt-driven babbitted-bearing molder. There was a test like this with a 6-in. electric molder equipped with a total of 33 hp, but when we turned on all four spindles and the feed motor, the power consumption was 3.2 hp. Now that 3.2 hp was consumed by electrical losses of the motor, by the action of the cutters against the air, and by the mechanical friction losses all the way through the machine. We ran it in competition with a 4-in. belt-driven molder which consumed 9.4 hp running idle. When we continued taking measurements of the power used to make an identical cut on the two machines, the electric molder required about 10 hp total to do certain work at 90 fpm, and the belt-driven smaller machine required over 17 hp. The question may come up why we put such large motors on the small molders. The answer is that one never knows how much power is going to be needed. One of the old troubles with belt-driven molders was that one did not have the power that he wanted. But as every electrical engineer knows, the motors only draw current in proportion to the cutting load.

R. L. TAYLOR (Jamestown Table Company): I have often wondered why they have not added a fifth or surfacing head. That is following our research. Why not add another head and therefore cut out an operation in the plant? Another thing, if there were a level or jump head on the molder, so that it could do fluting on a post that you do not care to carry all the way through, it might be a good thing. Is any work being done on that?

ANSWER: It depends of course upon the nature of the pattern, to begin with. If the problem were that of putting in a cut on the top of the post, it is comparatively simple. We have such a machine operating at Memphis, Tenn., but it is worked by gravity. There is an auxiliary head. As the end of the stock comes to a certain point it hits a little wheel, which turns the grooving saw into the cut. The point of entry into the cut is determined by a certain distance from this end. But this can become very much complicated and may develop need for a special machine. I believe the S. A. Woods Co. has a machine of that type. It is an auxiliary machine, not a part of a molder. The stock has to be turned to a 45-deg angle to do the work on that machine. As a universal machine, it is difficult to reply to the question. It might be too complicated. As long as you have a simple pattern to be duplicated, it would be a comparatively easy thing, but to build it to be used in many plants, I would say that it could not be done.

MR. TAYLOR: Would it not be possible to put a straightening device ahead of the molder to accomplish the same result as with the Oliver straitoplane?

ANSWER: Mr. Douse, of Grand Rapids, after becoming enthused over the Oliver straitoplane, asked why we could not do the same thing with a molder. We said we would try, and in 1927 we built such a machine for the Widdicomb Furniture Company, and as far as I know, it has worked out to expectations. For a year we made no more, so as to discover any deficiencies. In 1928 we built two more for use out on the Pacific coast. They are all giving satisfaction.

CHESTER L. BABCOCK (chairman): In the jointing of knives, what is the top speed at which you can joint effectively?

ANSWER: That is being done at 6000 and 7200 rpm. Whether it can be done at higher speeds, I do not know.

CHAIRMAN: Is that a test or would you recommend it in a furniture factory?

ANSWER: I am recommending it, but my general recommendation is to operate at one knife finish if you possibly can. I have recommended it to such an extent that I have been accused of being afraid that our molder would not hold up on joints.

CHAIRMAN: Would you do it on 1000 ft of linear molding?

ANSWER: We have not had much experience to encourage jointing, but on a pair of machines that were running a quantity of soft wood, one of our customers succeeded in feeding the molders at 250 ft with satisfactory results. They cut it down to 200 because that enabled them to handle the work better.

CHAIRMAN: Would you recommend a run of one knife or would you joint the knives in one head in a simple pattern?

ANSWER: I recommend one knife finish, even though it is a long run. That would slow down the rate of feed, but you will get a better quality of work. Some shops do good work with jointing where they have long runs to justify it. If you have a job of 50,000 ft, four-side surfacing, by all means joint, at whatever speed justified at the rate you can maintain.

CHAIRMAN: Would you not be safer at 3600 than at 7200?

ANSWER: The great trouble with jointing is the carelessness of the operator in not maintaining the joint equally true on all four knives on one head and all sixteen knives on four heads. The man that can joint at 3600 rpm and get good results can also joint at 6000, given the proper machine.

H. A. JOHNSON (Kling Factories, Mayville, N. Y.): We run our sticker at 6000 and get better work and more feeding speed than we did at 3600.

ANSWER: Speaking of four-knife work, one thing that has not been mentioned is that you would not think of running your shaper at 3600. What is the difference between a shaper and a molder? A molder has four spindles, but the principle of cutting is fundamentally the same. You want the same results with a molder as with a shaper.

CHAIRMAN: On account of the spindle speed, not much work has to be sanded.

MR. RICKETTS: I would like to ask about the sample of work done with four knives cutting at 190 fpm. Would it be possible to increase the speed of the feed if you increased the speed of the head?

ANSWER: There are certain other conditions that must be taken into consideration. That particular sample was run on

a 6 in. diam head, and 7200 rpm is about a maximum for that. If you tried to speed that cutter head up to 8400, you would have a knife speed that might be dangerous. We know that a 6-in. with good knives is safe at 7200. However, you could do that same work on a smaller machine, with smaller head diameters, and operate those heads at approximately 8400 rpm with exactly the same safety as in operating the larger head at 7200. Power consumption increases in direct proportion to the rate of speed. There is also a limit to the rate that you can feed due to the increase in strain that tends to splinter the stock.

Different Methods of Taking Lumber Out of Wind

By ARMEN S. KURKJIAN,[1] GRAND RAPIDS, MICH.

Boards are generally sawed out of the green log, and although as they come off the saw carriage they are quite straight, the saw has cut some fibers crosswise, others longitudinally, or across the grain in knot formations. The strains and stresses under which the cells adjacent to the saw were confined are now released, and the exposed surfaces of the board absorb moisture or lose it, this producing warp or wind in the lumber. In the drying of this lumber the fibrous cells often become rearranged, warping it out of shape. This condition is not objectionable for certain building applications such as baseboards and trim, where the stock is nailed in place, but when making furniture, musical cabinets, case goods, etc., it is important that the permanency of the joints be assured. For this reason machinery has been devised to overcome the warp or wind in boards to be used in these ways. The paper describes these mechanical processes.

FOR the purpose of this discussion the antiquated handtool methods of taking stock out of wind will be omitted, and the paper will be confined to the mechanical methods by the use of power-driven machinery. Because of the very nature of the substance and growth of trees it is impossible to find two logs exactly the same. This is true not only as between different species of trees, but as between trees of the same kind. The cellular construction or the fibrous mass forming the trunk of a tree consists of woody fibrous material, chemicals, and liquids commonly termed "moisture content." The distribution of these substances throughout a tree trunk is affected by many factors.

The influence of these factors changes the position of the wood fibers, causing strains and stresses in the cells that form the trunk of the tree. If one could in some manner reduce the moisture content in logs to 4 or 5 per cent before the log is sawed into boards, he might hope to have lumber less susceptible to being in wind or warp; but in general practice, boards are sawed out of the green log, and at the time of sawing as they drop off the saw carriage they are quite straight, although the saw has cut certain fibers crosswise, sliced other fibers longitudinally, or cut across the grain in knot formations to achieve straight-line sawing. The freshly cut cells and fibers of the two sides of the board are now exposed to the air, and the strains and stresses under which the cells adjacent to the saw cut were confined are now unequally liberated, causing a rearrangement of the internal stresses. This action, combined with the unequal loss or gain of moisture by the freshly cut cells, produces warp or wind in the lumber which cannot be physically prevented. Therefore there must be solved mechanically what cannot be solved physically.

Boards freshly sawn from the log are not usable until the moisture content is reduced to 3 to 7 per cent.

During both the natural air-drying and the kiln-drying methods of seasoning lumber of all kinds, as moisture leaves the lumber the fibrous cells often become rearranged in the board, so that the resultant dry board is warped out of shape and is said to be "in wind;" that is, when the board is laid on a perfectly flat table, only certain parts of it will touch the top of the table and other parts will extend away from it.

This warp or wind is not objectionable in certain applications. For example, in the home-building industry, in the case of baseboards, trim, etc., when the stock is finally finished and nailed in place, the nails draw it to an approximate straight position regardless of the warp or wind in the lumber; but in the manufacture of furniture, musical cabinets, case goods of all kinds, radio cabinets, etc., the straightness of the stock used is very important so as to assure the permanency of the joints; therefore lumber which is used in these industries must be taken out of wind.

The first concern should always be to minimize the warp or wind while the long boards are cut up into the necessary useful lengths for the article to be manufactured. Very often a long board which may have two or three twists endwise and a certain amount of warp crosswise can be so handled by the cutter that the resultant shorter pieces will be comparatively straight; they will at least have far less warp in them than the long board. The "wind" lengthwise is minimized by crosscutting certain lengths out of certain parts of the board. The warp crosswise and some of the warp endwise may be minimized by ripping the stock into narrower strips than the original width of the lumber.

In order to take stock out of wind it is very essential that in the planing process the lumber be passed over the cutters without any pressure to flatten out the board. Therefore the commonly known roll-feed, single- or double-surface planers cannot be used to take stock out of wind, because the pressure of the rolls flattens out the boards before a cut is taken.

The first mechanical method used for taking stock out of wind was to pass the warped board over the tables of a hand planer and jointer, the operator holding the board down by his hands only; the pressure of the hand on ordinary stock would not be sufficient to change its contour while it goes over the cutter head, and, depending upon the thickness of cut taken, either one, two, or three passes will eventually make one side of the lumber perfectly straight by removing the protruding portions

---

[1] Director and General Sales Manager, Oliver Machinery Company. Assoc-Mem. A.S.M.E. Armen S. Kurkjian was born of Armenian parents in Palu, Turkey, in Asia, on February 17, 1883. He was barely 14 years old when he fled from his native land in 1897 with his mother and three sisters to escape the Turkish massacres and came to America to join his father at Grand Rapids, Mich. He quickly mastered the language, and went to high school, and then worked his way through the University of Michigan, graduating in June, 1908, with the degree of B.S. in Engineering. In November, 1908, he entered the employ of the Oliver Machinery Company, and after filling positions in the shop, in the office, and in the field, both as salesman and branch office manager, he attained his present position. He is a member of the Executive Committee of the Wood Industries Division, A.S.M.E.

Presented at the meeting of the Wood Industries Division of THE AMERICAN SOCIETY OF MECHANICAL ENGINEERS, Jamestown, N. Y., November 15 and 16, 1932.

NOTE: Statements and opinions advanced in papers are to be understood as individual expressions of their authors, and not those of the Society.

only. The objection to this first or hand-planer method of taking stock out of wind is that the board, being held only by the hands of the operator on a table, the length of which is normally less than the length of the board being jointed, will naturally have the first end held down against the table while the tail end, being unsupported, may be warped downward or upward, and in its turn going over the cutter head will change the position of the stock while it is being planed. And so, ordinarily speaking, the full amount of the warp would have to be taken out of one end or the other of the stock before one side is perfectly straight. Another natural objection, of course, is the slowness of the operation and the fact that any hand operation of this kind is neither efficient nor safe.

The second mechanical method introduced was that of having a set of sectional spring-loaded rollers superimposed in a frame directly above the rear table immediately following the cutter head in a hand planer and jointer. In this method the operator,

FIG. 1 LONGITUDINAL DIAGRAM OF BOARD WITH EXAGGERATED WARP OR WIND

(Showing how the longitudinal wind is minimized or eliminated by cross-cutting the long board into shorter pieces, taking the cross-cuts at the points of maximum bend.)

FIG. 2 CROSS-SECTIONAL DIAGRAM OF WIDE BOARD WITH EXAGGERATED CROSS-WARP OR WIND

(Showing how the cross-warp is minimized or eliminated by ripping the board into narrower pieces before any attempt is made to face-joint or plane.)

FIG. 3 EXAGGERATED SKETCH OF DRESSING LONG BOARD

(Showing how the facer dresses comparatively straight stock down to a flat by an assumed single pass.)

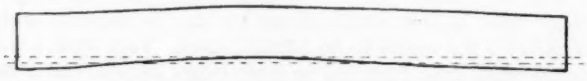

FIG. 4 TWO PASSES REQUIRED FOR BAD WARP IN BOARD

(With the machine set for average run of stock, two passes were required in this case. Had the depth of cut been set sufficient to clean up this and many pieces similar to it, the larger proportion of straight stock would have similarly suffered an unequally heavy cut.)

with his hands, advances the stock across the cutter head until the front end passes under the power-driven sectional rolls, which then in turn drag the stock forward and complete the passage across the cutter head. This method speeded up the process, but required that the front end of the stock be always held down; and furthermore the pressure of the sectional rolls necessary to feed the stock through was usually sufficient to flatten out the stock, making it impossible to secure an accurate face joint. But in many industries where the products were cheap and labor saving was the chief problem, this method was used effectively.

The third mechanical method of taking stock out of wind employed a "swing-out" feeding arrangement consisting of a series of sectional rolls mounted in a frame supported at one end by a vertical cylindrical bearing. The whole unit was arranged so that it could be swung around to a position immediately above the feed-in table, when power feed was required for the jointer; but when power feed was not required, this could be swung out of the way and the machine used as a regular hand jointer. This method was an improvement over the second method, because it tended to normalize the position of the board over the "feed-in" table before any cut was taken; however, the whole affair was not very satisfactory, because it lacked rigidity and definiteness and the pressure exerted downward was a considerable amount, and there was not a sufficient length in the feeding mechanism to hold the stock in an approximate mid-position while it was being fed forward.

The fourth mechanical method of taking stock out of wind consisted of superimposing on the normal hand planer and jointer an endless-chain feeding mechanism of a length almost equal to the total length of the tables of the hand planer and jointer, about one-half of this feeding arrangement being located directly over the front table and the remainder over the rear table of the jointer. In this case the multiplicity of the feeding fingers or cams, with slight pressure in each, simulated the hand method of shoving the board forward. Very little vertical pressure is applied, and since there are many fingers and the feeding mechanism is of sufficient length, the whole board is kept in practically the same contour and the same plane while being fed forward. In the first part of the machine the board is entirely rough, and in the latter part the already cut part of the board glides smoothly over the rear table of the jointer. The success of this method rests particularly in applying very little vertical pressure and having the dogs or feeding fingers come down on the upper face of the lumber just enough so as to have the forward-feeding effect without any flattening effect on the lumber. The first feeding device of this kind employed spring-loaded, vertical, chisel-point feed "fingers." The chief duty of the fingers, which contacted the upper face of the board, was to maintain the stock in a constant plane relative to the machine table. The power for moving the board forward across the cutter head was furnished by the row of fingers which would contact the rear end of the board. This method of using the facing planer has been very widely known and is one of the most successful mechanical means of taking stock out of wind. This method went far to overcome the objections to the former mechanical methods, but there remained one important point which had not been changed—namely, the necessity of running the stock, after it had gone through the facing planer, through a single-surface planer so as to cut down the top of the board, removing the superfluous stock and making the top straight and parallel with the first or bottom side, which had previously been face-jointed on a facing planer or jointer. Aside from the extra time and extra space required there is another important objection in the practical working out of running the stock through a facing jointer and then through a single surfacer to finish its rough planing, and that is the fact that usually in various factories stock is run through the facing planer and piled on a truck, and these truckloads stand around for a while before they are run through the roll-type planer; and since one side of the stock has gone through the facing planer and this has opened up the pores of the lumber afresh while the other side remains rough, the boards actually change their shape or again assume wind while they are waiting to go through the planer. This is due to the fact that the freshly opened pores will absorb moisture more quickly and to a greater degree than the rough side of the lumber.

Up to this point in the development of the art of mechanically taking lumber out of wind it was always necessary to first work on one side of the lumber and get that to be as nearly in a plane as possible, and then as a second operation the other side of the board was planed in a roll-feed surface planer of some kind to reduce the board to uniform thickness to make

the second side parallel to the first. These two separate operations were carried on for many years until about eight years ago, when a further advance in the art was made. This combined these formerly two separate operations into one tandem operation. Two machines were combined in one to effect sequential planing wherein the operations of face jointing and sizing down to uniform thickness are performed on the board in one pass through the machine, in one operation, at one handling, as follows:

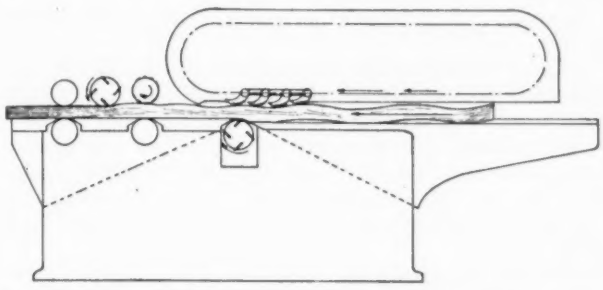

FIG. 5 PROGRESS OF BOARD IN WIND OR WARP THROUGH STRAITOPLANE

(This machine is described as the fifth or most modern method of correcting crooked lumber. The action of the cam dogs does not flatten out the warp. They feed the board in its natural contour across the bottom cutter head for face-jointing, which is immediately followed by the planing-to-thickness action of the top cutter head, so that the board leaves the machine as a flat slab, straight and sized to the uniform thickness desired.)

The fifth and most important method of taking the wind out of stock mechanically is by the use of a straitoplane, which may be described as a combination of a facing planer and a single-surface planer. In the first part of this machine the stock is fed with the least vertical pressure, but with a powerful forward pressure, by means of an endless chain having a multiple number of cam dogs. The stock moves forward over the long front table, and then, after the bottom of the board passes over the bottom cutter and is face jointed, the multiple cam dogs cause the stock to hug the rear table until in turn it glides under the sectional roll and is fed under the sectional chip breaker, the top cutter head, and the back pressure bar, and through the two outfeed rolls (similar to the arrangement in a single-surface planer). This finishes the work of planing the top side of the lumber, bringing it down to uniform thickness and having the top parallel to the bottom, which has been face-planed straight in the front part of the machine. In this method the face-jointing work and the single-surfacer work are done almost simultaneously on the stock, and therefore there is no time element left during which the stock may warp by having one side pick up moisture more than the other side. The result is that the boards which come out of the straitoplane are straight, having both sides planed perfectly parallel and to uniform thickness. They are easily piled on the trucks flat and remain flat. The straitoplane method of taking lumber out of wind is still very new, being only about eight years old, and therefore is the least known of any of the methods; hence, sometimes, people who have not seen the machine in operation advance an assumed objection to it by saying that since the stock passes through the machine once and the machine is set for the average boards, there might be waste in having the stock go through the machine and not having the bottom entirely cleaned while the top is planed off to the thickness that the machine is set. The fact is that in the straitoplane the front table is 6 ft long and the feeding mechanism over it is of such length that the boards up to 6 or 7 ft long are held in mid-position or in balanced contour over the front table before any cutting is done, and therefore only about one-half as much of a cut is necessary to take any certain amount of wind out of the board. Take for example, a double-twist warped board about 6 ft long and 10 in. wide, which has about $^1/_4$-in. wind in it; that is, when one end of the board is held down against a flat table, the other end of the board sticks up $^1/_4$ in. above the table. When this board is fed into the straitoplane, the cam dogs balance the same in an equipoised fashion over the 6-ft-long table so that diagonally opposite corners project only $^1/_8$ in. above the table and the board is pushed across the bottom cutter head without changing either the contour of the board or the plane of feeding. Therefore although the board has $^1/_4$-in. wind, a cut of only $^1/_8$ in. deep will face-joint the stock perfectly. In common practice it is not necessary that all of the rough spots be removed from both sides of the board in this first-cut stage, and therefore an extra thickness may be left in the board for the finishing cut, which is taken off either in a double-surface planer or single-surface planer. In actual practice in over 30 different woodworking industries the claim is that the straitoplane actually saves thickness rather than destroys it. In other words, out of the same grade and type of kiln-dried stock, the boards when finished can be kept thicker than the former method of face-planing in one machine until one side is all cleaned up and then surface-planing in another machine.

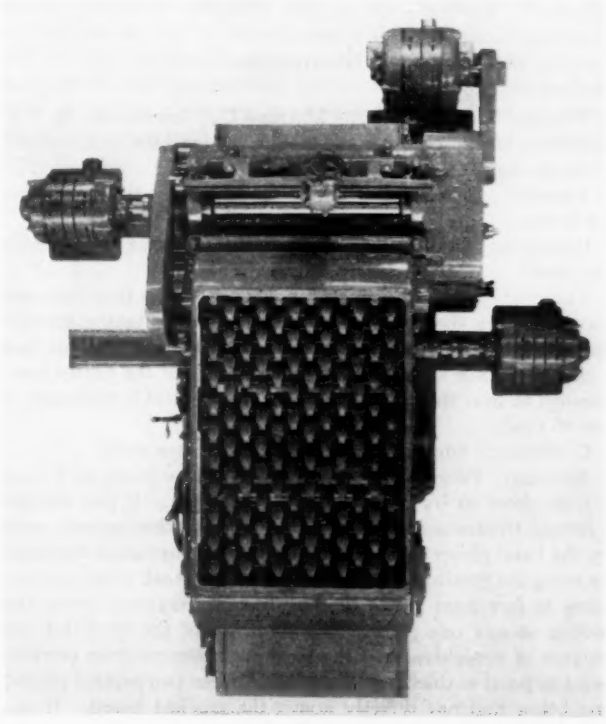

FIG. 6 MULTIPLE-CONTACT FEED MECHANISM OF STRAITOPLANE

(Knife-sharpening unit is shown over upper cylinder ready to sharpen the knives.)

In conclusion, the most modern or straitoplane method of taking wind out of stock has the following distinctive features in the operation of the machine:

1 The front table is 6 ft long, making it possible for stock up to 6 ft long to lie completely over the table before any cut is taken, and hence the feeding plane of the stock is not changed while going through the machine.

2 The endless chain is extra long, extending almost completely over the front table and at least one-third of the rear table. This makes it possible to equalize the position of the

stock with respect to the tables and to maintain that equipoised mid-position while being fed across the cutter head.

3 The cam-shaped multiple-feed dogs are pivoted from a fulcrum point well in the rear so as to minimize the vertical component and to augment the horizontal component of the forward feeding force, and hence the contour of the stock is not changed while going through the machine, and the result is more perfect face-jointing.

4 Immediately after the bottom of the board is face-jointed, it glides over the rear table and enters into the rear or single-surfacer part of the machine, where the top of the stock is planed down parallel to the bottom and the stock leaves the machine in the shape of straight, flat slabs planed on both sides to the uniform thickness desired.

5 The face-jointing operation on one side and the sizing or thickness-planing operation on the other side of the stock are performed almost simultaneously, in one pass through the machine. Thus, the freshly cut pores or cells on both sides of the stock are exposed to the air simultaneously, and since the action of the moisture in the air is the same on both sides, after the stock leaves the machine, there is greater surety of the stock remaining permanently straight.

Discussion

WARREN RICKETTS (Curtis Machine Co., Jamestown, N. Y.): In cutting stock, when it goes through the machine, is it brought down to size?

ANSWER: It is brought down to the size that the machine is set to cut.

QUESTION: If there is any wind left in it, what is done with the piece?

ANSWER: If the stock is still in wind, it means that there are rough spots in the board on both sides, and by taking another cut all wind can be taken out. Usually if the machine has had a chance to take a cut all over on both sides, if the knives have touched all over the face of the stock, the whole of it is straight—out of wind.

QUESTION: Supposing you have four-quarter stock?

ANSWER: Four-quarter stock may mean as much as $1^1/_4$ or $1^1/_8$ in. down to $^7/_8$ in. thickness in the rough. If you can get a certain thickness out of any board by any other process, even by the hand planer and jointer, you can get that same thickness by using the Straitoplane. The thickness of stock which you are going to face joint is not the physical measurement across the section at any one place. The thickness of the stock for the purpose of straightening is the total measurement from extreme point to point of thickness measured between two parallel planes, one below and one directly above the crooked board. If the machine is set for $^{15}/_{16}$ in., and the stock comes out with a little warp, the knives not having touched all over, no fault can be found. This is not a lumber-putting-on machine; it is a lumber-taking-off machine. The fact that there are rough spots on both sides shows that the machine is a lumber saver. If the board is put through the Straitoplane and does not clean up on both sides, it most likely does not come out straight. In that case it is run through again. We always get the proper thickness consistent with the stock.

QUESTION: Supposing you go through that process, and then put the board in the single planer, and it comes out not straight at the top, what do you do with it?

ANSWER: If you take enough of a cut on both sides, you will get your first thickness on this machine on any board.

CHESTER L. BABCOCK (President, Babcock Machinery Co., New York, N. Y.): Supposing a board is $^5/_{16}$ in. in wind, and you have the machine set for a definite thickness, what are you going to do with this piece—will it be spoiled?

ANSWER: If this board has a perfectly straight bottom, and the top of it varies as much as $^5/_{16}$ in. in thickness, the top cutter will make it straight, and you will get a perfectly straight piece out of it.

QUESTION: What if it is $^5/_{16}$ in. and the machine is set for only $^1/_8$ in.?

ANSWER: If this board has an exaggerated wind of $^5/_{16}$ in., then with one-half the cut, this machine will take twice the warp or wind out of it. If it is set for $^1/_8$-in. cut, then when the $^1/_8$ in. protruding part from each face is removed, it is equal to taking off $^1/_4$ in. by other methods, where the first part is pressed down first, and then gradually the hind part comes along.

QUESTION: But if it is a "dog" board—an unusually thick piece?

ANSWER: If I understand you correctly, you refer to a board in a truckload of 4/4 stock which is perhaps $1^1/_2$ in. thick at one end and $1^1/_4$ in. at the other end. If the operator knows his work, he does not put that board through the machine during the run of the truckload, but puts it on top of the machine. When he gets through with the load, he shifts the lever that moves the top of the machine, say, $^1/_8$ in., and he lowers the front table so as to take a heavier cut, and then he puts this special board through, and it comes out planed down properly. In a Straitoplane when one desires to reduce boards of great variations in thickness down to a common given thickness, the operator merely moves the front table up or down, but does not change anything else. The cut will be divided between the bottom and the top cutters as the set-up of the front table occasions.

QUESTION: What thickness do you usually set the bottom for? You must have some definite amount.

ANSWER: If I have 4/4 stock and I am taking a light cut on both sides, and I want to have a $^{15}/_{16}$ in. thickness left in those boards, then I will set the bottom knife cutter for a $^1/_{16}$-in. cut.

QUESTION: When you set the bottom head for the thickness you want to take, what do you do?

ANSWER: First you look at your order, and then at the truckload of lumber. The chances are that the operator will set the machine so that the bottom cutter will cut just a little under $^1/_8$ in. These boards all have some wind, and even though you set it for a $^1/_8$-in. cut at the bottom, it will not take off $^1/_8$ in. because of the wind in the stock. If it is all straight stock, you will set it at $^1/_{16}$ in. Any operator by just looking at the pile can tell how to do this.

QUESTION: If the stock is good and straight, can you set it for $^{30}/_{32}$ in. and will you get it straight?

ANSWER: If you do not have thickness enough in the board to clean up by any other process, it will not clean up by this machine. Say you have a truckload of 4/4 lumber. Assume that it has gone through the drying kiln and is supposed to clean up to $^7/_8$ in. Now in this truckload there may be some pieces that are nearly straight. With the Straitoplane set for the average board, you will take a thicker cut on the bottom of the straight boards than on the bottom of the crooked boards; and naturally you do not take as much of a cut at the top of the straight boards as at the top of the boards that are in wind because the latter have greater protruding portions; but in both cases you will get the thickness you want. In the Straitoplane, if the piece is straight, it is not going to be spoiled, because you will surely have enough material to get the thickness that you want.

QUESTION: Would you lose your thickness?

ANSWER: If you have lost the thickness, then it means that you could not have gotten it by any other process. The Straitoplane removes stock equal to only half the wind.

ARTHUR D. SMITH, JR. (President, Geo. W. Smith Woodwork-

ing Co., Philadelphia, Pa.): If I have a power feed jointer and place that in tandem with the single planer, what results will I get with the Straitoplane that I would not get with the two machines?

ANSWER: In jointers with feeding attachments you do not take as heavy a cut. Some of those boards would not have had sufficient cut at the bottom.

QUESTION: Why cannot one take a heavier cut?

ANSWER: Usually jointers with feeding attachment are built and recommended for taking a series of light cuts rather than one cut of sufficient thickness to remove the wind.

QUESTION: How does the price of the Straitoplane compare with a jointer with feeding attachment?

ANSWER: This machine face joints and sizes stock up to 36 in. wide. If you were to take the price of a 36-in. jointer with feeding attachment and add to that the price of a 36-in. planer, the price of those two would exceed the price of the Straitoplane.

QUESTION: But I have one planer.

ANSWER: Then of course your immediate outlay of money (since you already have a planer) would be about 40 per cent more for a Straitoplane than for a jointer with feeding attachment.

QUESTION: Would I get the same results by using a jointer with feeding attachment and a single planer in tandem as by using the Straitoplane?

ANSWER: You will get the same results, but if you have a lot of narrow stock, in the case of the Straitoplane two men feeding at one end and two men receiving at the other end and trying to pile, cannot keep up with it. In the case of the jointer and the planer in tandem, your boards will get mixed up and go in sideways instead of straight, and furthermore to do the same amount of work you would need extra men, which would be an extra expense.

QUESTION: Would we get the same jointing, with the same loss of thickness? Is there anything to be gained from the standpoint of thickness in stock from the one machine that you would not have in two?

ANSWER: I do not see what difference there would be. You should get out of one as much as out of the other.

AUTHOR'S CLOSURE

The questions by Mr. Ricketts and Mr. Babcock are based on the theory that if the Straitoplane is set for the final finished thickness of the stock and all of the excess material is cut away from the top and bottom of the board in its first pass through the Straitoplane without cleaning up both sides, the board cannot be used for its original purpose. This would be a fact if all of the conditions assumed are obtained; but in practice these conditions are not encountered. The Straitoplane is used chiefly for the first or rough planing operation. In practice it is never set to plane stock down to the ultimate cut once through the machine. Considering stock ordinarily used in any woodwork, where the straightness as well as smoothness is desired, the Straitoplane will face joint and size the stock to a uniform thickness in one pass through the machine, and it is left for the finishing or second cut either in the Straitoplane or in a finishing planer to remove all the rough spots from both sides of the stock and finish it to the ultimate thickness desired.

WDI-55-7

Moisture Content, Specific Gravity, and Air Space in Wood

By J. D. MACLEAN,[1] MADISON, WIS.

An exposition of the physics of wood is given in the paper. It describes the cell structure of wood and the physical changes that take place as it is dried to oven-dry condition or impregnated to maximum absorption. Formulas and graphs give the relation that exists between percentage of moisture content, specific gravity, water content, total weight, and percentage of air space. The data are of interest to those engaged in wood research or wood physics or in kiln drying, wood preserving, or fireproofing.

THE material wood contains wood substance, moisture, and air or gas. The wood substance includes both the cellular structure and extractives of the wood and usually has a variable quantity of water absorbed in the cell walls. When wood is green or wet, the water also occupies a part or all of the cell cavities. In addition there is usually more or less air in the wood cells depending on the density of the wood and the moisture content. In the present discussion the volume occupied by air or gas will be designated as air space.

The purpose of this article is to present graphic methods and simple formulas worked out at the Forest Products Laboratory from which the relations among moisture content, specific gravity, and air space in wood may be better understood and applied by the wood user to the many practical problems arising daily in the routine treating and seasoning of wood. For example, the amount of preservative that can be forced into the wood will be limited by the amount of air space, and when the moisture content and specific gravity are known, the approximate amount of air space can be computed. When this air space is known, it becomes possible to compute within reasonable limits about how much preservative can be absorbed as a maximum.

Moisture Content

The amount of moisture in wood, which is designated as moisture content, is commonly expressed as a percentage of the weight of the oven-dry wood. For example, if W is the weight of a sample before oven drying and D is the weight after oven drying, then the moisture percentage M is $(W - D)/D \times 100$. In order to obtain the weight of the wood when in an oven-dry condition, a small sample of the wood is heated at approximately 100 C (212 F) until the weight becomes constant. If the wood contains volatile substances that distill at the drying temperature, the term moisture by definition will also include these distilled volatile substances in addition to the water. In the following discussion, therefore, the terms "water in the wood" and "moisture content" include these volatile materials as well as the water.

When the weight of the oven-dry wood is used as a base, the moisture percentage shows the number of parts of water by weight to the number of parts of oven-dry wood by weight. For example, if a piece of wood has a moisture percentage M of 75, there are by weight 75 parts of water to 100 parts of oven-dry wood, or the water weighs three-fourths as much as the oven-dry wood. Again, if a timber has a moisture content of 100 per cent, the weight of the water is equal to the weight of the oven-dry wood. If the moisture content is 125 per cent, the water weighs one and one-fourth times as much as the oven-dry wood, or in other words the moisture is five-ninths and the oven-dry wood is four-ninths the total weight.

Since seasoning takes place most rapidly longitudinally, samples taken from near the ends of timbers that have been seasoning may show a moisture content considerably lower than samples taken at a point where end-drying would not affect the results. Furthermore, samples containing more or less sapwood may have a moisture content widely different from that of the heartwood. Samples should be weighed immediately after they are cut from the timber and as soon as they are taken fron the drying oven.

Plants impregnating wood with preservatives treat both round and sawed timbers, and it is therefore desirable to know the moisture content of the sapwood separate from that of the heartwood. Table 1 has been prepared with that in view. The moisture content values given in Table 1 were obtained at the Forest Products Laboratory and are average values determined as soon as possible after the trees were cut. These values probably show very closely the average moisture content of the living trees from which the samples were obtained. Individual timbers of any particular species, or timbers obtained from a given locality, however, may have a moisture content varying considerably from the average value given in Table 1. Variability in moisture content will also be found in wood from different parts of the sapwood and of the heartwood of the same tree.

Table 1 shows in general that the differences in the moisture content of the sapwood and heartwood are much greater in the softwoods, or conifers, than in the hardwoods, mainly because the heartwood is usually drier in the conifers than in the hardwoods.

Shrinkage and Fiber-Saturation Point

Water contained in the cell cavities of wood is commonly called free water, whereas that in the fiber walls is known as imbibed or hygroscopic moisture. The cell walls remain saturated until the free water has been removed. Any reduction of moisture in the cell walls causes the wood to shrink, and the amount of shrinkage will depend upon how much of the hygroscopic moisture is removed by seasoning.

The fiber-saturation point is defined as the moisture content of the wood when the cell walls are still saturated but no free water is present in the cavities. This moisture value varies for different

[a] Commercial, average of six species.

species and is also influenced by temperature, but for practical purposes it may be assumed as about 25 per cent.

The shrinkage[2] of wood occurs largely in the radial and tangential directions—that is, at right angles to the growth rings and parallel to them, respectively—and is generally negligible in the longitudinal direction. Tangential shrinkage is greater than radial. The difference in shrinkage in the two directions varies for different species and even in different boards or timbers of the same species. An average ratio of tangential to radial shrinkage for the various species is about 1.8 to 1. The shrinkage in the volume of wood going from the green to the oven-dry condition is usually about 12 to 18 per cent for the hardwoods and 8 to 14 per cent for the softwoods. If seasoned wood is soaked in water until all the fibers are wet, it will swell until the fiber-saturation point is reached, or in other words, it will regain the dimensions it had when green.

During the process of seasoning there is a moisture gradient from the surface to the interior part of the timber. The interior of a timber may have a moisture content well above the fiber-saturation point while the outer portion is below. The distribution of moisture will depend on variables, such as species, size of timber, seasoning conditions, original moisture content, and whether sapwood or heartwood. On account of these variable factors the moisture content at different distances from the surface may vary considerably from the average value for the whole cross-section, and most timbers, particularly the larger sizes, will not shrink uniformly from the fiber-saturation point. In many cases, however, the average moisture content is of particular interest and is the moisture value most easily found.

Specific Gravity

Specific gravity is the ratio between the density of the material and the density of pure water at 4 C (39.1 F). In the C.G.S. system the numerical values for density and specific gravity are the same. For the English system the density of water is 62.4 lb per cu ft, while its specific gravity is still unity.

[2] Data on the volumetric shrinkage from green to oven-dry condition, average weights per cubic foot when green and air dry, and specific gravities based on the weight of the oven dry wood and volume when green, may be found for various species in U. S. Department of Agriculture Tech. Bull. 174, "The Air Seasoning of Wood."

Since wood normally contains a variable quantity of water, the specific gravity of wood is commonly based on the weight of the water-free wood and the volume at the moisture content under consideration. In other words, the specific gravity is the ratio of the weight when oven-dry of a given volume of wood at the current moisture content to the weight of an equal volume of water at its maximum density.

When the volume of the wood is in cubic centimeters and the weight is in grams, the specific gravity S is equal to the weight of the oven-dry wood per cubic centimeter. If the volume is measured in cubic inches and the weight is in pounds, S is the weight of the oven-dry wood per cubic inch divided by the approximate weight of a cubic inch of water at maximum density, which is 0.0361 lb. Weights of wood are commonly expressed in the United States in pounds per cubic foot, and the specific gravity based on this unit is therefore the weight of the oven-dry wood in pounds per cubic foot divided by 62.4. The value of S will of course be the same whichever system of units is used, since it is the ratio of the weights of unit volumes of wood and water.

Wood is at its maximum volume for any moisture content at or above that corresponding to the fiber-saturation point. The specific gravity based on the weight of the oven-dry wood and volume when green, therefore, will apply for all moisture-content values above the fiber-saturation point regardless of the amount of water present. As wood seasons, however, the weight of the oven-dry wood per unit volume will increase in proportion to the moisture lost below the fiber-saturation point owing to shrinkage and the accompanying increase in the amount of wood substance per unit volume. For this reason the specific gravity of wood will increase as the moisture content decreases below the fiber-saturation point, and the difference in specific gravity for any two moisture values will depend upon the degree of shrinkage. Obviously, then, the term specific gravity when applied to wood has little significance unless the moisture conditions at which the volume was measured are stated.

Since volume changes occur between zero moisture content and the fiber-saturation point, the specific gravity of any timber will vary between that based on the weight of the oven-dry wood and the volume when oven-dry and that based on the weight of the oven-dry wood and the volume when green. Average figures

for these maximum and minimum values are given in Table 1 for the species listed.

Since the specific gravity is computed from the weight of the oven-dry wood, based on unit volume at the current moisture content, the weight of the water in the wood has no bearing whatever on the specific gravity as herein defined. The only effect the water has is its influence on the shrinkage or swelling which occurs between the condition when the wood is oven-dry and that when the fiber-saturation point is reached.

In addition to changes in specific gravity caused by shrinkage or normal moisture changes below the fiber-saturation point there is a condition which sometimes develops during seasoning known as collapse. In this case the cell walls become collapsed to a greater or less extent, thereby causing a reduction in the amount of air space in the lumena or cell cavities. This condition would tend to increase the specific gravity, since there would be a greater amount of wood substance per unit volume.

It must be clearly understood that the specific gravity of wood may vary to a greater or less extent for different timbers of the same species. This is mainly because of differences in growth conditions, but may be due also to variations in the amount of shrinkage if the timbers are partially seasoned. Even samples taken from different parts of the same timber may show more or less variation in specific gravity values. It is therefore evident that specific gravity values, like those of moisture content, are only approximate even when the determinations are made from wood samples taken from the timber under consideration.

Specific Gravity of Wood Substance. In addition to the specific gravity of wood based on the weight of the oven-dry wood and volume at the moisture content under consideration it is of interest in making certain computations to know the specific gravity of the wood substance itself—that is, the specific gravity of the oven-dry wood without any air space or water in it. A given volume of oven-dry wood normally contains a large proportion of air space in the cell cavities and cell walls, and the volume occupied by the wood substance itself is considerably less than the total volume. The specific gravity of wood substance has been found to be fairly constant for all species, and various methods of measurement indicate that it is commonly between 1.50 and 1.58. This indicates that if oven-dry wood could be compressed so that no air space were present, a given volume of the wood substance would weigh something over one and a half times as much as an equal volume of water. An average value of 1.55 for the specific gravity of wood substance is used for computations given in this paper.

The specific gravity of wood substance should not be confused with the specific gravity of wood as commonly known and which is designated as S in the present discussion. In the specific gravity of wood, the wood is assumed to have its normal cellular structure, and as a result a given volume of the oven-dry wood contains both air space and wood substance. The specific gravity S will therefore always be less than the specific gravity of wood substance alone.

Relation of Specific Gravity and Moisture Content. Although it is not always true that the change in specific gravity S with change in the volume of the wood going from a green to an oven-dry condition is directly proportional to the moisture loss below the fiber-saturation point, it is sufficiently close to assume that this proportional relation exists. If then it is desired to find the specific gravity at some moisture content K below the fiber-saturation point, the specific gravity S_k at the moisture content K can be computed, as indicated by formula [10] given in the Appendix. For example, from Table 1 the average specific gravity S_g (based on the weight of the oven-dry wood and volume when green) is shown for loblolly pine to be 0.50, and S_d (the specific gravity based on weight of the oven-dry wood and volume when oven-dry) is 0.57. The computed specific gravity at 10 per cent moisture content would be, $S_{10} = \left[0.57 - (0.57 - 0.50)\frac{10}{25}\right] = 0.542$, or approximately 0.54. The percentage shrinkage in volume to this moisture content would be (formula [9], Appendix) $100\left[\frac{0.54 - 0.50}{0.54}\right]$, or approximately 7.4 per cent.

Fig. 1 has been prepared so that approximate values of S_k can be determined directly for the various species given in Table 1 and is based on the values of S_g and S_d given in the table.

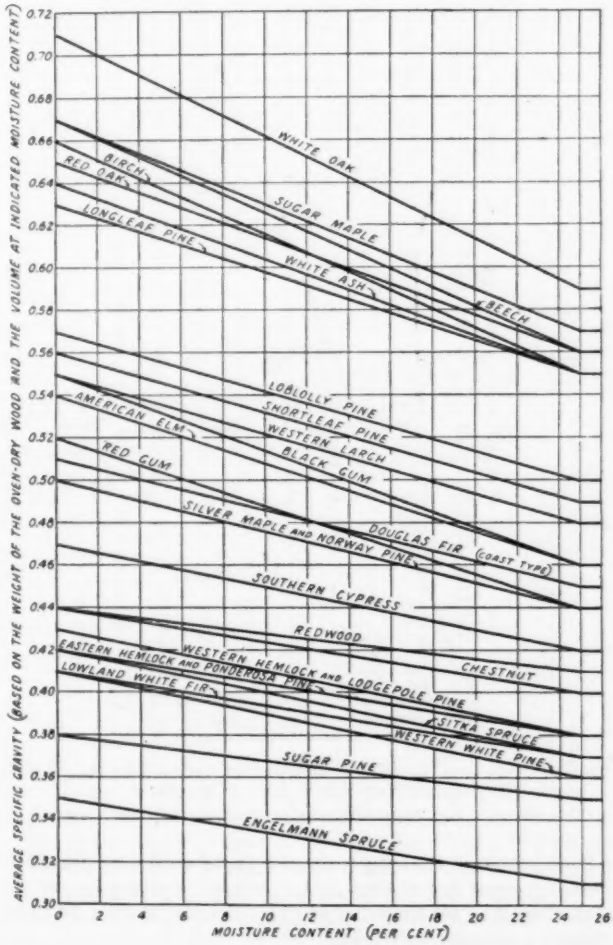

FIG. 1 RELATION OF AVERAGE SPECIFIC GRAVITY AND MOISTURE CONTENT

Specific Gravity Measurements. The specific gravity for any particular timber may be determined within reasonable limits from samples cut from the piece. Where this is not practicable, a hole about 1 in. in diameter and 2 in. deep can be bored to obtain the sample. The volume of wood removed can be computed from the diameter and depth of the hole, and the boring chips can be oven-dried in a paper bag. Samples cut from the timber should not be much over 1 in. in length (in the direction of the grain), as longer pieces require a considerable time for seasoning to the oven-dry condition. The samples should be taken far enough from the ends to avoid the influence of end-seasoning. Samples or borings must be weighed immediately after they are obtained and immediately after oven-drying to avoid unobserved moisture

changes. The moisture content and specific gravity may be determined in the same operation. For example, assume the original weight of a sample with dimensions 3 by 8 by 1 in. is 0.53 lb and the weight when oven-dry is 0.49 lb, the moisture content is then 0.53 minus 0.49 divided by 0.49, or approximately

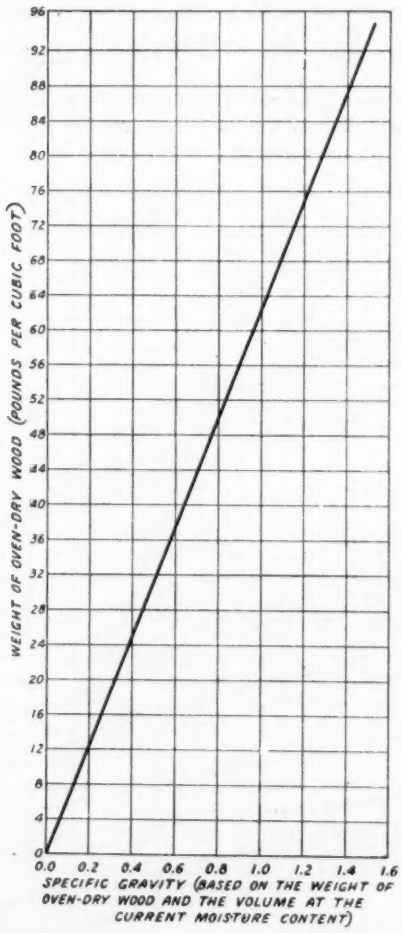

FIG. 2 RELATION BETWEEN WEIGHT OF OVEN-DRY WOOD PER CUBIC FOOT AND SPECIFIC GRAVITY
(The volume in each case being taken at the current moisture content.)

8.2 per cent, and the specific gravity, based on the weight of the oven-dry wood and volume at 8.2 per cent moisture content, is 0.49 divided by the weight of 24 cu in. of water (0.49 ÷ 24 times 0.0361), or approximately 0.57.

If the volume of the specimen is measured after oven-drying, the specific gravity based on the weight when oven-dry and volume when oven-dry can also be determined. For example, if the volume of the specimen, which was 24 cu in. at 8.2 per cent moisture content, is found to be 23 cu in. after oven-drying, the specific gravity based on this volume will be 0.49 divided by 23 multiplied by 0.0361, or approximately 0.59. By substituting 0.57 for S_k, 8.2 for K, and 0.59 for S_d in formula [10] of the Appendix, the specific gravity S_g, based on the weight of the oven-dry wood and the volume when green, is computed as about 0.53.

Relations Between Specific Gravity, Weight of Oven-Dry Wood, and Weight of Water in Wood. Figs. 2 and 3 have been prepared so that the weight of oven-dry wood per cubic foot and the pounds of water per cubic foot can be readily determined for wood having a known percentage of moisture and a given specific gravity. Since both moisture content and specific gravity are only average values, the indicated weights would of course be only approximate.

The maximum weight of water the wet wood can hold per cubic foot and the maximum percentage of moisture possible are found from Fig. 3 by reading the weight and moisture content corresponding to the point where a vertical line from the given specific gravity intersects the maximum moisture line which slopes downward to the right.

To illustrate the use of Figs. 2 and 3 by a concrete example, assume the species under consideration is loblolly pine, for which Table 1 shows an average specific gravity of 0.50 based on the weight of the oven-dry wood and the volume when green. For this specific gravity Fig. 2, or formula [2a] of the Appendix, shows the weight of the oven-dry wood to be 31.2 lb per cu ft of the green volume. At fiber-saturation point (25 per cent moisture) Fig. 3, or formula [5a], Appendix, shows that with the assumed gravity of 0.50 the wood has about 7.8 lb of water per cubic foot, and the maximum amount of water the wood could hold, assuming all the air space filled, would be about 42 lb per

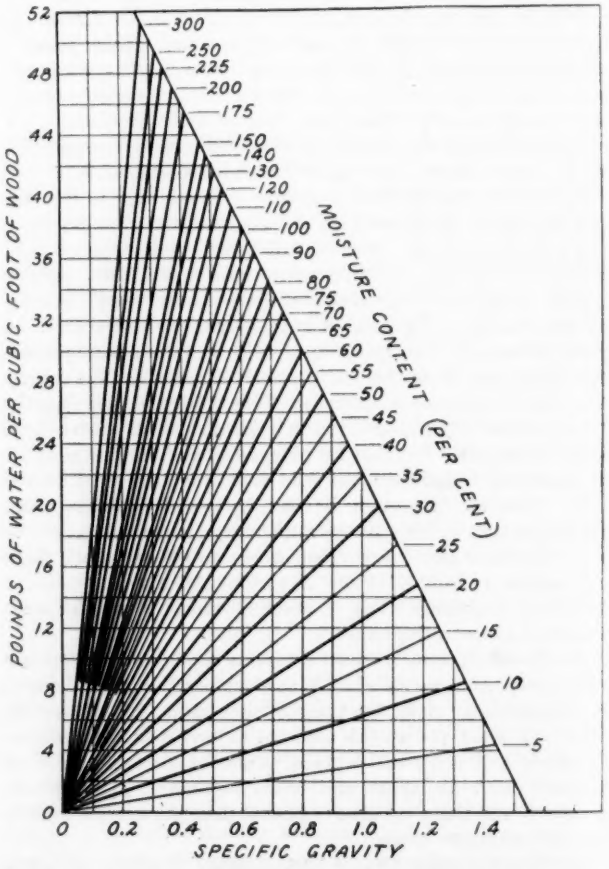

FIG. 3 RELATIONS BETWEEN WEIGHT OF WATER IN WOOD, SPECIFIC GRAVITY, AND PERCENTAGE OF MOISTURE
(Specific gravity based on the weight of the oven-dry wood and volume at current moisture content.)

cu ft. The volume occupied by the water (25 per cent moisture content) is found from formula [6] of the Appendix to be about 12.5 per cent. From Fig. 3, or formula [4] of the Appendix, it is also found that the maximum possible moisture content is about 135 per cent. The total weight of wood and water (formula [7a], Appendix) is the weight of the oven-dry wood per cubic foot found from Fig. 2, plus the weight of water per cubic foot found from Fig. 3.

A previous computation showed that if this species having a specific gravity of 0.50 based on the weight when oven-dry and volume when green were seasoned to 10 per cent moisture the specific gravity would be about 0.54. With this specific gravity and moisture content it is readily found, as in the preceding examples, that the weight of the oven-dry wood (based on the volume at 10 per cent moisture) would be about 33.7 lb per cu ft; the weight of water, 3.4 lb per cu ft; the volume occupied by the water, 5.4 per cent; and the total weight of wood and water, 37.1 lb per cu ft.

If in making moisture-content computations the weight of the oven dry wood is computed from the specific gravity (formula [2] or [2a], Appendix), it is important that the proper specific gravity figure be used. This specific gravity must be based on the weight of the oven-dry wood and the volume of the wood at the current moisture content—that is, the volume at the moisture conditions when the sample is taken.

For example, assume a green timber weighs 65 lb per cu ft, the specific gravity based on the weight when oven-dry and the volume when green is 0.53 and the specific gravity after air seasoning is 0.59. The weight of the oven-dry wood based on the volume when green is then (0.53 × 62.4), or 33.1 lb per cu ft, as can also be found from Fig. 2. From Equation [3a] of the Appendix the moisture content based on the weight of the oven-dry wood is found to be about 96 per cent. This can also be checked very closely from Fig. 3. Subtracting 33.1 from 65 gives 31.9 lb of water per cubic foot. By reading across from 31.9 on the vertical scale (Fig. 3) to the specific gravity 0.53, the chart shows that the moisture-content scale gives approximately 96 per cent.

If, on the other hand, the specific gravity based on the weight of the oven-dry wood and volume when air dry of this timber had been taken, the weight when oven-dry would be 0.59 × 62.4, or 36.8 lb, and the computed moisture content based on this weight would be about 77 per cent. The latter is an incorrect value, as it does not give, as in the first example, the same moisture content that would be shown if a sample were cut from the green timber and the moisture content computed as indicated in formula [3] of the Appendix, where $M = \left(\frac{W}{D} - 1\right) 100$.

Relation of Moisture Content and Total Weight of Wood. Frequently it is inconvenient to take samples for making a computation of moisture content and specific gravity. In such cases a rough estimate of the average moisture content can be made for moisture content values above the fiber-saturation point by weighing representative timbers, finding the weight per unit volume, and computing the average moisture content from the specific gravity data based on the weight of the oven-dry wood and the volume when green given in Table 1 for the species under consideration. For example, if red-oak timbers have an average weight of 50 lb per cu ft, it might be of interest to know about what the average moisture content would be for this weight. It would first be necessary to estimate whether the average moisture content is above the fiber-saturation point or not. This can be done by using the average specific gravity based on green volume (Table 1), assuming the moisture content at fiber-saturation point to be about 25 per cent, and computing the total weight by formula [7a] of the Appendix. With the specific gravity figure given for red oak, the weight at the fiber-saturation point is found to be 0.56 × 62.4 × 1.25, or about 44 lb per cu ft.

With a weight of 50 lb per cu ft, the average moisture content is evidently well above the fiber-saturation point, and is found by means of formula [3a] of the Appendix to be about 43 per cent.

Fig. 4 makes it convenient to determine approximately these moisture percentage values for variations from the fiber-saturation point to the maximum amount of water the wood can hold. The maximum weight line is the greatest weight (in pounds per cubic foot) the wood can have for the specific gravity given.

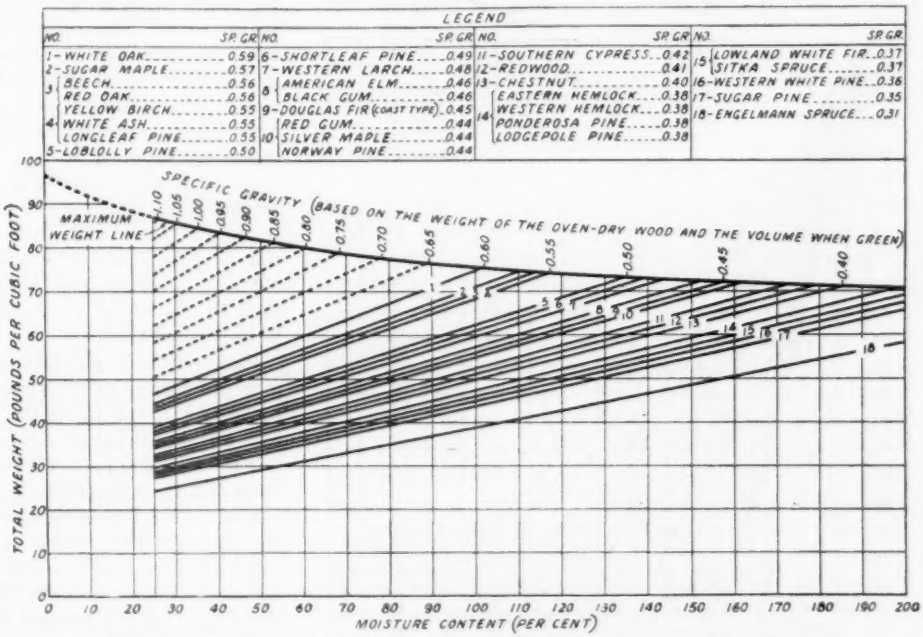

FIG. 4 RELATION OF WEIGHT OF GREEN WOOD AND MOISTURE CONTENT

The specific gravity figures in Fig. 4 are based on the weight of the oven-dry wood and the volume when green, since the wood is assumed at or above the fiber-saturation point.

Fig. 4 shows weights and moisture content values for differences in specific gravity of 0.05 and can be used for species other than those listed by interpolating between the lines connecting the different specific-gravity values shown on the maximum weight line. The dotted lines are for species that may have specific gravities higher than those of the species listed. If, for example, a wood had a specific gravity of 0.63 based on the weight of the oven-dry wood and the volume when green and weighed 60 lb per cu ft, the average moisture content is found to be approximately 54 per cent, a value lying between the lines for species having specific gravities of 0.60 and 0.65, respectively.

If weights of sample timbers are taken at intervals, Fig. 4 will also be found useful for estimating how fast the moisture content is changing during the seasoning period. The moisture content indicated from the weight of the timber will of course be only an approximate average value because of the uncertain influence of such variables as size and shape of the timber and amount of shrinkage at the surface where the moisture content may be below the fiber-saturation point. Furthermore, the specific gravity of the sample timbers may depart more or less from the average for the species.

The change in weight of oven-dry wood per unit volume below the fiber-saturation point offsets to some extent weight variations caused by changes in moisture content. On this account a considerable change in moisture content below the fiber-saturation point may cause only a relatively small variation in the total weight per unit volume.

Air Space in Wood

In a given volume of wood the air space is the proportion of the total volume that is left after subtracting the volume occupied by the wood substance and the water which the wood contains. The volume occupied by the wood substance will be the weight of the oven-dry wood divided by the weight of an equal volume of the wood substance. If, for example, a cubic foot of wood at 15 per cent moisture content weighs 36 lb when the wood is in an oven-dry condition, the volume occupied by the wood substance

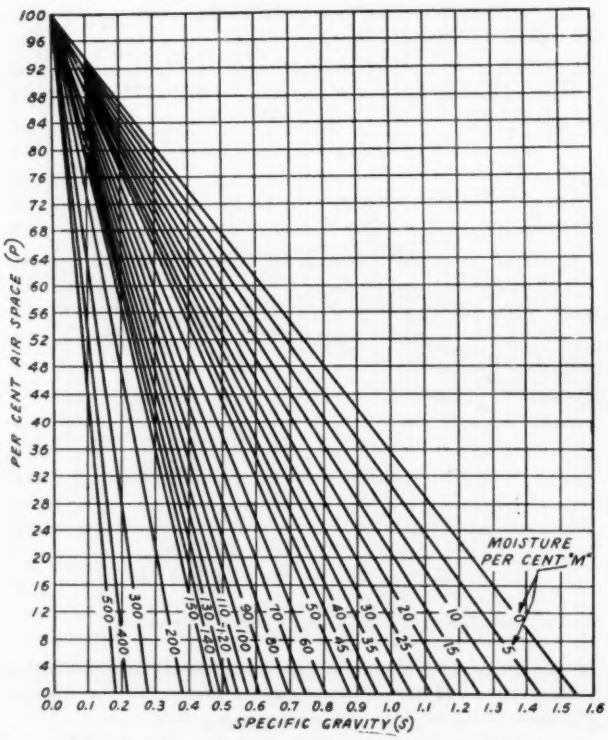

Fig. 5 Maximum Per Cent of Air Space in a Given Volume of Wood Having a Moisture Content M and Specific Gravity S (Specific gravity based on the weight of the oven-dry wood and volume at current moisture content.)

is 36 divided by (62.4 × 1.55), or about 0.372 cu ft. From formula [5] of the Appendix the weight of water equals 36 × 0.15, or 5.40 lb. The volume occupied by water is 5.40 divided by 62.4, or about 0.087 cu ft. The air space is then, by formula [8] of the Appendix, equal to [1 — (0.372 + 0.087)], or about 0.541 cu ft, or 54.1 per cent.

Fig. 5 has been prepared so that the percentage of air space can be found directly for a given moisture content and specific gravity. For example, with the loblolly pine having a specific gravity of 0.50 and moisture content of 25 per cent, the air space is found to be about 55 per cent, while at 10 per cent moisture (specific gravity = 0.54) the wood has about 59 per cent air space. The air space for intermediate moisture values can be found sufficiently close by interpolating.

Fig. 5 can also be used for finding the maximum percentage moisture content the wood can have, which is equal to P/S, where the value of P is the percentage air space, the value of which is found opposite the zero moisture content line, and S is the specific gravity based on the weight of the oven-dry wood and the volume when green. For example, when the specific gravity equals 0.50, the maximum air space is found from Fig. 5 to be 67.5 per cent at zero moisture content. In this case the green volume condition is assumed without any water in the wood. Dividing 67.5 by 0.50 gives 135 per cent moisture, which as previously noted was the moisture content shown in Fig. 3 as the maximum for this specific gravity. It may be of interest to observe that if, in formula [8a] of the Appendix, the moisture percentage M is zero and both sides of the equation are multiplied by $1/S$, the result gives formula [4] for finding the maximum possible moisture content. The point where a given moisture-percentage line intersects the abscissa (Fig. 5) is the average specific-gravity value of the species (based on the weight of the oven-dry wood and the volume when green), which would have the moisture content shown on the intersecting line as a maximum. For example, wood having a specific gravity of 1.0 could not have, at most, a moisture content of more than about 35.5 per cent even if completely saturated. In most growing trees, however, the heartwood has more or less air space, and this in many cases is also true of the sapwood.

In the wood-preserving industry computations based on the amount of air space may be of assistance in determining whether the wood has been sufficiently seasoned to obtain a given absorption of preservative or whether the specified absorption can be obtained, considering the moisture conditions at which the wood must be treated and the proportion of the total volume that can be impregnated.

If, for example, the loblolly pine timber having 10 per cent moisture content (specific gravity = 0.54 at 10 per cent moisture content) were treated with a preservative oil, the moisture content would not change, assuming the preservative does not contain water, and as far as the effect of the preservative is concerned there would be no appreciable change in volume, since the swelling caused by the oil absorbed is very slight. For this reason the absorption of preservative would depend on the amount of air space and how much of this air space was filled in treatment. Assume for illustration that the specific gravity of the preservative oil is 1 at the treating temperature, that all of the wood volume can be impregnated, and that all of the air space can be filled with preservative. When the air space (59 per cent) is completely filled, the maximum absorption that can be obtained is 62.4 × 0.59 = 36.8 lb per cu ft. On the other hand, if the wood at the same moisture content (10 per cent) were treated with a water solution, water would be absorbed in the cell walls as well as in the air space, and the volume would increase up to the fiber-saturation point, while the specific gravity would decrease to that based on the weight of the oven-dry wood and volume when green. The increase in volume would be about proportional to the change in specific gravity; that is, $\frac{0.54 - 0.50}{0.54} = 0.074$, or roughly 7 per cent. Since a cubic foot of the wood at 10 per cent moisture was found from Fig. 3 to have about 3.4 lb. of water, the amount of original water per cubic foot after treatment would be 3.4/1.07, or about 3.2 lb. From Fig. 3 it was found that the maximum quantity of water the wood could hold would be about 42 lb per cu ft. Then 42.0 minus 3.2 gives 38.8 lb of solution that could be absorbed as a maximum when the specific gravity of the solution is 1, or the same as that assumed for the preservative oil.

As another illustration, assume that at the time of treatment the sapwood in a charge of Southern pine poles averages about 60 per cent of the total volume, the average moisture content of the sapwood is 50 per cent, and the average specific gravity based on the volume when green is 0.50. A specification calls for a

net absorption of 18 lb of coal-tar creosote per cubic foot, and it is assumed that only the sapwood is penetrated. The question arises whether it is possible to obtain this absorption without further seasoning.

From Fig. 5 it is found that with a moisture content of 50 per cent and a specific gravity of 0.50, the sapwood has about 43 per cent air space, but since only 60 per cent of the timber is to be treated, the air space in the treated portion is equivalent to 0.6×43, or approximately 26 per cent based on the entire volume. The absorption is in pounds per cubic foot, and the specific gravity of the preservative at the treating temperature will be assumed as 1.03 for the purpose of computation.

The maximum gross absorption possible if the air space were filled would be $1.03 \times 62.4 \times 0.26$, or about 16.7 lb per cu ft. Furthermore, the net absorption is generally less than the gross absorption, even when a so-called full-cell treatment is employed, and under ordinary treating conditions not all of the air space in the treated portion could be completely filled. This is particularly true in the case of preservative oils which penetrate the cell walls only to a very slight extent. With the conditions assumed it is evident that it would be impossible to meet the specification requiring an absorption of 18 lb per cu ft.

If it is assumed that 80 per cent of the air space is filled with preservative, the percentage of air space necessary, based on the total volume, is evidently (18×100) divided by $(1.03 \times 62.4 \times 0.80) = 35$ per cent. Since only the sapwood comprising 60 per cent of the total volume is impregnated, the required air space in the treated portion is 35 divided by 0.6, which equals approximately 58 per cent. Fig. 5 shows that to obtain this amount of air space the timber would require seasoning below the fiber-saturation point if the specific gravity is 0.50. A close estimate of the moisture content and specific gravity giving this air space can be made by using Fig. 1. Assuming the species is loblolly pine and that the moisture content is 15 per cent, Fig. 1 shows the corresponding specific gravity for this moisture content to be nearly 0.53. With this specific gravity and moisture content, Fig. 5 indicates that the air space would be about 58 per cent.

Except in the case of sapwood or easily treated heartwood, only the outer part of the timber is impregnated. A simple calculation like the foregoing, however, shows the limitations of gross absorption which sometimes are not considered in the preparation of treating specifications.

It may also be of interest to know how much of the air space is filled with preservative for a specified treatment. For example, assume that a loblolly pine tie (all sapwood) has an average moisture content of 20 per cent and is to be impregnated by an empty-cell process with a net retention of 6 lb of creosote per cubic foot. At 20 per cent moisture content formula [10] of the Appendix, or Fig. 1, shows that the specific gravity would be about 0.514, or approximately 0.51. Fig. 5 shows that with a specific gravity of 0.51 and a moisture content of 20 per cent, the wood has about 56 per cent air space. If this space were all filled with preservative having a specific gravity of 1.03, the gross absorption would be $62.4 \times 1.03 \times 0.56$, or about 36.0 lb per cu ft. Since the tie is to be impregnated by means of an empty-cell method, there will be a "kickback," that is, a quantity of preservative rejected by the wood after pressure is released. This kickback may vary from about 50 to 65 per cent of the gross absorption. Assuming the kickback to be 60 per cent, the gross absorption would need to be 6 divided by 1 minus 0.6, or 15 lb per cu ft. That is, only 15 divided by 36, or about 42 per cent of the available air space would be filled during the treatment. Similarly only one-sixth, or less than 17 per cent, of the air space would be filled when the treatment was completed.

Computations such as the foregoing, of course, apply whether a full-cell or an empty-cell process is used.

Appendix

FORMULAS FOR COMPUTING RELATION OF MOISTURE CONTENT, SPECIFIC GRAVITY, AND AIR SPACE IN WOOD

The notations used have the following meanings:

- M = percentage moisture
- M_m = maximum percentage moisture when air space is completely filled with water
- S = specific gravity based on the weight of the oven-dry wood and volume at current moisture content M
- W = original weight of moisture specimen
- D = weight of moisture specimen when oven-dried
- W_v = weight per unit volume of wood at moisture content M
- W_m = weight of water in wood at moisture content M (weight per unit volume)
- W_d = weight of oven-dry wood per unit volume at moisture content M
- W_t = total weight of wood and moisture per unit volume at any moisture content M; that is, $W_t = W_v$
- W_w = weight per unit volume of water at maximum density (W_w equals 1 in C. G. S. system, and equals 0.0361 lb per cu in. or 62.4 lb per cu ft in the English system)
- P = percentage air space in wood having a specific gravity S and moisture content M
- 1.55 = specific gravity of wood substance
- P_w = percentage of volume occupied by moisture
- S_g = specific gravity based on the weight of the oven-dry wood and volume when green
- S_d = specific gravity based on the weight of the oven-dry wood and volume when oven-dry
- S_k = specific gravity based on the weight of the oven-dry wood and volume at current moisture content K below fiber-saturation point
- P_s = percentage shrinkage in volume in seasoning from fiber-saturation point to moisture content K.

Specific gravity:

$$S = \frac{W_d}{W_w} \quad [1]$$

When W_d and W_w are in pounds per cubic foot:

$$S = \frac{W_d}{62.4} \quad [1a]$$

Weight of oven-dry wood:

$$W_d = W_v \div \left[1 + \frac{M}{100}\right] = S(W_w) \quad [2]$$

When W_d is in pounds per cubic foot:

$$W_d = S(62.4) \quad [2a]$$

Moisture content in per cent:

$$M = 100\left[\frac{W}{D} - 1\right] = 100\left[\frac{W_v}{S(W_w)} - 1\right] \quad [3]$$

When W_v is in pounds per cubic foot:

$$M = 100\left[\frac{W_v}{S(62.4)} - 1\right] \quad [3a]$$

Maximum moisture content in per cent:

$$M_m = 100\left[\left(W_w - \frac{W_d}{1.55}\right) \div W_d\right] = 100\left[\frac{1}{S} - \frac{1}{1.55}\right] \quad [4]$$

Weight of water per unit volume of wood:

$$W_m = (W_v - W_d) = (W_d)\left(\frac{M}{100}\right) = W_w\left[\frac{MS}{100}\right] \quad [5]$$

When W_m is in pounds per cubic foot:

$$W_m = 62.4\left[\frac{MS}{100}\right] \quad [5a]$$

Percentage of volume occupied by water:

$$P_w = 100\left[\frac{W_v - W_d}{W_w}\right] = MS \quad [6]$$

When W_v and W_d are in pounds per cubic foot:

$$P_w = 100\left[\frac{W_v - W_d}{62.4}\right] \quad [6a]$$

Total weight of wood and water at any moisture content M:

$$W_t = \left[W_d + \frac{MW_d}{100}\right] = (S)\,(W_w)\left[1 + \frac{M}{100}\right] \quad [7]$$

When W_t and W_d are in pounds per cubic foot:

$$W_t = S\,(62.4)\left[1 + \frac{M}{100}\right] \quad [7a]$$

Percentage air space in wood:

$$P = 100\left[1 - \left(\frac{W_d}{W_w(1.55)} + \frac{W_v - W_d}{W_w}\right)\right] \quad [8]$$

$$= 100\left[1 - \left(\frac{S}{1.55} + \frac{MS}{100}\right)\right] \quad [8a]$$

Percentage shrinkage in volume in seasoning from fiber-saturation point to a moisture content K:

$$P_s = 100\left[\frac{S_k - S_g}{S_k}\right] \quad [9]$$

Specific gravity at any moisture content K below the fiber-saturation point:

$$S_k = [S_d - (S_d - S_g) \times (K/25)] \quad [10]$$

WDI-55-8

Modern Developments in Wood-Finishing Materials

By M. J. PEARCE,[1] READING, PA.

Wood-finishing materials as used today are classified according to composition, color, drying time, use, or other properties. The paper details the development work that has produced the modern finishes, and covers the purpose that they are designed to serve and the materials upon which they are used. The many stains, wood fillers, coaters and sealers, lacquers, and varnishes are described, their constituents are revealed, and their method of application is fully covered.

WOOD-FINISHING materials as used today are of many varieties and may be classified in many ways—according to composition, color, drying time, use, or other properties. Interest centers primarily in the practical angle of the use of finishing materials on such wooden objects as furniture, store fixtures, radio cabinets, pianos, and other similar commercial articles rather than in the scientific or theoretical angles of composition and chemical reaction connected with the manufacture and behavior of the individual materials. For the purpose of this paper, therefore, wood-finishing materials will be considered in a general way—first, according to the purpose which they serve, and second, according to the type of material. To further clarify the subject, the discussion will be limited to those materials used in producing a transparent or semi-transparent finish and not solid-covering primers, enamels, and other opaque finishing materials.

Many changes have taken place in finishing materials and methods during the last three decades. It is a far cry from present-day finishing methods to the "French polish" of 30 years ago, when a finish was worked up only after days of laborious rubbing with the shellac pad. The development or perfecting of the spray gun has been paralleled by an improvement in the drying time, toughness, durability, and other properties of finishing materials, so that it is possible to give a piece of furniture in one day a finish far superior in appearance and durability to that produced ten or fifteen years ago in ten days to two weeks.

The finishing of wooden articles has been effected with greater speed, more economy, and improved durability during recent years. The improved practical results are due to new raw materials, new technical research, and modification in methods of use. Through cooperation of the practical and laboratory technician, the finishing industry has improved the formulation of stains, fillers, lacquers, and varnishes, resulting in faster drying, greater durability, and lowered production costs. An examination of what has been accomplished may point the way to still greater expected improvements.

Stains

In the early days of the furniture and woodworking industry, the natural color of the wood was frequently the only color given to the finish. The early American maple, cherry, and walnut furniture illustrates this point. Mahogany and other well-grained woods gave a pleasing color when finisbed without stains.

With toe advent of large factories that turn out thousands of wooden articles in a year, such large quantities of the more desirable woods have been used that the quality of the color and figure has become less perfect. Furthermore, many species of wood which do not give such beautiful results without the use of stain, such as gum, elm, beech, and birch, have come into general use for such parts as posts and rails, and must therefore be made to closely match the color and figure of the more expensive woods used in other parts of the same article. These factors, together with the decided preference of the buying public for richer and deeper shades than those given naturally by many of the woods, have led to the use of stains.

Early in the use of stain, each operator made his own stain according to a special formula, sometimes inherited. Today few make their stains.

All stains may be divided into two general classes—powder stains and liquid stains. The powder stains are called water-soluble, spirit-soluble, or oil-soluble, according to the liquid in which they are dissolved. Liquid stains are divided into acid stains, spirit stains, penetrating oil stains, pigment oil stains, chemical stains, and non-grain-raising stains.

Powder Stains. Powder stains, or stain powders, are the dry coloring matter which gives the color to stains. Many are dyes made from intermediates manufactured from benzol, naphthalene, anthracene, and other coal-tar derivatives. Two or more intermediates must be mixed to produce a dye. Each color is a definite chemical compound with characteristic properties. Some are soluble in water, some in alcohol, and some in benzol, toluol, solvent naphtha, turpentine, lacquer solvent, and other so-called oils. Some are fast to light, while others fade easily. Mixtures usually are necessary to obtain a range of shades. Since not all of the colors can be used together safely, it is necessary to know their characteristics. Only experts in the blending of the powders can insure uniformity.

Of the powder stains, the water-soluble ones are the best and the most widely used. They are aniline dyes derived from coal-tar by-products. Sometimes they are incorrectly called "acid stains" because in the textile industry the colors frequently are mixed with acid materials. In the wood-staining industry acid is seldom added to stains, and when used it is very weak.

---

[1] Manager, Eastern Direct Sales, The Glidden Company. M. J. Pearce was born on September 28, 1897, in Sebree, Ky. He completed his grammar and high school education at Johnston City, Ill., and completed the course in chemical engineering at the University of Illinois, being graduated in 1920. He has been with the Glidden Company since July 1, 1920; in the factory and laboratory at Cleveland, Ohio, for one year, and for seven years in charge of the technical division of the industrial sales department; for three years manager of industrial sales at Chicago, Ill.; and since July, 1931, in his present position. Mr. Pearce is author of "Modern Automobile Painting" and numerous articles in various trade journals on the use of finishing materials.

Presented at the meeting of the Wood Industries Division of The American Society of Mechanical Engineers, Jamestown, N. Y., November 15 and 16, 1932.

Note: Statements and opinions advanced in papers are to be understood as individual expressions of their authors, and not those of the Society.

There is no doubt of the merits of water-soluble aniline stains for all fine work. They are fast to light and permanent in color, while oil-soluble and spirit-soluble stains soon fade upon exposure to sunlight. Furthermore, water stains produce more uniform tones, and thus aid in bringing out the beauty of the wood. The water stains are inexpensive, since 4 to 8 oz of powder to 1 gal of water produces most of the popular shades.

The chief drawback of water stains is that they raise the grain and loose fibers of the wood, producing a rough surface, which must be sanded again before finishing. To aid the sanding it is customary to apply a wash coat of shellac made by adding eight to ten parts of denatured alcohol to one part of a 4-lb cut shellac, after the stain has dried. This stiffens the fibers and allows the sandpaper to cut them off smoothly. The water in a water stain has a natural affinity for the fibers of the wood, and from 24 to 48 hr should be allowed after staining the work before the next finishing operation, in order to let this excess moisture evaporate. Water stains are therefore not well suited to fast production schedules. Despite the low initial cost of water stains, they are expensive to use, when all of the costs in connection with a given finish are considered.

Spirit-soluble powders, as a rule, are aniline colors. They are generally conceded to be the least fast to light of all stains, but where extra-quick drying is desired, they are the logical stains to use, especially if not exposed to strong light. Formerly, they were used quite extensively for blending, matching, and unifying the figure or color of one piece of wood to that of another piece in the same article.

Spirit stains always contain some water, and therefore raise the grain of the wood to some extent, and for this reason and also because of their extreme sensitiveness to light, they are rarely used for finishing furniture, other than in overtoning or color patching to even up the color of the work.

Oil-soluble powders are usually aniline dyes and are more frequently purchased in the liquid form than are water stains or spirit stains. From the standpoint of fastness to light, oil stains are somewhat better than spirit stains, but they are not nearly so permanent as water stains. The red, orange, and yellow shades of oil stains are especially fugitive to light. Oil stains do not raise the grain of the wood, and for this reason have received much consideration.

Oil stains are quite penetrating, and consequently do not produce so uniform a color tone as water stains. The oil stain penetrates the soft portions of the wood and gives a much darker color here than over the harder spots. Oil stains are partially soluble in alcohol and are wholly soluble in most of the solvents used in the manufacture of varnish and lacquer. This causes an oil stain to "bleed," or to become partially dissolved, in succeeding coats of finishing materials applied over it. This bleeding tendency frequently spoils the work, not only from the color-change standpoint, but also because any appreciable quantity of oil stain in the succeeding coat of varnish or lacquer will interfere with the drying of that coat and result in a "mushy" or "rotten" finish, which eventually becomes brittle.

This slow-drying and "rottening" effect of oil stains is intensified by the fact that many of the colors are precipitated on a stearic-acid base at the time of manufacture. This stearic acid and other constituents of oil stains interferes with the adhesion and drying of nitrocellulose lacquer, and in some cases goes so far as to precipitate the nitrocellulose in the lacquer, which in turn causes a decided blushing of the lacquer. For these reasons, oil stains, except certain special shades recommended by stain manufacturers, should never be used under lacquers, and they should not be used under varnishes where best results are desired.

Liquid Stains. Liquid stains are made from powders dissolved in the proper liquids, although materials other than powder colors, such as dry pigments and asphaltum, are frequently added to liquid stains. So-called liquid acid stains are little more than water solutions of water-soluble powders, to which small quantities of other materials are sometimes added. Spirit liquid stains are usually solutions of spirit-soluble powders. Penetrating liquid oil stains consist essentially of a solution of oil-soluble powders.

Pigment oil stains are never shipped in the powder form and are so-called "surface stains" in that they do not penetrate deeply into the fibers of the wood. Pigment oil stains are made from dry pigment colors such as umbers, siennas, Van Dyke brown, and rose pink. They are usually mixed with drier, turpentine, naphtha, linseed oil, asphaltum and similar liquids which serve as a suspending medium until the stain is applied and as a binding medium for the pigment particles after the stain is dry.

Pigment oil stains are applied by spraying or dipping, on chairs and cabinet work of the less expensive and less beautifully figured woods. They are inexpensive, fairly permanent in color, do not raise the grain of the wood, and because of the tendency to hide the figure of the wood slightly, they give quite uniform tones, which, however, are not as clear as the colors produced with the other stains. To even up the color tones still further and reduce the tendency of the stain to hide the grain of the wood too much, pigment stains are usually wiped with a dry cloth shortly after being applied.

Chemical stains are liquid stains that depend upon a chemical reaction to produce the color effect. Some of the more common materials are permanganate of potash, iron acetate, tannic acid, and picric acid. These stains require such careful handling that they are seldom used where time is an important factor.

Perhaps the best example of the use of chemical stains is the imitation fumed oak formerly produced with ammonia fumes in an airtight chamber. The modern method is to apply a water solution of tannic acid, which does not materially change the color of the wood, but does even up the quantity of tannic acid in the wood, so that when another chemical solution is applied, the reaction between the tannic acid in the wood and the chemical in the stain produces a fairly uniform fumed-oak color.

Non-Grain-Raising Stains. From the foregoing discussion it will be seen that an ideal stain would be one having the permanency, uniform color tone, and non-bleeding properties of a water stain, coupled with the non-grain-raising and quick-evaporating properties of an oil stain. In other words, if the good qualities of a water stain and the good qualities of an oil stain could be combined, a new stain would be produced which would be fast, durable, and beautiful. After much development work, the modern so-called non-grain-raising stains were produced. This type of stain varies greatly, depending upon the manufacturer, but all have the same general aim—to prevent the raising of the grain of the wood, coupled with fast drying and permanence of color.

While non-grain-raising stains are not quite as fast to light nor of as uniform staining properties as water stains, they are satisfactory for all practical purposes. Because of the cost of the solvent, non-grain-raising stains have a higher initial cost than water stains. The saving in time, labor, and material, due to the elimination of the wash coat of shellac and the sanding operation, often compensates for the slight increased cost of the stain itself, however, and many woodworking companies have found non-grain-raising stains adaptable to their needs. Because of the fast evaporating nature of the solvent, the next finishing operation after the staining operation can proceed within 30 minutes to an hour, although it is wise to allow more time than this.

These non-grain-raising stains may be used under shellac, lacquer, or varnish. It is not necessary to apply a coat of shellac over the stain before varnish or lacquer is applied, as the non-grain-raising stains are non-bleeding. Another advantage is that the color of the stain is not picked up when paste wood filler is applied directly over the stain.

Other Miscellaneous Stains. Uniforming stains, glazing stains, shading stains, and other special stains are often used, either by themselves or with the other stains heretofore discussed. Uniforming stains are intended to unify the color of sap streaks and other defects in veneer or for matching the color of one type of wood to that of another type. Glazing stains or overtoning stains are frequently little more than pigmented oil stains, which are applied over other colors and wiped off to produce a glazed effect. Shading stains of the best quality are made on a lacquer base and by spraying lightly on parts of the work produce a darker color. The shading stains are usually applied after one or more coats of finishing material, but before the final coat. They are used more often with lacquer finishes than with varnish finishes.

Paste Wood Fillers

Practically all of the woods used in furniture and similar articles have open pores which must be filled before a smooth finish can be secured. In the old days, many thin coats of shellac or varnish were applied and rubbed down so that most of the finish was removed except that in the pores. For modern production methods the paste wood fillers have been developed.

In the woodworking industry today, paste wood filler is applied to fill the open pores of the wood and to prevent the succeeding coats of finishing materials from being absorbed. A good paste wood filler is composed essentially of silex, linseed oil, japan drier, and coloring matter. On most work, the filler is applied following the staining operation. It should be the same shade as the stain, or possibly a little darker.

Filler is usually reduced with naphtha, which should contain no grease, water, or sulphur. As a rule 10 to 12 lb of filler is used to 1 gal of naphtha. The more open the pores, the more heavy the filler should be. Also, a little heavier filler coat should be used under lacquer than under varnish.

The reduced filler is usually applied by brushing, although it may be applied by dipping or spraying. By the brushing method there is less likelihood of unfilled pores. After the filler has flattened on the work, it is padded into the pores with a pad of burlap or hemp, using a circular motion. The excess filler is then cleaned off with a cloth, first wiping across the grain and then lightly with the grain, being careful not to pull the filler out of the pores.

Until recently, paste wood fillers required at least 48 hours to dry before the next coat or finishing material was applied. Through development work, the drying time of fillers was reduced 16 to 24 hours, and peak-production demands brought about the fast-drying fillers that are sometimes referred to as "four-hour fillers."

Quick-Drying Fillers. The four-hour fillers were developed primarily for use on conveyor lines where the padding-in and cleaning-off operations can be done immediately after the application of the filler. The use of conveyors in the finishing room is the exception rather than the rule, and these extremely fast-drying fillers are therefore not well adapted for the average plant. Four-hour fillers have all the qualities of 24-hour fillers, but they must be padded in and cleaned up shortly after application or they will set up so hard that this operation is almost impossible.

Several filler manufacturers have revised the four-hour filler somewhat by lengthening the drying time to about 12 hours, without sacrificing the easy working properties of a 24-hour type of filler. This 12-hour filler is fast becoming the standard in woodworking plants because it does dry to recoat in that length of time, but still can be applied and worked in a normal manner.

So-called combination stains and fillers have also been developed to stain and fill the wood in one operation. To the ordinary type of filler an extra quantity of coloring material is added. Obviously, the range of color is quite limited, and so this type of filler is used only where low cost is more important than extremely sharp or clear color tone. High-grade furniture is seldom finished with a combination stain and filler.

Filler Quality Is Important. The filler is the foundation of any finish. Some fillers contain soap, borax, soda ash, weak alkali, and water solutions to partially saponify the oil and help hold the inert pigment in suspension. These materials give the filler a false body and prevent them from filling the pores properly. Another fault is a lack of permanence of color after wood lacquer has been applied. If the filler is not bone dry, a bleeding action frequently takes place, the finish taking on a muddy appearance and the filler turning gray in the pores. If the proportion of color or the character of the color itself is not right, the same grayish trouble develops. Wood lacquer is a natural solvent of oil-soluble or spirit-soluble colors. If these are present in the fillers, the powerful lacquer solvents are likely to bleed them out and leave the gray silex showing in the pores.

Many of the wood fillers which gave good results under varnish are unsatisfactory under lacquer because of the faults mentioned. Several manufacturers have improved their fillers so that they are equally well suited for use under lacquer or varnish.

Nitro-Cellulose Lacquers

Although clear nitro-cellulose lacquers had been used for years on metal articles to produce hard, tough finishes, it was not until about ten years ago that their use became practical for finishing furniture and other wooden articles. The old metal lacquers were viscous, requiring considerable solvent to thin them for spraying. This resulted in a low proportion of solid materials and made it necessary to apply many coats to build up a dried film of sufficient thickness to permit rubbing and polishing operations. Furthermore, they lacked proper adhesive qualities, especially when applied to wood, and could be peeled or stripped from the work quite easily.

Although the first attempts to use these metal lacquers for finishing wood were not successful, they led to the development of so-called "wood lacquers," which at first were little more than bronzing liquids or waterproofed substitute shellacs. They adhered to the wood better than the old metal lacquers, but the solid content was still so low as to give a very thin coating, suitable only for producing "shellac and wax" or other open-pore finishes. This type of lacquer is mentioned only because of the stimulating effect upon further research, which led to the development of more modern wood lacquers.

A little over ten years ago methods were developed for lowering the viscosity of nitro-cellulose solutions, enabling four times as much solid matter to be incorporated in a lacquer. This made it possible to put as much finish on the work in one coat as was formerly put on in four coats. Methods were also developed, at about the same time, for adding a proportion of varnish resins to the lacquer which greatly improved the adhesive qualities without impairing the hard, tough, waterproof features. New, better, and less expensive solvents and other ingredients were also made available at about the same time, thus making it possible to improve the spraying and rubbing properties at lower costs.

While many formulas have been developed since that time,

to meet specific plant requirements and conditions, the early formulation was so well and carefully done that certain clear lacquers which were first commercially available are still in use today, and cannot be improved upon for general use where a medium, solid content is satisfactory. They have such well-balanced working properties that they can be used under most all factory conditions to produce a tough, horny, durable film of medium thickness. Variations from these original clear lacquers are, in reality, only changes which have been made to meet production needs of higher solid content and lower costs. To be sure, in accomplishing these improvements, new raw materials have been utilized as fast as they have been made available.

Wood lacquers today, however, consist essentially of four classes or types of raw materials, namely: (1) Nitro-cellulose, (2) gums or resins, (3) solvents and thinners, and (4) softeners or plasticizers. Broadly speaking, the nitro-cellulose imparts hardness, toughness, and waterproofness; the resins give improved adhesion and greater film-forming and easier rubbing properties; the solvents and thinners dissolve the nitro-cellulose and resins and give the proper spraying, blush-resisting, and drying properties; the plasticizers counteract the brittle effect of the resins, increase the solid content, and prolong the life of the dried film.

While nitro-cellulose today is essentially the same chemical compound that it was a few years ago, many improvements have been made to give greater durability and lower viscosity to the finished product. Development work is continuing in this field and additional improvements may be expected from time to time.

Synthetic resins have been developed which partially or completely replace the older type of natural resins in many modern lacquers. Any manufactured resin can be classed in a sense as a synthetic resin, and the variety of results that can be produced is as unlimited as the number of resins themselves. The use of many of these synthetic resins imparts unusual properties to a lacquer film, such as increased solid content, toughness, hardness, flexibility and resistance to water, alcohol, acids, alkalis, etc. Still greater developments are expected in this very important group of raw materials.

The family of solvents, non-solvents, and thinners has been enlarged greatly during the last decade. Many new products have been developed, many of them from entirely new sources, which do their job better and at lower cost than the old solvents. There are three classes of liquids in this family. First come the nitro-cellulose solvents, which are used to dissolve the nitrated cotton; then there are the solvents for the resins; and finally come those materials which within themselves are poor solvents for either the nitro-cellulose or the resins, but which can be added in certain proportions to combined solutions of nitro-cellulose and resins to reduce their viscosity, dilute their solid content, and lower their cost. New developments in this field are announced almost daily.

Important strides have been made in the plasticizer field, also. Camphor and castor oil were the principal plasticizers in the old days, but a host of new products have been added to this group. Not of the least importance are the new processed vegetable oils, which through partial polymerization and other special treatment can now be used in large amounts to increase the solid content of the lacquer without sacrificing the drying or hardening properties. Some of the new synthetic resins also act to a certain extent as plasticizers, and the family of resins and plasticizers are often closely related to each other.

Research in the plasticizer field has resulted in the production of lacquers with greater toughness, flexibility, and durability. Undoubtedly many other developments in this field can be expected, since new improvements are being discovered from time to time.

The net result of improvements in each of these four types of raw material has been the gradual lowering of the cost of a lacquer finish on the work, through increased solid content, better working properties, and improved methods of use. A few years ago a satisfactory lacquer could not be made to contain more than 15 to 18 per cent total solids, without spraying, drying, and rubbing difficulties. Today, through the combined use of improvements in many raw materials, lacquers are available that contain approximately 25 per cent total solids and yet are low enough in viscosity to be sprayed without reduction. Certain development work is now being done that may result in raising the solid content another 5 or 10 per cent. If these hopes materialize, lacquers will then be available which will approach the long-sought goal of the spreading, film-forming, and low-cost properties of varnish combined with the quick-drying and durable features of lacquer.

Lacquer Sealers or First Coaters. For some time after the advent of lacquer finishing materials, shellac was used as the sealer coat over the stain and filler, or in many instances the sealer coat was eliminated entirely. Since shellac required a minimum drying time of three to five hours before sanding and the clear lacquers dried so hard they could be sanded only with difficulty, there gradually arose a demand for a sealer or first-coat material which would spray smoothly, dry rapidly, and sand easily.

The first developments in this direction resulted in the incorporation of finely ground translucent pigments, such as silica, into an ordinary clear lacquer. While these original sealers were more waterproof, less brittle, and quicker drying than shellac, much was lacking in body on the work, clarity of film, and easy sanding properties.

By replacing these pigments with metallic soaps, such as zinc stearate and zinc palmitate, and by substituting certain synthetic resins for some of the natural resins, it was possible to improve the drying time, sanding properties, clearness of film, body on the work, and durability of the ultimate finish.

Synthetic resins, new solvents, new metallic soaps, and many other raw materials not available a few years ago make it possible to produce sanding lacquer sealers today which contain 25 per cent total solids as compared to a former solid content of only 15 per cent.

These modern sealers spray smoothly, can be sanded in 30 minutes after application without gumming the sandpaper, and hold succeeding coats of lacquer much better than the earlier sealers. They have contributed their part to the reduction of number of coats, quicker finishing schedules, and lower costs of production demanded by the woodworking industry.

Flat Drying Lacquers. At first, after clear furniture lacquers were placed on the market, there were no flat drying lacquers. All of the lacquered work was brought up with clear gloss lacquers which were rubbed with pumice stone and oil to a dull finish. With the production demand for faster and more economical schedules and for lower unit costs, there arose a need for lacquers which dry to a dull (or rubbed effect) luster. These flat lacquers were produced, at first, by incorporating finely ground, transparent pigment particles into a clear lacquer vehicle. Lack of clearness of the dried film, poor water resistance, and low tensile strength were some of the defects of these early flat lacquers.

As time went on, new flattening agents, such as metallic soaps, waxes, and flat drying resins, were developed, and flat lacquers are now obtainable whose dried films are transparent, resistant to water, and practically as durable as clear lacquers. There has been a constant demand for flat lacquers containing more and more total solids, just as in the case of lacquer sealers

and clear lacquers. Flat lacquers are obtainable today which contain approximately 25 per cent total solids, which is from 5 to 10 per cent higher than two or three years ago.

Varnishes

For a time after the advent of clear furniture lacquer, rubbing and polishing varnishes took a back seat because of slow drying, lack of hardness and toughness, and other defects in the old-style varnish film which had been overcome by the nitro-cellulose lacquer. Varnish manufacturers have been constantly experimenting, trying to speed the drying of varnish products so as to approach the working properties of lacquer as nearly as possible and still retain the higher solid content of the old-style oil varnish. From the standpoint of spreading capacity, film-forming properties, and low initial cost per gallon, the oil type varnish is and has always been superior to lacquer, and if the fast drying, hardness, toughness, water resistance, and other good properties of lacquer could be approached without sacrificing the solid content, varnishes would again come into their glory.

Many new synthetic resins and specially treated oils have been developed which give promise of making this goal obtainable, although to date no so-called synthetic varnish is equivalent to lacquer for speed, hardness, toughness, or adhesion, unless the drying and polymerization are hastened by heat. Synthetic varnishes are available, however, which can be recoated within a few hours and satisfactorily rubbed after an overnight drying period.

It must be remembered that in the case of lacquer the hardening or drying of the film is accomplished almost entirely by evaporation, and oxidization or other chemical reactions enter into the drying phase only to a small extent. As soon as the solvents have evaporated sufficiently, the film is hard. In the case of varnish, however, the drying phenomenon is divided into two distinct phases. The solvents evaporate and set the varnish on the work so that it will not run or sag, but the principal hardening action comes about through a very complex chemical reaction, consisting chiefly of oxidization and polymerization of the vegetable oils in the varnish. This explains why it has not been possible to duplicate the fast hardening of lacquer in an air-drying varnish.

The development of suitable synthetic resins, partially polymerized oils, faster evaporating solvents, and more efficient metallic driers has made it possible to produce varnishes, however, which approach the drying speed of lacquers. It has also been possible to combine specially prepared varnishes with nitro-cellulose solutions to produce what might be called varnish-lacquers, although these materials are more often thought of as lacquers rather than as varnishes, because of the similarity of odor to that of lacquer. Development work in this field is going on constantly, and undoubtedly it may be expected that lacquers and varnishes will become nearer and nearer alike as time goes on.

On medium- and low-priced furniture there has been a decided tendency to return to the use of varnish, for economical reasons only. Varnish will spread further, costs less per gallon, and will produce a finish of a given depth with fewer coats than lacquer. Therefore, where the price of the furniture is not sufficiently high to justify the cost of using lacquer, varnish is being used.

Flat Drying Varnishes. For a long while, flat drying varnishes have been manufactured by incorporating finely divided, transparent pigment particles in an ordinary type of rubbing varnish. These flat drying varnishes have had certain defects, such as the gray appearance in the film, poor resistance to water, and brittleness. Much development work has been done recently to improve flat drying varnishes, and as a result many of these defects have been eliminated. A new style of flat varnish that has only recently been developed contains little or no pigment. It therefore does not settle or skin over in the package, it dries much faster than the ordinary type of flat varnish, and it gives much clearer results on the work.

The film of all flat drying varnishes is necessarily not quite as tough nor durable as the same grade of clear rubbing varnish. The flatting agents all have a deteriorating effect upon the varnish, but where a rubbed effect is desired, without the expense of an actual rubbing operation, some very beautiful results can be secured with modern flat drying varnishes.

Conclusion

It will be seen from the foregoing discussion that as a need develops in the wood-finishing industry, the finishing-material manufacturers try to solve the problem, and in many cases with success.

During the last five or six years, the development has primarily been in keeping with the increased pace of production. The cry has constantly been for faster drying, fewer coats, and lower costs. Some woodworking factories have carried this matter so far that today the finish often lasts only a little longer than the time necessary to get the article to the hands of the consumer.

After all, the finish on a wooden article goes a long way toward attracting the customer and keeping him satisfied. It would be far better to spend a little more money on the finish and build a reputation for the future.

Note: Discussion of this paper jointly with that of R. H. McCarthy and L. A. Lefcort by F. L. Browne appears in the discussion following the latter paper.

Accelerated Varnish Drying

By R. H. McCARTHY[1] and L. A. LEFCORT,[2] MASPETH, N. Y.

R. H. McCarthy

Varnish drying on wood at a temperature of 150 F, instead of the usual lower limit of 100 to 110 F, has been attained after experimentation and tests by the authors. This finish process retains the desirable factors of appearance, durability, economy, and speed. Varnish finishes at elevated temperatures are shown by tests to be superior to ordinary finishes in durability and resistance to marring. Samples made by this system have undergone accelerated weathering for several months without failure, indicating that those finishes that take advantage of the toughness and hardness resulting from the heat treatment of synthetic and some natural resins are superior to the ordinary run of long-oil varnish finishes. A feature of the system is that it makes feasible the conveyorization of varnish finishes as well as lacquer finishes.

L. A. Lefcort

GIVEN the desired appearance, durability, and cost of material and labor for wood finishes, furniture manufacturers have consistently favored quick-finish processes. In many processes, however, appearance, durability, economy, and rapid drying are not all possible because of inherent limitations of the materials. Thus many slow-drying varnishes produce fine appearance and excellent durability only by sacrificing economy and speed. Some lacquers and varnishes, on the other hand, offer appearance, economy, and speed, but are lacking in durability. Therefore a great amount of time has been spent to secure speed without loss of durability and appearance. The results have been greatly improved materials, particularly the phenol formaldehyde, glyptal, and other synthetic resin varnishes, and radical changes in finishing procedures, such as the use of accelerated drying at relatively high temperatures.

Most high-grade long-oil varnishes ordinarily take from 8 to 48 hours per coat to dry satisfactorily at room temperatures, dependent upon atmospheric temperatures, humidity, and varnish formulations. Acceleration of shellac and varnish drying by the use of ovens operating at 100 to 110 F has been common practice for many years in the woodworking industry. Likewise it has been common practice to bake varnish finishes on metal at much higher temperatures.

The following description of a wood-finishing process employed by the Western Electric Company in the manufacture of telephone booths is illustrative of what the new-type varnishes have made possible in acceleration of drying schedules and in increased durability of finishes. The development proposed to raise the drying temperature as far as the materials involved would permit—i.e., wood, glue, filler-stain, and varnish. As a result the drying time has been reduced to $1^1/_2$ hours per coat regardless of atmospheric conditions, thereby putting varnish into a class with lacquer in respect to speed of production. The investigation was initiated and developed by the authors in connection with the finishing of wood products at the Queensboro Works of the Western Electric Company. Dr. A. E. Schuh and Mr. W. L. VanArnam, of the Bell Telephone Laboratories, cooperated in the investigation and conducted the laboratories' tests to determine durability,[3] which resulted in the selection of two varnishes having synthetic resins and one having natural resins as superior in resistance to abrasion, impact, and accelerated weathering.

A steam-heated oven, Figs. 1 and 2, insulated with a 2 in. thickness of 85 per cent magnesia and equipped with an automatic recording temperature regulator, was installed. Fresh air is drawn from outdoors through a filter box, past a regulating damper, through a fan and steam coil, and forced into the oven proper through adjustable louvers. From another set of louvers in the opposite wall of the oven the air is drawn back to the regulating damper, which is set to discharge a portion outdoors and to recirculate the remainder with the incoming fresh air. The amount of recirculation was fixed so that the fresh-air supply was sufficient to avoid any possibility of explosive mixtures. No attempt was made to humidify the air, since it was thought that the moisture change of wood during the relatively short time in the oven would not be serious. Subsequent tests (shown in Fig. 4) verified this belief.

TABLE 1 TESTS OF SHEAR BLOCKS

(All tests made immediately after heating)

	Load at failure, lb					
	Heated 3 hours			Heated 6 hours		
	Walnut	Mahogany	Oak	Walnut	Mahogany	Oak
Room temp, average of 5 samples	2668	1588	2394	2668	1588	2394
140 F, average of 5 samples	1948	1426	1828	1840	1466	1640
150 F, average of 5 samples	1952	1286	1834	2094	1258	2098
160 F, average of 5 samples	1890	1170	1758	2176	1362	2138

NOTE: All samples when fully cooled showed same strength as before heating.

An investigation was planned to furnish the following information:

1 Proper operating temperature with respect to (*a*) the wood and (*b*) the glue joints

2 Minimum drying time for various coats
3 Most advantageous sequence of operations
4 Method of varnish application.

It should be stated that the system described herein was applied to solid and veneered exposed mahogany, oak, and walnut telephone-booth parts; to end assemblies, doors, door frames, backs, seats, and shelves, as shown in Fig. 3; and to a few other

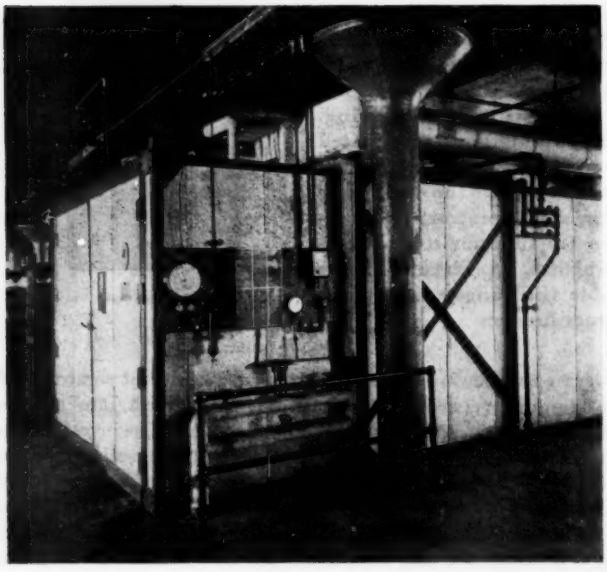

FIG. 1 EXTERIOR OF STEAM-HEATED VARNISH-DRYING OVEN
(Showing automatic controls.)

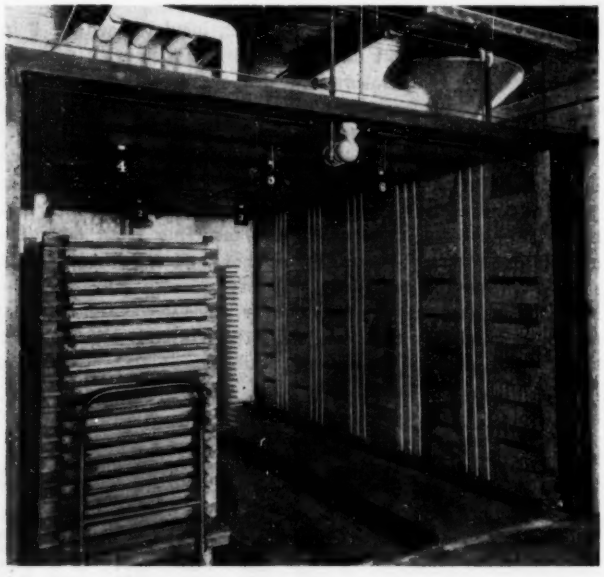

FIG. 2 INTERIOR OF STEAM-HEATED VARNISH-DRYING OVEN
(Showing adjustable louvers for cross-ventilation.)

items of miscellaneous furniture. Prior to the investigation an all-varnish system had been adopted wherein the use of non-bleeding filler-stains eliminated the use of sealers other than the varnish itself.

OPERATING TEMPERATURES

Guided by a series of preliminary tests that had indicated a temperature range from 140 to 160 F for more detailed investigation, several complete unfinished unit assemblies were subjected to oven temperatures of 160, 150, and 140 F for 5-hour periods to determine what defects, if any, would result from the heat treatment. The assemblies were carefully inspected for warpage, surface checks, shrinkage, and defective glue joints. At 160 F the mahogany and walnut showed no visible damage, but quartered white oak exhibited small surface checks and open glue joints in the faces of veneered panels. Upon lowering the temperature to 150 F, there were no indications of surface checks and very little opening of face-veneer joints. Similar results were obtained at 140 F. A further examination proved that in every instance of open veneer the joints had been improperly jointed or glued before the tests were made.

At the outset of the test a fear was expressed that unhumidified oven treatment would create serious changes of the wood moisture content, with resulting warps, hairlines due to inset-panel shrinkage, and deterioration of the finish. For this reason a series of tests were made to show the successive moisture changes during each step of the finishing process. Eight adjacent test sections were sawed from the middle of a five-ply $^{7}/_{16}$-in. oak-plywood panel. Two of these sections, Nos. 1 and 8, were tested at the

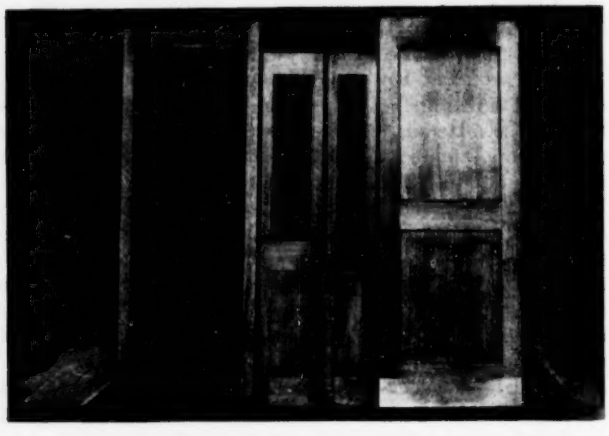

FIG. 3 VARNISHED TELEPHONE-BOOTH PARTS
(Showing seat, door frame, folding door, end panel, and shelf.)

outset for moisture content and taken to be representative of the initial condition in other sections. The remaining six sections then received a coat of filler stain, were sealed back into the large panel, and air-dried for 24 hours at room temperature. When dry, section No. 2 was taken out, the filler stain was sanded off, and the section was tested for moisture content. The same procedure was followed for the two succeeding varnish coats after their respective oven-drying periods.

The results as given in Fig. 4 show clearly that the fluctuations of moisture content are not large, since the stock when ready for rubbing was little different in condition from that in the ordinary air-dried system. Undoubtedly these results were approximate, because thinners and oils from the finishing materials not removed by sanding and process-drying appeared as moisture content. Since the tests were made, the air-drying of filler-stains has been replaced by oven-drying, which would reduce the high indicated moisture content shown in the graph at this stage of the cycle (see sample 2, Fig. 4).

In order to determine the effect of temperature on glue joints, tests were made on oak, mahogany, and walnut blocks that had been heated at 140, 150, and 160 F for periods of 3 and 6 hours. For this purpose shear test blocks constructed of three thicknesses of lumber were made according to accepted practice and were

tested to destruction. The results are given in Table 1. It should be noticed that they were tested immediately upon withdrawal from the oven; hence the results showed, as might be expected, decreased joint strength while the wood was warm. But after the blocks had cooled for several hours, the glue joints returned to their original strength, thus indicating no permanent deterioration. The net results of these tests pointed to surface checking and opening of veneer joints in oak as the limiting condition, and therefore 150 F was chosen as the proper operating temperature for further work.

Filler-Stain Drying Time

Five combination filler-stains are used in the standard variety of product: light red, dark red, and walnut brown applied on mahogany solid and veneered construction, a dark walnut on black walnut, and a medium golden oak on quartered white oak. All these filler-stains except the dark mahogany were readily adapted to the accelerated schedule, drying satisfactorily in 1 1/2 hours at 150 F. After extended trials with dark-mahogany stains in which a deep-red color had to be obtained without bleeding through varnish, yet had to be permanent and adaptable to forced drying and suitable for application in combination with a filler, a non-grain-raising water-soluble stain appeared to be acceptable. It does not dry so hard as the other filler-stains, but after the additional drying that it receives during varnish-coat drying, the finished product proves satisfactory.

The brush application of filler-stains is followed after a 15-min hardening period by padding and wiping off. The stained and filled articles are immediately placed in the oven and remain for 1 1/2 hours at 150 F. They are then ready for varnishing.

Varnish-Drying Time

The problem of accelerated drying had been greatly simplified by the results of considerable experimentation at the Kearny Works of the Western Electric Company and the Bell Telephone Laboratories, in which it became evident that for durability and appearance a finish using varnish directly over the filler-stain compared very favorably with other methods of sealing. This simplified the problem, because it left only the filler-stains and varnish to deal with, eliminating sealers as a third variable.

Various combinations of drying times and temperatures for the first and second varnish coats were tried. Some of these combinations are given in Table 2.

TABLE 2 VARNISH-DRYING TESTS

	Combination				
	A	B	C	D	E
Temperature, F	140	140	150	150	150
First coat, drying time, hours	1	1.5	1	1.5	1
Second coat, drying time, hours	1	1.5	1	1.5	2

Combination A gave incomplete drying over air-dried fillers. Combination B produced a film dry and hard to the touch, but required (dependent upon atmospheric conditions) 5 to 16 hours' additional air-drying to put it into proper condition for sanding. Combination C produced incomplete drying when using ordinary filler-stains, but was satisfactory over filler-stains especially prepared for oven treatment. Combinations D and E, with the exception of one varnish that showed incomplete drying of the first coat in 1 hour, were both satisfactory. Materials dried in this way were ready to sand when cooled at ordinary room temperatures in about 3 hours, except during the summer hot weather and high humidity, when the drying time at room temperature before sanding was extended to overnight. For operating simplicity combination D was chosen, because it gave a uniform drying period for filler-stains and varnishes. The overnight drying period preliminary to rubbing can be reduced to less than 1 hour by lengthening the oven-drying periods 1/2 hour each and employing forced cooling. Similar results can be obtained by forced air circulation for 1 1/2 hours at room temperature preliminary to rubbing. Again, for uniformity of operation and adaptability to a conveyorized sequence, the 1 1/2-hour drying with forced circulation will be adopted. If the system were not to be conveyorized, the overnight drying would be more economical in view of the fact that the shop works only 8 hours out of the 24

Sequence of Operations

To summarize, the following sequence of operations has been adopted:

1 Apply filler-stain, pad, and wipe
2 Dry 1.5 hours at 150 F
3 Apply first varnish coat and allow to dry under room conditions at least 5 min before placing in oven
4 Oven dry at 150 F for 1 1/2 hours
5 Apply second varnish coat immediately after the first oven-drying period without cooling or sanding
6 Oven dry at 150 F for 1 1/2 hours

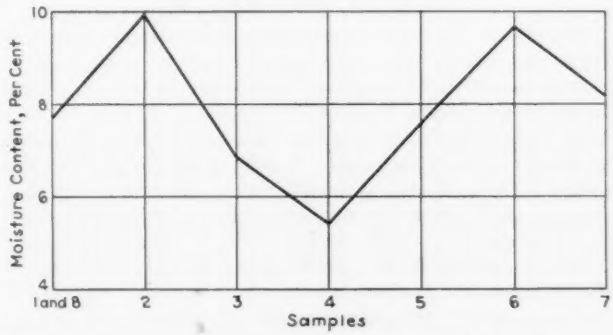

Fig. 4 Change in Moisture Content of 7/16-In. Oak-Plywood Panel During Finishing Cycle

7 Cool to approximately 75 F. (As has been stated, this cooling period varies with atmospheric conditions. It can be greatly reduced by forced cooling with fans. On the other hand, when atmospheric temperature and humidity are high, stock should be allowed to stand overnight.)
8 Sand with 6/0 aluminum-oxide paper. (Since there is no sanding between coats, particular attention must be paid to securing a thorough sanding job at this stage. The greater toughness of varnish as compared with ordinary lacquer sealer or shellac sealer makes it more difficult to sand.)
9 Rub with pumice and oil.

Method of Varnish Application

Several precautions must be observed during the finishing process to insure satisfactory results. All lumber should be uniformly dried to a moisture content that will bring it to the finishing department at about 7 per cent. The filler-stain must be thoroughly dried or the varnish drying will be greatly retarded. Of the greatest importance, however, is the thickness of the varnish film. This is necessarily the resultant of two variables: the percentage of solids in the varnish and the amount of material sprayed per square foot. For purposes of this development varnishes with approximately 54 per cent solids content and a viscosity of E on the Gardner-Holdt bubble-tube viscometer were used.

Many difficulties will be experienced if the proper thickness of coating is not applied. If it is too thin, the surface will not be protected adequately, and it will appear starved or lacking in

depth. On the other hand, if the coating is too heavy, the varnish will blister or wrinkle. Blistering is more likely to occur than wrinkling. It is caused by the presence of volatile thinners imprisoned within a slightly heavier-than-medium coat of varnish. When the parts are placed in the oven at 150 F, the surface of the film immediately begins to harden, and at the same time the thinners expand and attempt to escape. Due to the increasing toughness of the varnish, the expanding thinners stretch the film that is just forming and make blisters that harden on the surface. In some particularly large blisters the pressure generated by the thinners is sufficient to rupture the film while still plastic and leave circular impressions upon the surface. With the materials used in this investigation, wrinkling is caused by the presence of an unusually heavy coating, which is puckered or drawn together by the action of the high temperature. The dried varnish film averages 0.0024 in. in thickness, corresponding to an average coverage of about 350 sq ft per gal on large areas of flat stock. It will be readily understood that the importance of refraining from heavy varnish coats emphasizes the need for good filling work.

Quality of Finished Product

The system proposed has now been in satisfactory operation for a year. From laboratory tests we are convinced that the varnish finishes dried at elevated temperatures as made during these trials are distinctly superior to ordinary finishes in durability and resistance to marring. This conviction is readily verified by ordinary shop tests. A series of samples made by this system for tests of each of the different woods were produced in the shop and have undergone accelerated weathering cycles for a period of several months without failure. The results have indicated conclusively that those finishes that take advantage of the toughness and hardness resulting from the heat treatment of the resins used are distinctly superior to the ordinary run of long-oil varnish finishes.

For simplicity the system described leaves little to be desired in reduction of numbers of raw materials and cost for application of materials. The outstanding merit of the process is that it makes feasible the conveyorization of varnish finishes as well as lacquer finishes.

Discussion

Paul Kennedy.[4] The paper is an interesting addition to the all-too-meager fund of authentic research work on wood finishing. That this system has proved satisfactory in production for a year automatically removes it from the "theory" or "small-scale laboratory" class. Nevertheless, it is an apparent contradiction of certain accepted knowledge. It evidently denies the necessity of maintaining a fairly constant relative-humidity ratio when accelerating varnish drying. It also employs varnishes of synthetic-resin types, which are conceded to be faster setting than natural resin types of varnish and hence more sensitive to case hardening.

It has been an accepted theory that the kiln drying of varnish requires both heat and humidity for safest results. Most chemical reactions are accelerated by heat, and the oxidation of varnish is so stimulated. Humidity is conceded to be a retarder of varnish drying proportionate to its relative percentage in the atmosphere.

In the past there have been several types of kilns employing temperatures usually from 100 to 125, with no humidity control, but moisture was usually artificially introduced into them. This was supplied in the cruder outfits from pans or troughs of water, open steam jets, etc. In the more scientific designs, the air was heated and humidified in a mechanical air conditioner, located outside the kiln, and this conditioned air was automatically regulated for relative humidity and air change. The conclusion was that the humidity kept the varnish film "open," while the heat accelerated the oxidization of the varnish. The humidity would act as a sufficient retarder to make the film dry from the "bottom up," whereas minus this counter-action of humidity the impulse of the heat would be to oxidize and harden at the points of least resistance—namely, the "top of the film."

"Case-hardened" film drying was particularly serious in piano finishing—for example, where practice demanded the application of a number of heavy coats of varnish, and subsequently reflected itself in "tearing," "pulling out" when rubbed, "scaling," "sweating," and "printing." Worst of all, if the first coat was not thoroughly dried, the hardening of the second coat would be much less than that of the first, even with the same film thickness and heat, and this condition became further abnormal with subsequent coats.

These actual production facts are recounted because there is apparently here a paradox, inasmuch as the integrity of the paper under discussion is not to be questioned. There must be some explanation.

The baking of varnishes has long been standard practice, and no field is more conspicuous than the Jamestown metal furniture and trim industry. These companies employ an average varnish-baking temperature of about 175 F, occasionally higher, and sometimes as low as 150 F. It has long been felt that at temperatures from 150 F up, a unique reaction occurs in the hardening of varnish films, which might be termed a "shock action." When varnish films are suddenly exposed to these higher temperatures, a rearrangement of molecules probably takes place.

Further corroboration of this is found in the similar behavior on baking of certain strictly synthetic-resin solutions and the fact that the same varnish when baked (at 150 to 200 F) will have far greater resistance than if air-dried normally or stimulated by the comparatively gentle acceleration of ordinary kiln drying (100 to 120 F). Dr. A. E. Schuh has noted this same phenomenon in his examination of the film produced by the process under discussion. This would seemingly confirm that this "shock action" had occurred with his varnishes. As before stated, 175 F is generally accepted as the best average baking temperature, but synthetic varnishes unquestionably would make a reduction in temperature feasible and even safer practice. These synthetic-resin varnishes outstand for their quick "setting out of dust" even with air dry. This is because they have the faculty of expelling the volatile solvents from the varnish film far more rapidly than natural resins. This feature is entirely distinct from any action they may have in conjunction with the oil of the varnish in the hardening of the film, and is doubly to be noted if the application of the varnish is by spray gun.

When varnish is atomized in the course of spraying, the minutely divided particles dissipate most of their solvent into the air when traveling from the point of the gun to the surface of the work. Hence, the varnish as applied on the work contains only a small percentage of the solvent originally present in it. With synthetic resins this dissipation of solvents is even higher than with old-type varnishes. To the writer's mind this factor is one of the vital drawbacks, in the present exposition, when considering its general adaptability. The authors of the paper have shown their appreciation of this in stressing the point of "proper film thickness of coating to be applied" and their comments on "blistering" and "wrinkling." The wrinkling is a particular factor to be avoided, and the conditions just outlined make synthetic varnishes extremely sensitive to this difficulty.

Much work has already been done in the baking field with this type of varnish, but unless radically modified, the results have

[4] Vice-President, Murphy Varnish Company, Newark, N. J. Mem. A.S.M.E.

been rather discouraging, particularly from the standpoint of wrinkling. On the other hand, this type of varnish has proved extremely successful in the tin-decorating and metal-package field, mainly because the application is by coating machine, and a thin and uniform film can be applied to the tin plate. Of course, this method of application is ideal, because it is mechanical, but even so, carelessness sometimes creeps in, resulting in wrinkled finishes or ones with indifferent adhesion to the tin plate. We have the human element solely to consider in the varnishing of woodwork, and also the factor of a wide range of designs (especially on fancy furniture) which are conducive to the collection of excessive quantities of varnish at certain spots. These sections would most certainly wrinkle on drying.

The authors comment upon the economic superiority to lacquer. It is granted that from the standpoint of material cost and film building the varnish finish has a decided advantage. On the other hand, there are the factors of clean spraying and the "hospital" work that usually involve an expensive repair department. If dirt or specks collect in the varnish, "pull outs" are almost certain when rubbed, and the varnish naturally attracts and retains such foreign matter. There is rarely any difficulty of "pull outs" with lacquer.

Of even greater importance is the refinishing of damaged panels etc. There is usually no requirement for a special section to repair a lacquer film, as only a few minutes are needed to patch up damage, and it can be done on the line. To repair varnish-finish damage, it is often necessary to repeat the original finish system. How these factors offset each other is an important determination of the relative economies.

The writer has purposely not commented upon the points of glue joints, air changes, recirculation, etc., feeling that other discussers may be better qualified and will develop such possibilities of further fact and interest. To sum up, he would call attention to the following points:

1 Employing the temperature of 150 F does not make for a true comparison with the lower temperatures of general kiln-drying practice, because a "shock action" is involved that produces a different type of hardened film, as confirmed by the improvement in durability and resistance noted by Dr. Schuh.

2 The practice admittedly requires close supervision, particularly from the standpoint of uniform application and film thickness.

3 The human element is a critical factor, particularly from the standpoint of spray application, cleanliness, and handling.

4 In the instance cited, the same general type of work is constantly being handled by the human element and might be likened to mass production. With low turnover in help, the spray operators can logically be expected to acquire almost mechanical accuracy in their work.

5 Considering the factors of the human element and the chemically active varnishes employed, it would be the writer's conclusion that this process would have definite possibilities for adoption in such classes of production as sash and trim and certain fixtures where the parts to be coated are generally uniform. He questions, however, whether it would prove economical for general furniture production and especially for high-grade cabinet work where the designs change very rapidly and repair or "hospital" expense is important.

6 Emphasis is stressed on maintaining a wood-moisture content of 7 per cent. Offhand, it would seem that this could be better controlled in mass production than where a number of different designs are employed, or where for sound reasons work proceeds through the factory rather slowly and the wood must be exposed for considerable periods "in the white."

7 The writer believes that the practice should be termed "baking" rather than "accelerated drying," as these two terms have distinctively different meanings, just as they produce films of different character, even with the same varnishes. A typical example of this is the long-service records of baked varnish on steel cars of the Pennsylvania Railroad. The same varnish, air dried, does not approach by many months the durability it has when baked.

8 The thought is suggested of further research work in better adapting such varnish for this particular practice of baking on wood. This would involve the introduction of some slow evaporating solvent into the varnish, which would not be dissipated in spraying, but require some time and heat to expel it. Meanwhile it might act to temporarily give a greater margin of safety against the two factors of danger, wrinkling and case hardening.

H. F. Payne.[5] The authors have carried to a successful conclusion, in a highly practical way, a problem in wood finishing which many said was impossible. The writer was able to show some time ago in a theoretical and small-scale experimental way that, given the wood in correct condition, the right oven facilities, and most important of all, some modern finishing materials, furniture could be finished in one day ready for rubbing the next day.

The finishing materials referred to dry more by polymerization than by oxidation. Heat is a well-known accelerator of polymerization, and polymerized films dry through, thereby eliminating the danger of surface hardening, with its detrimental after-effects of "sweating out." A nicely proportioned solvent is necessary to keep the film open long enough for the heat to penetrate the entire film; the coefficient of heat conductivity of a varnish film is quite low. The authors' statements regarding the necessity of maintaining a limited film thickness illustrates this point. In a thick film the top dries before the heat has reacted on the bottom of the film. The final penetration of heat and the drying of the bottom cause strains to be set up in the film, with consequent wrinkling. In this connection the type of oven is quite a factor. If the satisfactory results obtained by the authors could be attained in a box-type oven, with almost sudden application of the full heat, then, given a conveyor-type oven with gradual application of the heat, it has been the writer's experience that the process is more "foolproof," with less danger of wrinkling and particularly blistering. The authors' finding that blistering "is caused by the presence of volatile thinners imprisoned within a slightly heavier than medium coat of varnish" would suggest that the imprisoned thinners were not sufficiently good solvents for the film. The final evaporating thinner must not be just a "high boiler," but a true solvent, thereby keeping the film open.

The varnishes tested by Dr. Schuh were designed for baking and not air drying. The drying of these varnishes could have been accelerated in a number of ways, such as the manipulation of the cooking process, addition or change of catalysts or driers, and subjection of the drying film to the rays of a carbon-arc or mercury-vapor lamp. The use of the term "baking" would therefore have been more definite than "acceleration."

F. L. Browne.[6] Of the two papers dealing with wood finishing, the one by M. J. Pearce presents the point of view of the maker and seller of finishing materials, while the one by R. H. McCarthy and L. A. Lefcort presents that of a large user of such materials. The user in this case differs from most industrial purchasers of wood-finishing materials in one important respect. The Western Electric Company sells its telephone booths to an affiliated corporation that retains possession of them, and there-

[5] John L. Armitage & Co., Newark, N. J.

[6] Senior Chemist, Forest Products Laboratory, Forest Service, U. S. Department of Agriculture, maintained at Madison, Wis., in cooperation with the University of Wisconsin.

fore thinks of the durability of the finish in terms of maximum years of service at minimum expense for maintenance rather than in terms of initial appearance and sales arguments to impress purchasers. For that reason the conclusions reached by McCarthy and Lefcort deserve unusually serious consideration.

A reading of these two papers in sequence inspires comments from a point of view not specifically considered in either one of them. Pearce's paper surveys the great variety of finishing materials that are made available by their manufacturers and shows how their numbers have multiplied in recent years. It might reasonably be supposed that a new material distinctly better than an old one would force the old one from the market, while a new material not distinctly superior would make little headway. Experience shows, however, that new finishing materials often win a place for themselves, but rarely displace the old ones. In explanation of this curious tendency it is sometimes suggested that new materials are developed to meet an increasing diversity in requirements of the users. To the writer, at least, the argument is unconvincing; it seems more likely that the chief urge toward multiplication lies rather in the desire of raw-materials manufacturers to find new outlets for such basic products as nitro-cellulose, synthetic resins, and organic solvents and in the eagerness of makers of finishing materials to cater to the caprices of a market in which standards of value are not yet well defined.

To the woodworking industries this multiplication of finishing materials may be more of a menace than an opportunity. New materials usually offer certain advantages, but so far the improvements have nearly always been accompanied by serious disadvantages that must be taken carefully into consideration. Not only must the merits of the new material itself be determined, but its compatibility with the other finishing materials with which it is to be used must be established. At best, wood finishing is a complicated operation beset with many pitfalls. When the field of choice is broadened, the problem of wise selection becomes still more complex and the chance of an unwise choice is greater.

In revamping a finishing process the woodworker faces a major difficulty in the fact that a most important characteristic, the durability of the finish, has not heretofore been measurable by accepted laboratory or practical tests and must usually be determined by experience. In other words, the woodworker's customers often make his durability tests for him, and not infrequently they are also the durability tests for the maker of the finishing materials. Such testing by the ultimate consumer is economical enough as long as the results are satisfactory, but gives rise to a heavy charge against good will when a test turns out unfavorably. Since each change in a finishing process involves the hazard of a serious loss of reputation, the woodworker must be very conservative about making changes, and consequently has good reason to view the rapid development of new materials with some alarm.

The woodworker traditionally has relied upon craftsmanship for wood-finishing operations. Craftsmanship, however, has been breaking down rapidly under modern economic conditions and is being replaced only slowly by engineering control. For technical information about wood finishing the woodworker has turned more and more to the makers of finishing materials, so much so that the selling of finishing materials tends to become incidental to the furnishing of engineering service, with the cost of the service carried as overhead in the price of the materials. To the materials maker this arrangement is desirable as long as it remains profitable to him, because it makes the woodworker more dependent upon him and gives the large materials maker a decided advantage in competition with his smaller rival, who is less generously supplied with engineers and chemists. In the writer's opinion the woodworking industries will not gain the full benefit of technical service in dealing with their wood-finishing problems until they employ their own engineers more generally than is now the case.

Both Pearce and McCarthy and Lefcort show clearly that the dominant trend in wood-finishing development has been toward faster production schedules. Apparently durability has sometimes been sacrified to attain that end. The materials maker has sought to hasten finishing operations chiefly by developing products that dry more rapidly at ordinary room temperatures, which has led to the wood lacquers that yield a finish inferior to varnish in certain important respects. It is natural that the materials maker should approach the problem from that direction because he is interested primarily in the sale of materials rather than in redesigning equipment and processes that would be equally suitable for some other maker's materials.

McCarthy and Lefcort, however, show how the application of engineering knowledge from the woodworker's point of view achieves rapid production and simplification of procedure without resort to lacquer by designing equipment to take advantage of a property of some modern varnishes. The finishing process is accelerated so greatly that the production schedule can be set in accordance with convenience in plant operation rather than by the time required for coatings to dry.

Development of the new process involved three steps that required engineering knowledge rather than craftsmanship:

1 Establishment of laboratory tests to determine the relative serviceableness and durability of wood finishes
2 Design of a drying oven and determination of temperatures necessary to achieve sufficient acceleration of drying
3 Proof that the heat treatment is not injurious to the wood or to glued joints.

Varnish-drying kilns are by no means new in wood finishing, of course, but the temperatures and degree of acceleration attained are distinctly new, at least for articles as large and complicated as telephone booths. Furthermore, in varnish kilns of the past, control of humidity has always been considered necessary, usually in the belief that the rate of drying of varnish depends upon humidity as well as upon temperature. The writer has suspected, however, that the principal reason for controlling humidity was to hold the moisture content of the wood constant. The new process requires so little time that humidity control is not necessary to maintain the moisture content of the wood and is evidently unnecessary to secure thorough drying of varnishes of the type for which it is designed.

Speed in production is attained by McCarthy and Lefcort, not only by hastening varnish drying, but also by simplification of the finishing process. Staining and filling are done in one operation, two coats of varnish are applied, the surface is sanded, and finally rubbed with pumice and oil. When the number of operations are minimized, it is of course essential that each one of them be performed in exactly the right way, and therefore closer control of material, equipment, and operation is necessary than under a more complicated finishing schedule.

When engineering skill is applied more generally by the woodworking industries in dealing with their wood-finishing problems, the multiplicity of materials and complexity of processes will, in the writer's opinion, become greatly simplified. The notion that each woodworker's finishing problems are unique will give way to a realization that there are relatively few basic operations, the various combinations of which produce the different finishes in use. Means will be developed to determine unambiguously the relative merits and costs of the available finishes, so that the less desirable ones can be eliminated from practical consideration. New materials must then demonstrate their right to consideration, and if successful will usually displace the less satisfactory

ones. Changes in process rather than in materials may then play a more important part in future developments. The present uncomfortable plethora of materials may be reduced with advantage to the woodworker, the materials maker, and to the ultimate consumer.

Authors' Closure

By Mr. McCarthy. Mr. Kennedy has emphasized the use of synthetic resins in forced drying. As was stated, one of the three satisfactory varnishes had a natural resin base. While determining the amount of solvents liberated in the oven in order to serve as a basis for avoiding any possibility of combustible mixtures, the authors incidentally secured the following data concerning the mechanism of film drying and hardening. Test metal panels were spun and sprayed with a varnish of known solids and thinner content and were dried at room temperature for 30 min, and then placed in a laboratory oven for 60 min and weighed periodically. It was expected that the panels would at first decrease in weight due to loss of solvents, and then increase in weight due to oxygen absorption. Morrell[7] has reported that drying oils of the type used in varnishes increase their weight from 13 to 17 per cent upon exposure to air at room temperatures.

TABLE 3

	Film spun		Film sprayed	
Time, min.	Weight	Per cent	Weight	Per cent
0	0.71	100.0	1.21	100.0
5	0.54	80.3	1.08	89.3
10	0.50	70.4	1.01	83.5
15 (at 78 F)	0.45	63.3	0.94	77.7
20	0.42	59.2	0.89	73.6
25	0.39	54.9	0.84	69.4
30	0.37	52.1	0.81	67.0
60 (at 150 F)	0.31	43.7	0.53	43.8
90 (at 150 F)	0.31	43.7	0.53	43.8

Varnish analysis: Solids content, 43 per cent; thinner content, 57 per cent.

The data in Table 3 show that the varnish decreased in weight as expected until about 2 per cent higher than the value indicated by the initial analysis for solids. Apparently then the film had become sufficiently hard for sanding operations when only about one-third of the oxygen absorption that might be expected from a linseed-oil vehicle had taken place. The data indicate that completion of the oxidation process is not important to the hardening of the film, from the production standpoint.

The same data shed light on the much-discussed question of what happens when spraying varnish. Rather than retaining "only a small percentage of the solvents," practically all of it is retained in the passage between the spray gun and the panel, since the loss of weight of the film on the panel corresponds practically with the original solvent content shown in the varnish analysis.

Mr. Kennedy is quite correct in concluding that the accelerated process is not foolproof. Nevertheless it has been used successfully on a rather wide variety of special, high-grade woodwork in addition to the telephone booth, work requiring three and four coats of varnish and highly polished surfaces.

As Mr. Payne has pointed out, the word "accelerated" as used in this article is perhaps misleading, since it seems to have a technical meaning in connection with the formulation of the varnish. The authors intended it to describe a process which had been made faster.

The authors concur heartily with the opinions advanced by Dr. Browne. Wood finishing, at best, seems bound to be a highly complicated process because of the extreme variations or complexity of the materials involved—i.e., wood variability in structure, condition, surface preparation, color and variability of the natural ingredients of stains, sealers, and varnishes. A given finished appearance may frequently be secured by a hundred different procedures and formulations, some producing good results, some otherwise. Each of the different procedures is defended persistently, although many of the results are never examined critically by the producers and purchasers or the defects which develop are taken for granted. Thus there is thrown about the art a veil of complexity and deep mystery which even the large number of variables does not justify.

A.S.M.E. Record and Index, 1933

THIS section of the Transactions contains a record of the activities of The American Society of Mechanical Engineers for the year 1933, together with an index of its publications. It includes all the reference material likely to be of permanent value and of interest to future searchers. As an index it provides a means of locating the technical information in the Society's publications. It includes the separate indexes of the Transactions and *Mechanical Engineering*, together with a miscellaneous index to reports or other technical publications of the Society that have appeared during the year and a list of papers issued in mimeographed or similar form for meetings in 1933, but not published.

A considerable portion of the Record and Index is devoted to memorial notices of members who have died during the year. Special care has been given to the preparation of these brief biographies with the idea in mind that fitting attention should be given to significant events in the lives of deceased members, even though they may fall outside the immediate field of mechanical engineering.

COMMITTEE ON PUBLICATIONS

Harris & Ewing

ANDREY A. POTTER

PRESIDENT OF THE AMERICAN SOCIETY OF MECHANICAL ENGINEERS
1932–1933

Andrey A. Potter

ANDREY A. POTTER, dean of the Schools of Engineering of Purdue University, Lafayette, Ind., served as president of The American Society of Mechanical Engineers for the term 1932–1933.

Dean Potter was born in Vilna, Russia, on August 5, 1882, the son of Gregor and Rivza Potter. He came to the United States in 1897 and in 1903 was graduated from the Massachusetts Institute of Technology with the degree of B.S. He received his doctor's degree in engineering from Kansas State College in 1925.

Upon his graduation from M.I.T. Dean Potter entered the employ of the General Electric Company, at Schenectady, N. Y., during the early stages of the development of the steam turbine. He resigned in 1905 to become a teacher of engineering with the title of assistant professor of mechanical engineering at Kansas State College, where he was advanced to a full professorship in 1910 and to the position of dean and director of the engineering experiment station of that institution in 1913. Since 1920 he has been associated with Purdue University as dean of the Schools of Engineering, director of the engineering experiment station, and professor of power engineering.

From 1924 to 1931 Dean Potter also was advisory editor to Ginn & Co., and from 1928 to 1930 consulting expert to the Bureau of Education of the United States Department of the Interior. He was an associate member of the United States Naval Consulting Board from 1917 to 1919 and district educational director for the Committee on Education and Special Training of the War Department during 1918 and 1919. He is a pioneer in personnel work as applied to engineering colleges. Since 1910 he has served as a consulting engineer for utilities and industries in the field of power engineering.

Dean Potter became a member of the A.S.M.E. in 1912. His services to the Society include membership for five years on the Committee on Relations With Colleges; membership for three years on the Main Research Committee; chairmanship of the Indianapolis Section of the Society; representative on the Science Advisory Committee for the Century of Progress Exposition, Chicago, Ill., 1933; and representative for three years on the American Engineering Council.

In 1924–1925 Dean Potter was president of the Society for the Promotion of Engineering Education; in 1919–1920 president of the Kansas Engineering Society; in 1922–1923 president of the Indiana Engineering Society; in 1921–1922 vice-president and acting president of the Association of Land Grant Colleges; and in 1929–1930 chairman of the Engineering Section of the Association of Land Grant Colleges and Universities. From 1920 to 1933 he was a member at large of the Prime Movers Committee of the National Electric Light Association.

Dean Potter is an honorary member of the American Association of University Professors, a fellow of the American Association for the Advancement of Science, and a member of the honorary societies of Tau Beta Pi, Sigma Tau, Phi Kappa Phi, Sigma Xi, and Scabbard and Blade. He is the author of "Farm Motors," "Elements of Steam and Gas Power," "Engineering Thermodynamics," as well as of numerous articles which have been published in engineering and educational magazines.

Whither Engineering?

By A. A. POTTER

THINKING INDIVIDUALS and progressive social groups must reflect on the past and plan for the future, must take stock of their objectives and seek improved goals. The engineer must analyze his work, study trends, and adjust himself to changing conditions. He has in the past said little about his work and has infrequently concerned himself with public questions. It is timely for us to inquire, whither engineering? What are the thoughts, plans, and attitudes affecting our profession? If we know what is going on about us and what to do, let us consider the means by which we may best apply our knowledge and experience for the public good.

Our times are distinctive, owing to the introduction of science and engineering in the everyday affairs of everyday people. Whether civilized man likes it or not, he is destined to live and to work in an environment affected to an increasing extent by science and technology. While some blame the engineer for the sufferings of our times, the fact is that scientists and engineers should really be credited with the delivery of humanity from the so-called Malthusian doom. Whereas in past civilizations man had difficulty in producing enough to maintain himself above the level of mere existence, the engineer, by applying science to practical uses, assures an abundance of the world's goods for all, given only an effective mechanism of exchange. Present ills are not due to a lack of material wealth to satisfy human needs, but to our inability to distribute it rationally. However, our present problems, serious though they be, should not prove as difficult as those resulting from scarcity and want.

Also, it should be recognized that while the work of the engineer in improving methods of production has reduced employment in some specific cases, the engineer is primarily a creator both of wealth and of opportunities. By proper application of science he has created, during the past 65 years, where nothing was before, such giant industries as those which manufacture automobiles, typewriters, radios, talking machines, airplanes, and telephones, as well as new utilities which are concerned with electric communication, electric transportation, and electric light and power. These are creations, not developments. These are not displacing labor, but are adding new opportunities for profitable employment and happy careers for millions of people. It is reasonable to expect the engineer to develop new industries in the future as he has in the past, creating new opportunities, new jobs, and new careers. He knows what developments are needed and is able to direct the scientific researches and the manufacturing methods to produce results of value.

The engineer has contributed to the general welfare by reducing drudgery, by providing new entertainment, by saving time, and by increasing material possessions. His contributions are being fully appreciated, as to an increasing extent it is realized that America's predominant industrial position is due largely to the engineer. There is a general feeling, however, that he can make additional contributions by taking a greater interest in social and economic problems. Not that the engineer is a miracle worker who can bring about, through his own efforts, a perfect social order, but it is felt that, dealing as he does with facts rather than opinions, he should be able to help with the social problems affecting us. He is skilled in the proper use of science and machinery and is in a position to forestall movements likely to hinder invention and discovery or retard the introduction of improved methods. He may even be able to contribute, by his straight thinking, to a better solution of the social and economic problems which at present confront us.

The engineer has substituted knowledge for guesswork in dealing with technological problems. Has he the wisdom to apply the same straight thinking in his dealings with human relations, social welfare, economics, and finance? It is to be hoped that we are now standing on the verge of a new and better epoch, a period during which the actions of engineers as individuals and as members of a great profession will be influenced still more by clear thinking and by true measurements, and less by irrational opinions, prejudices, traditions, and precedents.

Even though the engineer may not be able to solve, offhand, the problems of human organization, where supposed social experts have apparently failed, it is high time that he seriously consider them. Having developed the necessary technique for almost unlimited production of wealth, he can no longer afford to stand aside while financiers, promoters, and politicians so tragically bungle the problem of its distribution. Primarily, engineering must deal with the technological problems of research, development, design, production, testing, and operation, yet the engineer is becoming more and more interested in finance and is to an increasing extent the directing head of industry and of public works; his success in financial, administrative, and executive posts may be attributed to his talent for dealing with the human phases of industry. He is beginning to interest himself in and to appreciate social and economic trends and is already taking his place among the leaders of our times. Engineers must think more, write more, and talk more on social and economic questions in order to assist in the solution of the major problems confronting humanity.

At the dedication of the Engineering Societies Building in 1907, Dr. Hadley, president of Yale University, said: "Let a man or group of men arise who can add to their technical knowledge a readiness to use that knowledge in the public service, and the people will be ready to put them in charge of affairs and follow their lead." If our profession is to maintain public leadership, we must conscientiously dedicate ourselves to public service and take our rightful places in the affairs of men. This we can do by giving major attention to the following:

Active Interest in Government and Politics

The engineer must actively interest himself in government and politics, realizing that his contributions to society may be lost without stable government. He must work for good government and for obedience to law, and must apply clear thinking and courageous action to public questions. Furthermore, members of our profession must stand for elective public offices and campaign on well-thought-out policies of action, because a democratic state depends upon participation by the ablest of its citizens in political affairs. Perhaps the greatest contribution of engineers, politically, will come through their familiarity with the technological problems which arise in our civilization, since the government of our cities, states, and nation is very largely concerned with engineering matters.

In these days when unrest is too prevalent to be ignored, the greatest need of this or any democratic government is men and women in political office who think logically, conclude honestly, and act courageously. There is a grave danger that in the present

Presidential Address delivered at the Annual Meeting, New York, N. Y., Dec. 4 to 8, 1933, of The American Society of Mechanical Engineers.

popular and indiscriminating demand for economy and for reduced taxes our cultural advance, our educational system, and our social institutions may be seriously crippled. When we realize that the total cost of maintaining activities indispensable to national welfare, such as education, public health, national defense, good roads, police protection, and scientific research, is less than that which we spend for amusements, cosmetics, and tobacco, we gain perspective in social values. In many localities education, which is our hope for the future and our main bulwark against unwise changes, is being sacrificed to extravagances in governmental activities. This can be remedied only by insisting upon a higher type of political office holder. Education cannot be postponed or its effectiveness reduced without great penalties in the future. It should also be recognized that the consumer demand of two and a half million Americans is fixed every year, and the schools influence the upper limit of nearly half of these; to close or to impoverish our schools is to dry up our markets for a generation at least, a market which can be developed through schools—more schools—better schools. Industry, jobs, and prosperity depend upon customers and the will to have; the determination to be a customer depends upon education. Similarly, reduction of the essentials for national defense, police protection, public health, and research will prove costly in the days to come. The engineers owe it to themselves and their country to utilize their habits of analytical thought in the solution of public questions. In this they must maintain the same regard for truth and fairness as when they deal with their professional problems.

Contributions to Social Welfare and Economic Readjustment

Before the engineer can take his rightful place in the affairs of the nation and contribute most effectively to social welfare and economic readjustment, we, as a professional body, must take an active and leading part in engineering education, insisting on definite educational standards as a qualification for membership. As engineers we have taken little active part in shaping or in directing engineering education, and our engineering schools have not had the serious backing of the engineering profession. What aid has been given to engineering education by engineers has been largely individual and unofficial, and has not represented the concerted thought or the unified action of the profession. It may be expected that the Engineers' Council for Professional Development, representing as it does the leading engineering societies and with its program definitely focused upon the educational preparation of the engineer, will take a definite stand which will insure that the engineer of tomorrow will be fully prepared to take advantage of the new opportunities and responsibilities which are bound to be his. The Engineers' Council for Professional Development provides an opportunity for The American Society of Mechanical Engineers, and for the other major engineering societies as well, to take a leading part in improving the educational preparation of the engineer. However, it must be realized that reports and recommendations of this Council will not improve the engineering profession without the unified cooperative action of the engineering societies, engineering colleges, and licensing agencies of the various states. The American Society of Mechanical Engineers will, I trust, lead in backing the reports of the Engineers' Council for Professional Development. In the end we may expect that recognition of professional attainment on the basis of education and actual achievement, as tested by examinations, will be substituted for the present haphazard methods of certifying to Society membership. Then we shall find that membership in a society such as ours will unqualifiedly admit to good standing in the great profession of engineering.

At the annual meeting of this Society exactly forty years ago, E. B. Coxe, in his presidential address, decried the tendency of engineering educators to magnify the differences between civil, electrical, mechanical, mining, and other branches of the engineering profession. Unfortunately, this condition still persists, although in practice the work of the engineer is organized largely along the functional lines of research, design, production, operation, and sales, rather than the fields indicated by our engineering societies. Undoubtedly there is still a definite need to revise the engineering programs of study so that the young engineer may have a keener interest in the engineering profession as a whole.

Engineering education is now confronted with two radically different requirements. There is, on the one hand, a very definite demand for engineers particularly well prepared in science, mathematics, and technology. At the same time, engineering colleges are urged to give more attention to social sciences. The demand for a more thorough scientific preparation comes from a realization that the major achievements of our profession can only result when the engineer has sufficient preparation to make full use of the foundations laid by pure science, mathematics, and engineering. The pressure brought to bear upon engineering colleges for more social science comes from an appreciation of the fact that the technical graduate lands flat-footed in a world of men with whom he must cope and cooperate, and sadly needs such knowledge as is available regarding the organization of men into society.

In considering the preparation of the engineer, or, in fact, any educational problem, we must keep two things clearly in mind: In the first place, education is an opportunity to gain knowledge, resulting, we like to think, in greater wisdom. But education is not a guarantee of happiness or wealth or position or security or anything else. In the second place, no amount of education or special training will make two people of unequal talent equal. Leaders are not developed from people naturally inclined to follow. The most any educational program can do is to assist the students to attain the highest level which their natural endowment allows. Mentally and temperamentally, men differ far more than in their physical make-ups, and these differences, being inborn, cannot be overcome by education. When by a fortunate combination of natural ability, environment, and industry a technical graduate proves a leader, a driving force in our profession, we are all apt to class as failures all those less fortunately equipped who suffer by comparison, and are inclined to ascribe the inability of some to reach their goal, or the position desired for them by relatives or friends, to the educational system. Straight-thinking people will not make this error, but will remember that not every freshman entering college is even potentially endowed with the leadership of a Napoleon, the technology of a Steinmetz, the scientific prowess of an Einstein, the inventive genius of an Edison, or the wisdom of a Solomon; most people must derive such consolation as may be had from the reflection that society needs a goodly supply of earnest, conscientious, industrious, painstaking followers who, after all, assume the burden of the world's work. These qualities, together with worthy ideals of character and conduct, we may properly expect educators to stress in all their contacts with students. We may also expect such an environment in college that the student will be imbued with a keen interest in knowledge and a continuing desire for its achievement.

Aside from preparation for a career, engineering education is the modern type of general liberal education, acquainting the learner, as it does, with the processes, devices, and methods which make our civilization distinctive. Cultured people are those who understand their environment—the world in which they live—and no type of education so directly assists the individual to understand his surroundings as engineering educa-

tion, which familiarizes one with the machines and the techniques of the modern world. So we of the engineering profession as well as the public at large are interested in making engineering education more effective as a preparation for happy living. As Herbert Spencer stated, "To prepare us for complete living is the function which education has to discharge." This applies to engineering as well as to other types of education.

Some of the graduates of engineering colleges should be given encouragement to continue their preparation for engineering as a career, but a much larger number should be assisted in entering non-engineering vocations with engineering education and possibly even with some engineering practice as a foundation. There is a definite need for clear-thinking and fact-finding technique in the professional, economic, business, and political fields.

A.S.M.E. Stand on Present-Day Problems

Present conditions make new demands upon a professional group. Our own society must assume leadership in the field of mechanical engineering, taking a definite stand in connection with the problems which are confronting our country and our profession. To be specific:

(*a*) The American Society of Mechanical Engineers must discourage the present movement to replace machine processes by hand labor. During recent months an effort has been made to decry capital expenditures, to urge the substitution of human and animal labor for mechanical power and machinery, and to hinder economical methods of production. The present will not be improved and the future will be greatly impoverished if this type of thinking prevails. Surely, we cannot have too many or too effective devices for relieving men from drudgery or for supplying human beings with more comforts. It may be recalled that during the years of greatest prosperity millions of people, even in this most favored land, lacked many of the material comforts which are essential for well-being and happiness. We are far from the saturation point in our need to utilize science and engineering.

(*b*) Our Society must take the lead in the stabilization of the so-called durable-goods or capital-goods industries. In 1928 more than half of the industrial workers of the country were engaged in these industries, which comprise tool making, machine making, power production, equipment manufacture, construction, and the development of the heavy industries such as iron and steel, coal, copper, and oil. Activity in these industries is absolutely essential to insure the welfare of a highly industrialized land such as ours. At the same time, however, care must be taken not to have industry over-tooled for the production of the market demand for consumers' goods, and it is clearly within the province of a Society such as ours to aid in the preparation and dissemination of accurate statistics regarding production capacity and consumer demand.

(*c*) The American Society of Mechanical Engineers must lead in a policy of rational distribution of the leisure dividends of quantity production. To this end it should encourage investigations of the shorter work week, not only for the manual workers but for the clerical, engineering, and executive staffs as well. Perhaps consumer demand may be fully satisfied with fewer man-hours of work and the resulting leisure more equitably divided than is now the case. Also we should cooperate individually and through our Sections with the adult-education programs in the different parts of our land and should definitely become exponents of cultural advance.

(*d*) Our Society should give even greater attention than it does now, in its publications and in its meetings, both national and local, to discussions and papers which are definitely concerned with the scientific, technological, social, and economic problems of the present industrial age. Among the most important of these are the art of industrial management, correlation of agriculture and industry, re-estimating fundamental social values, and aesthetic objectives in engineering design. The engineering society must be constantly contributing to public welfare and must be working to widen the horizon and to enlarge the usefulness of the engineer, so that he may be better prepared to render broad and effective service.

(*e*) The American Society of Mechanical Engineers must keep in close touch with science, as the great engineering achievements of the future will definitely depend upon more scientific knowledge. It must aid in scientific research, in the development of rational designs, in national and international standardization, and in the perfection of labor-liberating machinery to ease the burdens of everyday living.

Unifying the Engineering Profession

Said Sir Francis Bacon more than 300 years ago: "I hold every man a debtor to his profession; from the which as men of course do seek to receive countenance and profit, so ought they of duty to endeavor themselves by way of amends to be a help and ornament thereto." Can we today better define the relation of the individual to his profession? Can we as a society hold to a higher objective than the fostering of this attitude?

It is gratifying that our own society has always reviewed its own accomplishments with a critical eye and has promptly moved forward in the line of progress. Among the recent advances may be mentioned its leadership in coordinating the joint activities of the engineering profession, its interest in human and economic problems, evidenced by the Society publications, its activity in the stimulation of the capital-goods industries, and its initiative in organizing the Engineers' Council for Professional Development.

The engineering profession must be unified in its viewpoint, thought, and action. Engineers must assume professional status individually and collectively. An individual becomes a professional man when he regards himself as a public servant first and as a private practitioner second. A society like The American Society of Mechanical Engineers becomes a professional body when, and only when, the conscious object of public service underlies all of its actions. Codes of professional conduct and concerted action in matters of general interest will help to focus the attention of the members of a professional group upon the public aspects of their calling; perhaps the individualistic attitude of some persons may even be changed by the effective public opinion of their peers, thus unifying the engineering profession in its efforts for the public weal.

Until recently the engineer has been an individualist who surveyed, designed, constructed, tested, and operated public works, machines, and tools, and gave little attention to the wider significance of his work or to his social responsibilities. He has worked within the confines of his own field and has had no sense of professional responsibility; neither has he appreciated the strength potential in cooperation among engineers. He has usually joined a professional society when it appeared that his immediate interest would be served, and this in turn has compelled the engineering societies to devote first attention to serving the member's immediate needs, that is, to provide for his technological advance. Gradually this attitude has changed—has given way to the larger conception of an engineering profession; and it only remains for us to consolidate the gains, realizing in formal unified organization the progress already achieved, and to prepare for a rapid further advance.

The work of the engineer is not of recent origin; his contributions date back to the earlier periods of human history, and antedate some callings which have long enjoyed professional

standing. Members of the professions of religion, law, and medicine received public recognition when among themselves they realized the public character of their work and developed principles of action or codes of ethics. Engineers must think, act, and appear as a unified and well-coordinated group; a well-knit and well-integrated solid body, not as a collection of individuals, each going his separate way; nor can the profession be properly represented by several distinct societies going their separate ways. This is the time for definite action to perfect the unity and solidarity of our profession, and I am glad that the Founder Engineering Societies are now working on this important problem. We may expect that their efforts will result in some form of central agency, competent to deal with the joint activities of all engineering societies and to pass upon questions of general import without, however, interfering with the technical field or with the autonomy of the various engineering groups. Engineers have been credited with outstanding success in organizing industrial projects of great magnitude; let us now utilize some of the ability displayed in this work to unify and coordinate our professional advance.

Unifying the engineering profession will enable us to work more effectively on public questions of truly national scope. A central national agency should soon be supplemented by regional or state joint committees to assist governmental authorities in the solution of economic, social, political, and other policy-planning programs. Such groups, composed of engineers, informed and alert, can do the things needful to help governmental agencies in dealing with public questions and particularly with those which have technological aspects.

Whither Engineering?

Whither Engineering? Inevitably toward public service—toward the ideal that the engineer is a public official, charged first with a public function, as a lawyer is an officer of the court, responsible for its dignity and honor. Inevitably toward a wider responsibility—toward the ideal that he is responsible for maintaining that balance in the social structure which modern conditions have sometimes so violently upset. Inevitably toward active participation in political affairs where clear thinking and courageous action are badly needed. Inevitably toward a higher type of education—toward the ideal that men shall appreciate their time and understand its trend. Inevitably toward a more closely knit professional organization and a more pronounced professional consciousness—toward the ideal that the wider duties and greater responsibilities of our calling may be met promptly and effectively.

The American Society of Mechanical Engineers

THE personnel records and other information presented in this section of the Record and Index refer, except where otherwise noted, as in the case of Local Section and Student Branch chairmen, to the official year beginning in December, 1932. Such information is purely of historical nature and is included here as a permanent record. Further information may be secured from the Office of the Society.

Officers and Council[1]

Vermont, Univ. of, Burlington, Vt.	E. L. Sussdorff
Villanova College, Villanova, Pa.	J. S. Morehouse
Virginia Polytechnic Inst., Blacksburg, Va.	N. W. Conner
Virginia, Univ. of, University, Va.	H. C. Hesse
Washington, State College of, Pullman, Wash.	F. W. Candee
Washington Univ., St. Louis, Mo.	E. H. Sager
Washington, Univ. of, Seattle, Wash.	B. T. McMinn
West Virginia Univ., Morgantown, W. Va.	L. D. Hayes
Wisconsin, Univ. of, Madison, Wis.	B. G. Elliott
Worcester Polytechnic Inst., Worcester	M. L. Price
Wyoming, Univ. of, Laramie, Wyo.	R. S. Sink
Yale Univ., New Haven, Conn.	S. W. Dudley

[12] Resigned August 22, 1932. E. G. DeCoriolis appointed to complete term.

[13] In office December 31, 1933.

Awards

The following paragraphs deal with the awards, scholarships, and loan funds which come within the jurisdiction of the A.S.M.E. The Society also participates with other engineering societies in a number of joint awards, a brief statement regarding which will be found on page 49.

Honorary Membership, to which persons of acknowledged professional eminence are elected by unanimous vote of Council under the provisions of the By-Laws and Rules. A list of honorary members is given on page 16.

Life Membership, which may be conferred by the Council for distinguished service to the Society; or secured by a member by payment for an annuity in accordance with the provisions of the By-Laws.

A.S.M.E. Medal, established by the Society in 1920 to be presented for distinguished service in engineering and science. May be awarded

for general service in science having possible application in engineering.

Holley Medal, instituted and endowed in 1924 by George I. Rockwood, Past Vice-President of the Society, to be bestowed for some great and unique act of genius of engineering nature that has accomplished a great and timely public benefit.

Worcester Reed Warner Medal, provision for which was made in the will of Worcester Reed Warner, Honorary Member of the Society, is a gold medal to be bestowed on the author of the most worthy paper received, dealing with progressive ideas in mechanical engineering or efficiency in management.

Melville Medal, established in 1914 by the bequest of Rear-Admiral George W. Melville, Honorary Member and Past-President of the Society, to be presented for an original paper or thesis of exceptional merit, presented to the Society for discussion and publication, to encourage excellence in papers. The medal may be presented annually.

Spirit of Saint Louis Medal, endowed by members of the Society and citizens residing in St. Louis, Mo., to be awarded for meritorious service in the field of aeronautical engineering. This medal will be awarded at the discretion of the Council of the Society at approximately three-year periods upon the recommendation of a Spirit of Saint Louis Medal Board of Award made up of six members, each appointed for a term of nine years and the terms of two members expiring at each three-year period. The St. Louis Section and the Aeronautic Division will each be responsible for the nomination of three members.

Junior Award, annual cash award of $50, established in 1914, from a fund created by Henry Hess, Past Vice-President of the Society, to be presented, together with an engraved certificate, for the best paper or thesis submitted by a Junior Member.

Student Awards, two annual cash awards of $25 each, established in 1914, from a fund created by Henry Hess, Past Vice-President of the Society, to be presented, together with engraved certificates, for the best papers or theses submitted by members of Student Branches.

Charles T. Main Award, annual cash award of $150, established in 1919 from a fund created by Charles T. Main, Past-President of the Society, to be awarded to a student of engineering, preferably a member of a Student Branch of the Society, for the best paper within the general subject of the "Influence of the Profession Upon Public Life." The exact subject is assigned by the Committee on Awards, subject to the approval of the Council, and is announced each year through the Honorary Chairmen of the Student Branches.

SCHOLARSHIPS AND LOAN FUNDS

Max Toltz: Loan Fund of $15,000 established by Major Max Toltz, former member of the Council of the Society, the income to be used for assistance to students.

John R. Freeman: Fund of $25,000 established in 1926 by John R. Freeman, Past-President of the Society, the income to be used for travel scholarships and research.

Woman's Auxiliary: Scholarship or Fellowship offered by the Woman's Auxiliary to the Society to assist sons and daughters of members or worthy students of mechanical engineering.

RECIPIENTS OF AWARDS

The names of the recipients of the different awards to date are given in the following lists, together with the dates of presentation, and the services or papers for which the awards were made. There were no awards for the years not listed.

A.S.M.E. Medal

1921 Hjalmar Gotfried Carlson, in recognition of the services rendered the Government because of his invention and part in the production of 20,000,000 Mark III drawn steel booster casings used principally as a component of 75-mm high-explosive shells, but also used extensively in gas shells and bombs

1923 Frederick Arthur Halsey, for his paper describing the premium system of wage payments presented before the Society at the Providence Meeting in 1891, as the adoption of the methods there proposed has had a profound effect toward harmonizing the relations of worker and employer

1923 John Ripley Freeman, for his eminent service in engineering and manufacturing by his meritorious work in fire prevention and the preservation of property

1926 R. A. Millikan, in recognition of his contributions to science and engineering

1927 Wilfred Lewis, for his contributions to the design and construction of gear teeth

1928 Julian Kennedy, for his services and contributions to the iron and steel industry

1929 William LeRoy Emmet, for his contributions in the development of the steam turbine, electric propulsion of ships, and other power-generating apparatus

1931 Albert Kingsbury, for his research and development work in the field of lubrication

1933 Ambrose Swasey, for his contributions to the advancement of the engineering profession and for his part in the development of the turret lathe and the astronomical telescope.

Holley Medal

1924 Hjalmar Gotfried Carlson, for his inventions and processes which made possible the timely production of drawn steel booster casings for artillery ammunition, thereby aiding victory in the World War

1928 Elmer Ambrose Sperry, for achievements and inventions that have advanced the naval arts, including the gyroscope that has freed navigation from the dangers of the fluctuating magnetic compass

1929 Baron Chuzaburo Shiba, for his contributions to knowledge through fundamental research, including the field of aerodynamics, by the development of ultra-rapid kinematographic methods.

Worcester Reed Warner Medal

1933 Dexter S. Kimball, for his contributions to efficiency in management as exemplified by his recently revised "Principles of Industrial Organization" and by his many articles, engineering society papers, and public addresses.

Melville Medal

1927 Leon P. Alford, "Laws of Manufacturing Management"

1929 Joseph Wickham Roe, "Principles of Jig and Fixture Practice"

1930 Herman Diederichs and William D. Pomeroy, "The Occurrence and Elimination of Surge or Oscillating Pressure in Discharge Lines From Reciprocating Pumps"

1931 Arthur E. Grunert, "Comparative Performance of a Pulverized-Coal-Fired Boiler Using Bin System and Unit System of Firing"

1932 Alexey J. Stepanoff, "Leakage Loss and Axial Thrust in Centrifugal Pumps"

1933 William E. Caldwell, "Characteristics of Large Hell Gate Direct-Fired Boiler Units."

Spirit of Saint Louis Medal

1929 Daniel Guggenheim, founder of the Guggenheim Fund for the Promotion of Aeronautics

1932 Paul Litchfield, for his work in encouraging and sponsoring airship design and construction in this country.

Junior Award

1915 Ernest O. Hickstein, "Flow of Air Through Thin Plate Orifices"

1916 L. B. McMillan, "The Heat Insulating Properties of Commercial Steam-Pipe Coverings"

1919 E. D. Whalen, "Properties of Airplane Fabrics"

1921 S. Logan Kerr, "Moody Ejector Turbine"

1922 R. H. Heilman, "Heat Losses From Bare and Covered Wrought-Iron Pipe at Temperatures up to 800 Degrees Fahrenheit"

F. L. Kallam, "Preliminary Report on the Investigation of the Thermal Conductivity of Liquids"

1923 S. S. Sanford and S. Crocker, "The Elasticity of Pipe Bends"

1924 R. H. Heilman, "Heat Losses Through Insulating Material"

1925 Gilbert S. Schaller, "An Investigation of Seattle as a Location for a Synthetic Foundry Industry"

1927 Wm. M. Frame, "Stresses Occurring in the Walls of an Elliptical Tank Subjected to Low Internal Pressure"

1928 M. D. Aisenstein, "A New Method of Separating the Hydraulic Losses in a Centrifugal Pump"

1929 Arthur M. Wahl, "Stresses in Heavy Closely Coiled Helical Springs"

1930 Ed Sinclair Smith, Jr., "Quantity-Rate Fluid Meters"

1931 M. K. Drewry, "Radiant-Superheater Developments"

1932 Edmond M. Wagner, "Frictional Resistance of a Cylinder Rotating in a Viscous Fluid Within a Coaxial Cylinder"

1933 Townsend Tinker, "Surface Condenser Design and Operating Characteristics."

STUDENT AWARD

1916 BOYNTON M. GREEN, Stanford University, "Bearing Lubrication"
HOWARD STEVENS, Rensselaer Polytechnic Institute, "An Investigation of the Dynamic Pressure on Submerged Flat Plates"
M. ADAM, Louisiana State University, "The Adaptability of the Internal Combustion Engine to Sugar Factories and Estates"

1917 H. R. HAMMOND and C. W. HOLMBERG, Pennsylvania State College, "Study of Surface Resistance With Glass as the Transmission Medium"

1919 C. F. LEH and F. G. HAMPTON, Stanford University, "An Experimental Investigation of Steel Belting"
W. E. HELMICK, Stanford University, "An Experimental Investigation of Steel Belting"

1920 HOWARD G. ALLEN, Cornell University, "Wire Stitching Through Paper"

1921 KARL H. WHITE, University of Kansas, "Forces in Rotary Motors"
RICHARD H. MORRIS and ALBERT J. R. HOUSTON, University of California, "A Report Upon an Investigation of the Herschel Type of Improved Weir"

1923 CHARLES F. OLMSTEAD, University of Minnesota, "Oil Burning for Domestic Heating"
H. E. DOOLITTLE, University of California, "The Integrating Gate: A Device for Gaging in Open Channels"

1924 GEORGE STUART CLARK, Stanford University, "Two Methods Used for the Determination of the Gasoline Content of Absorption Oils in Absorption Plants"
L. J. FRANKLIN and CHARLES H. SMITH, Stanford University, "The Effect of Inaccuracy of Spacing on the Strength of Gear Teeth"

1925 HARRY PEASE COX, JR., Rensselaer Polytechnic Institute, "A Study of the Effect of End Shape on the Towing Resistance of a Barge Model"
W. S. MONTGOMERY, JR., and E. RAY ENDERS, JR., Pennsylvania State College, "Some Attempts to Measure the Drawing Properties of Metals"

1926 R. E. PETERSON, University of Illinois, "An Investigation of Stress Concentration by Means of Plaster of Paris Specimens"
CECIL G. HEARD, University of Toronto, "Pressure Distribution over U. S. A. 27 Aerofoil With Square Wing Tips Model Tests"

1927 ALFRED H. MARSHALL, Princeton University, "Evaporative Cooling"
ROGER IRWIN EBY, University of Washington, "Measurement of the Angular Displacement of Flywheels"

1928 CLARENCE C. FRANCK, Johns Hopkins University, "Condition Curves and Reheat Factors for Steam Turbines"

1929 FRANK VERNON BISTROM, University of Washington, "An Investigation of a Rotary Pump"
WILLIAM WALLACE WHITE, University of Washington, "An Investigation of a Rotary Pump"

1930 GERARD EDEN CLAUSSEN, Polytechnic Institute of Brooklyn, "High-Temperature Oxidation of Steel"
HAROLD L. ADAMS and RICHARD L. STITH, University of Washington, "A Wind Tunnel for Undergraduate Laboratory Experiments"

1931 JULES PODNOSSOFF, Polytechnic Institute of Brooklyn, "Pressure and Energy Distribution in Multi-Stage Steam Turbines Operating Under Varying Conditions"

1932 H. E. FOSTER, JR., University of Tennessee, "Factors Affecting Spray Pond Design"
WILLIAM A. MASON, Stanford University, "An Experimental Investigation of the Flame Propagation in Internal-Combustion Engines"

1933 HUGO V. CORDIANO, Polytechnic Institute of Brooklyn, "Thermal Analysis of the Lithium-Magnesium System of Alloys"
JAMES A. OSTRAND, JR., Princeton University, "Sudden Enlargement in the Open Channel."

CHARLES T. MAIN AWARD

1925 CLEMENT R. BROWN, Catholic University of America. Subject: "The Influence of the Locomotive on the Unity of the United States"

1926 W. C. SAYLOR, Johns Hopkins University. Subject: "The Effect of the Cotton Gin Upon the History of the United States During Its First Seventy Years"

1927 No award. Subject: "Scientific Management and Its Effect Upon the Industries"

1928 ROBERT M. MEYER, Newark College of Engineering. Subject: "Scientific Management and Its Effect Upon Manufacturing"

1930 JULES PODNOSSOFF, Polytechnic Institute of Brooklyn. Subject: "The Value of the Safety Movement in the Industries"

1931 ROBERT E. KLISE, University of Michigan. Subject: "Interchangeability—Its Development and Significance in Industry"

1932 MARSHALL ANDERSON, University of Michigan. Subject: "Apprenticeship and Vocational Training"

1933 GEORGE D. WILKINSON, JR., Newark College of Engineering. Subject: "Progress in the Prevention of Smoke and Atmospheric Pollution."

FREEMAN TRAVEL SCHOLARSHIP

1927 HERBERT N. EATON and BLAKE R. VAN LEER
1929 ROBERT T. KNAPP
1931 REGINALD WHITAKER
1932 G. ROSS LORD.

Past-Presidents

A list of past vice-presidents, managers, treasurers, and secretaries will be found in the 1930 Record and Index, pages 10–12. Dates in parentheses denote year of death.

ALEXANDER LYMAN HOLLEY, *Chairman of the Preliminary Meeting for Organization of The American Society of Mechanical Engineers* (1882)

1880–1882 ROBERT HENRY THURSTON (1903)
1883 ERASMUS DARWIN LEAVITT (1916)
1884 JOHN EDSON SWEET (1916)
1885 JOSEPHUS FLAVIUS HOLLOWAY (1896)
1886 COLEMAN SELLERS (1907)
1887 GEORGE H. BABCOCK (1893)
1888 HORACE SEE (1909)
1889 HENRY ROBINSON TOWNE (1924)
1890 OBERLIN SMITH (1926)
1891 ROBERT WOOLSTON HUNT (1923)
1892 CHARLES HARDING LORING (1907)
1893–1894 ECKLEY BRIXTON COXE (1895)
1895 EDWARD F. C. DAVIS (1895)
1895 CHARLES ETHAN BILLINGS (1920)
1896 JOHN FRITZ (1913)
1897 WORCESTER REED WARNER (1929)
1898 CHARLES WALLACE HUNT (1911)
1899 GEORGE WALLACE MELVILLE (1912)
1900 CHARLES HILL MORGAN (1911)
1901 SAMUEL T. WELLMAN (1919)
1902 EDWIN REYNOLDS (1909)
1903 JAMES MAPES DODGE (1915)
1904 AMBROSE SWASEY
1905 JOHN RIPLEY FREEMAN (1932)
1906 FREDERICK WINSLOW TAYLOR (1915)
1907 FREDERICK REMSEN HUTTON (1918)
1908 MINARD LAFEVER HOLMAN (1925)
1909 JESSE MERRICK SMITH (1927)
1910 GEORGE WESTINGHOUSE (1914)
1911 EDWARD DANIEL MEIER (1914)
1912 ALEXANDER CROMBIE HUMPHREYS (1927)
1913 WILLIAM FREEMAN MYRICK GOSS (1928)
1914 JAMES HARTNESS
1915 JOHN ALFRED BRASHEAR (1920)
1916 DAVID SCHENCK JACOBUS
1917 IRA NELSON HOLLIS (1930)
1918 CHARLES THOMAS MAIN
1919 MORTIMER ELWYN COOLEY
1920 FRED J. MILLER
1921 EDWIN S. CARMAN
1922 DEXTER SIMPSON KIMBALL
1923 JOHN LYLE HARRINGTON
1924 FREDERICK ROLLINS LOW
1925 WILLIAM FREDERICK DURAND
1926 WILLIAM LAMONT ABBOTT
1927 CHARLES M. SCHWAB
1928 ALEX DOW
1929 ELMER AMBROSE SPERRY (1930)
1930 CHARLES PIEZ (1933)
1931 ROY V. WRIGHT
1932 CONRAD N. LAUER
1933 A. A. POTTER

A.S.M.E. Representatives on Other Activities

The A.S.M.E. is also represented on a number of special boards and on many committees of other organizations. Dates in parenthesis denote expiration of terms.

AMERICAN ASSOCIATION FOR THE ADVANCEMENT OF SCIENCE

SECTION M, ENGINEERING

W. S. Monroe (1933) Ralph Earle (1933)

Representatives appointed annually from locality in which meeting is to be held.

AMERICAN ENGINEERING COUNCIL

Terms expire January 1, 1934	*Terms expire January 1, 1935*
L. P. Alford	B. M. Brigman
Paul Doty	W. S. Conant
C. E. Ferris	Hugo Diemer
R. E. Flanders	W. A. Hanley
E. C. Hutchinson	Ernest Kreher
C. N. Lauer	G. E. Pellissier
J. H. Lawrence	J. W. Roe
R. C. Marshall, Jr.	B. R. Van Leer
A. A. Potter, *Chairman*	T. R. Weymouth
W. H. Trask, Jr.	D. Robert Yarnall, *Vice-Chairman*

AMERICAN SOCIETY OF SAFETY ENGINEERS

ENGINEERING SECTION, NATIONAL SAFETY COUNCIL

H. W. Mowery Ernest Hartford

AMERICAN STANDARDS ASSOCIATION

C. M. Chapman (1933)
K. H. Condit (1934)
C. B. LePage, C. W. Spicer, V. R. Willoughby (*Alternates (Serve one year)*)

THE ENGINEERING FOUNDATION

D. Robert Yarnall (1934) E. R. Fish (1935)[14]
A. E. White (1936)

ENGINEERING SOCIETIES EMPLOYMENT SERVICE

NATIONAL BOARD

Calvin W. Rice, *Chairman*

ENGINEERS' COUNCIL FOR PROFESSIONAL DEVELOPMENT

C. F. Hirshfeld J. H. Lawrence
W. E. Wickenden

NATIONAL RESEARCH COUNCIL

DIVISION OF ENGINEERING AND INDUSTRIAL RESEARCH

D. S. Jacobus (1936)[15] Herman Diederichs (1933)
W. D. Ennis (1935)[16] Albert Kingsbury (1934)

Calvin W. Rice, *Ex-Officio*

UNITED ENGINEERING TRUSTEES, INC.

E. R. Fish (1934) W. L. Batt (1935)
H. V. Coes (1936)

U.E.T. COORDINATION COMMITTEE OF ENGINEERING SOCIETIES

D. S. Kimball R. I. Rees
John Lyle Harrington

[14] A.S.M.E. representative from Board of United Engineering Trustees, Inc.
[15] Special member appointed June, 1933.
[16] Transferred from membership at large of Division of Engineering and Industrial Research, upon its reorganization in April, 1933.

Exchange of Courtesies

Special arrangements have been made between the A.S.M.E. and the following organizations whereby their members will be mutually accorded such courtesies as the use of reading and writing rooms, assistance in securing general information and in arranging to visit industrial plants, receipt of mail, etc.

OUTSIDE THE UNITED STATES

Austria—Vienna: Osterreichischer Ingenieur und Architekten Verein;
Belgium—Bruxelles: Federation des Associations Belges d'Ingenieurs. Société Belge des Ingenieurs et des Industriels.
Canada—Montreal: The Engineering Institute of Canada.
Cuba—Havana: Sociedad Cubana de Ingenieros.
Czechoslovakia—Prague: Association of Czechoslovakian Engineers and Architects in Praha; Masarykova Akademie Prace; Spolek Ceskoslovenskych Inzenyru.
Denmark—Copenhagen: Dansk Ingeniorforening.
England—London: British Association for the Advancement of Science; British Engineering Standards Association; British Engineers Association; Chemical Society; The Institute of Fuel; The Institute of Marine Engineers; The Institute of Metals; The Institution of Automobile Engineers; The Institution of Civil Engineers; The Institution of Electrical Engineers; The Institution of Engineering Inspection; The Institution of Mechanical Engineers; The Institution of Mining Engineers; Institution of Naval Architects; The Institution of Structural Engineers; International Electrotechnical Commission; The Iron and Steel Institute; Junior Institution of Engineers; The Royal Aeronautical Society; The Society of Engineers.
Newcastle-on-Tyne: North East Coast Institution of Engineers and Shipbuilders; North of England Institute of Mining and Mechanical Engineers.
South Kensington: Newcomen Society.
France—Paris: l'Association Technique Maritime et Aeronautique; Société des Ingènieurs Civils de France; Société Francaise des Electriciens.
Germany—Berlin: Verein deutscher Ingenierue.
Italy—Rome: Sindacato Nazionale Fascista delgi Ingegneri.
Japan—Tokyo: Kogakkai.
Mexico—Mexico City: Asociacion de Ingenieros y Arquitectos de Mexico.
Netherlands—The Hague: Koninklijk Instituut van Ingenieurs.
Norway—Oslo: Den Norske Ingeniorforening.
Scotland—Glasgow: Institution of Engineers and Shipbuilders in Scotland.
South Africa—Johannesburg: South African Institution of Engineers.
South America—Colombia: Sociedad Colombiana de Ingenieros.
Sweden—Stockholm: Svenska Teknologforeningen.
Switzerland—Winterthur: Verein Schweizerischer Maschinen-Industrieller.

UNITED STATES

California—Los Angeles: Engineering and Architects Association.
District of Columbia—Washington: Society of American Military Engineers.
Florida—Gainesville: Florida Engineering Society.
Illinois—Chicago: Western Society of Engineers.
Louisiana—New Orleans: Louisiana Engineering Society.
Maryland—Baltimore: Baltimore Engineers Club.
Massachusetts—Boston: Boston Society of Civil Engineers.
Michigan—Detroit: Detroit Engineering Society.
Missouri—St. Louis: Engineers Club of St. Louis.
New York—New York: American Gas Association; American Institute of Electrical Engineers; American Institute of Mining and Metallurgical Engineers; American Society of Civil Engineers; American Society of Refrigerating Engineers; American Society of Safety Engineers; Chemists Club Library; Columbia University Library; New York Railroad Club.
Rochester: Rochester Engineering Society.
Syracuse: Technology Club of Syracuse.
Utica: Mohawk Valley Engineers' Club.
Ohio—Cleveland: Cleveland Engineering Society.
Dayton: Engineers' Club of Dayton.
Pennsylvania—Philadelphia: Engineers Club of Philadelphia.
Pittsburgh: Engineers Society of Western Pennsylvania.
Scranton: Engineers Society of Northeastern Pennsylvania; Scranton Engineers Club.
Rhode Island—Providence: Providence Engineering Society.
Tennessee—Nashville: Engineering Association of Nashville.
Washington—Seattle: Pacific Northwest Society of Engineers.
Spokane: Associated Engineers of Spokane.

Honorary Members

HONORARY MEMBERS IN PERPETUITY

ALEXANDER LYMAN HOLLEY, Founder of the Society. Died 1882.

JOHN EDSON SWEET, Founder of the Society. Died 1916.

HENRY ROSSITER WORTHINGTON, Founder of the Society. Died 1880.

DECEASED HONORARY MEMBERS

	ELECTED	DIED
HORATIO ALLEN	1880	1889
SIR WILLIAM ARROL	1905	1913
SIR BENJAMIN BAKER	1886	1907
JOHANN BAUSCHINGER	1884	1893
SIR HENRY BESSEMER	1891	1898
SIR FREDERICK JOSEPH BRAMWELL	1884	1903
JOHN ALFRED BRASHEAR	1908	1920
GUSTAVE CANET	1900	1908
ANDREW CARNEGIE	1907	1919
DANIEL KINNEAR CLARK	1882	1896
RUDOLPH JULIUS EMMANUEL CLAUSIUS	1882	1888
SIR JOHN COODE	1889	1892
PETER COOPER	1882	1883
CARL GUSTAF PATRIK DE LAVAL	1912	1913
RUDOLPH DIESEL	1912	1913
JAMES DREDGE	1886	1906
VICTOR DWELSHAUVERS-DERY	1886	1913
THOMAS ALVA EDISON	1904	1931
ALEXANDRE GUSTAVE EIFFEL	1889	1923
MARSHAL FERDINAND FOCH	1921	1929
SIR CHARLES DOUGLAS FOX	1900	1921
JOHN RIPLEY FREEMAN	1932	1932
JOHN FRITZ	1900	1913
MAJOR - GENERAL GEORGE WASHINGTON GOETHALS	1917	1928
FRANZ GRASHOF	1884	1893
REAR-ADMIRAL ROBERT STANISLAUS GRIFFIN	1920	1933
OTTO HALLAUER	1882	1883
CHARLES HAYNES HASWELL	1905	1907
FRIEDRICH GUSTAV HERRMANN	1884	1907
GUSTAV ADOLPH HIRN	1882	1890
JOSEPH HIRSCH	1889	1901
IRA N. HOLLIS	1928	1930
ROBERT WOOLSTON HUNT	1920	1923
BENJAMIN FRANKLIN ISHERWOOD	1894	1915
HENRI LÉAUTÉ	1891	1916

OSKAR VON MILLER	1912
RIGHT HONORABLE LORD WEIR	1920
ORVILLE WRIGHT	1918

Report of the Council

During the year, two important phases of our Society's affairs have had the principal attention of the Council. These are matters of direct interest and value to our members.

First, the response to the necessity for the most prudent operation of the Society in the face of a constantly decreasing income was prompt and effective. Far-reaching economies have been made in every activity. Policies have been adopted which will be of inestimable value to the Society in the years to come as well as the present. As a result, the Society is on a sound financial basis and with the advancement in general business conditions, further improvement in the affairs of the Society can be looked for. While there is still need for proceeding providently, the outlook is such as to cause confidence in the future.

Second, greater thought than ever before has been given to the interests and views of our members. Every effort has been made to promote these interests in so far as it has been within the power of the Society to do so. The utmost consideration has been given to members' views.

Constructive action has been initiated for the benefit of mechanical engineers in the capital-goods industries. The code of fair competition for professional engineers has been endorsed. Relief and unemployment and the problems of the junior engineer have had appropriate attention. The foundation has been laid for the development and unification of the profession. These are activities which are of direct and personal value to all members, particularly in these times.

The detailed reports submitted to the Council by the Standing and Special Committees of the Society and by its representatives on joint activities reveal an amount of constructive activity which is phenomenal in view of the reduced income and the many serious problems that faced the individual members of the Society as well as the Society as a whole. A greater degree of interest in the welfare of the Society than ever before evidenced by the members, indicates a loyalty strong enough to sustain the Society through the period of necessarily reduced activity still ahead.

The low ebb of the industries employing engineers, particularly the mechanical, has brought a serious condition and a challenge to our Society. Recognizing the fact that activity in the capital-goods industries is essential to the welfare of engineers, the Council has appointed a Committee on the Capital-Goods Industries to study the facts involved. This committee will attempt to gage the attitude of industry and of the Federal Government regarding the purchase of capital goods at this time, with a view to the development of a constructive program for bringing about increased expenditures for machinery and materials in the manufacture of which engineers are largely engaged. It is suggested that such a program might be carried out with the cooperation of the American Engineering Council through the Local Sections and Professional Divisions of the Society and other influential groups of engineers.

The Status of the Engineer

Notwithstanding the pressure of many new problems, members of the Council have been continuously thoughtful of measures to improve the status of the engineer as a professional man. With this object in mind the Council approved the Code of Fair Competition for the Professional Engineer Division of the Construction Industry covering relations between professional engineers, clients or employers, employees, and others in respect to construction work, including the investigation, design, and selection of mechanical components of structures. This Division of the Code is of direct concern to mechanical engineers, and the Society has therefore assumed the responsibility of participating in the Board of Control which will administer its provisions. The Council has also authorized the formation of a committee to prepare a manual of engineering practice which will clarify the problems of the consulting engineer who is retained to aid in the design, construction, and installation of mechanical equipment.

Related to this is the suggestion of the Committee on Professional Conduct that the major engineering societies join in the preparation of a uniform Code of Ethics.

The Society is participating actively in the Engineers' Council for Professional Development which is engaged in a program for the accrediting of engineering schools and the development of an accurate definition of an engineer. It is hoped that this will also result in some recommendation looking to a standardization of membership grades in the various engineering societies.

During the year the Council of the Society approved the model law for the registration of professional engineers and land surveyors as a basis for the framing of new registration laws and the amendment of existing laws with a view to attaining a uniform high standard throughout the United States. The Council also authorized the appointment of a representative of the Society as an advisory member to the National Bureau of Registration, which is operated under the auspices of the National Council of State Boards of Engineering Examiners. This body has been established primarily to minimize the effort and expense of securing registration, especially by engineers practising in more than one state.

Unifying the Profession

For the past three years leaders of the engineering profession have been concerned with the general problem of improving the effectiveness of the profession by bringing together in a coordinated way the activities of the several joint bodies sponsored by engineering societies. This question is in the hands of the Coordination Committee of Engineering Societies, which has before it a plan for a central administrative agency that will provide the necessary coordination, administration, and representation. Some of these joint bodies are the United Engineering Trustees, Inc. (the holder of the Engineering Societies Building in New York and trustee for the funds of The Engineering Foundation), The Engineering Foundation, the Ameri-

can Engineering Council, the Engineering Societies Library, the American Standards Association, and the newly formed Engineers' Council for Professional Development.

Relief and Unemployment

The Employment Service, another of the joint activities, with offices in New York, Chicago, and San Francisco, in spite of reduced financial support has carried on in an increasingly helpful way, securing every possible opportunity for the employment of engineers.

Furthermore, in several cities, special campaigns have been instituted by the Local Sections to provide relief for engineers who are in straitened circumstances. Wives of members have cooperated by visiting the families of unemployed engineers and rendering aid urgently necessary.

Special recognition should be given to the work of the Professional Engineers Committee on Unemployment operated by the New York Sections of the four Founder Societies, which has collected and distributed large sums of money and has been successful in securing the cooperation of various other municipal committees. This committee points out that in the period before the depression there were more than enough jobs for engineers, with the result that the engineer was not obliged to concern himself with the technique of securing a job. The P.E.C.U. stresses the need for a concerted attack on the problem of instructing the engineer how to acquire skill in job hunting and even in job making.

Engineers and the Federal Government

The present times have brought added responsibilities to the representatives of the Society on the American Engineering Council and to the Washington office of that body. The report of the Society representatives on the American Engineering Council points out that the centering of unusual national activities in Washington during recent months has given the A.E.C. an opportunity to render a greater and more direct service to the profession than ever before.

The Society itself has supported the proposal made through The Engineering Foundation that sixteen million dollars be appropriated from the Public Works Administration for a six-year program of research in the natural sciences and their applications. This support was given because scientific research is an essential element of any far-sighted and comprehensive program for planning and improving the national prosperity.

Junior Participation

The importance of Junior Members in the Society and the need for providing organized participation by them in the Society's work are increasingly evident. Several Sections, notably the Los Angeles Section, have successfully brought Junior Members into Society work. The Committee on Meetings and Program has had a Junior advisor during the past year. Junior Members are taking increasing responsibility in the work of the technical committees. In order to record this progress and to explore all possibilities, the Council authorized the appointment of a special Committee on Junior Participation, made up of seven Junior Members, which will present a report to the Council at its meeting in December, 1933.

Policies and Program for 1933–34

By far the most constructive task performed by the Council during the past year was the reduction of current operating expenses and the curtailment of plans for expenditures for 1933–34. It should be realized, however, that the reduction in Society expenditures began in 1930. In 1929–30 the total operating expense was $893,126.64; in 1930–31, $840,681.67; in 1931–32, $644,588.52; and in 1932–33, $432,848.99.

The principal difficulty that the Society faces during a period of dropping income is due to the fact that its budget of expenses must be made on the basis of income estimated four months before the opening of the fiscal year. Plans involving commitments for many large items must be made several months before the fiscal year begins, but not until six or seven months later can an accurate check of the dues income be obtained. Therefore, if the income drops seriously below the amount estimated, the Society must reduce expenditures long after the commitments for those expenditures have been made.

This difficulty became acute during 1932–33. As early as November, 1932, only a month after the opening of the fiscal year, it became evident that many of our members were finding increasing difficulty in paying dues. (See statistics in the Finance Report, page 21.) In January of 1933, sharp reductions in advertising income made necessary a reduction of the budget by 14 per cent, or about $78,000. At the Council Meeting in December, 1932, therefore, the Special Committee on Revenues was called into service. This Committee, subsequently organized as the Special Committee on Policies and Budget, was given a twofold task. First, to study the situation that faced our Society because of the depression and devise measures to improve that situation, particularly as regards the immediate future, and to report recommendations to the Executive Committee as a guide for shaping the 1933–34 budget. Second, to determine the future aims and objectives of our Society and propose long-range policies for attaining them, and to make recommendations as a guide for the future conduct of the Society.

This Committee presented an exhaustive report at the meeting of the Council in Chicago in June. In preparing this report, the Committee had studied the activities of the Society for the past ten years, made an analysis of the general situation, studied the detailed statement of income and expenditures and the balance sheet, investigated curtailment of membership activities already made, presented an exhaustive analysis of membership growth, pointed out that the criticism and feeling of the membership had resulted in deterioration of Society morale, and made a careful study of the status of other engineering societies. It reviewed the detailed cost of all of the activities of the Society and classified them into their relative importance in serving the individual members of the Society; made certain suggestions as to reductions in the operating costs which were reflected in the budget for the next year; canvassed new sources of income; and reviewed the activities and obligations of the Society to other organizations.

The final report on the first half of the Committee's work, a mimeographed document of more than one hundred pages of typewritten and diagram matter, was the basis for establishing the budget for 1933–34 and also the basis for policies and a program which the Council adopted and which are summarized in the following paragraphs.

Policies

Dues. The Committee on Policies and Budget made a painstaking analysis of the question of dues reduction. It considered the wishes of many members and earnestly endeavored to find feasible means to reduce the rate of dues. After careful study of all the factors involved, however, the Committee presented as its findings that at the present time a reduction in dues would not make it possible for a sufficiently greater number of members to pay their dues to maintain an adequate income but instead would result in a considerable decrease in income to the Society. These findings were concurred in by a special committee appointed at the conference of Local Section delegates at the 1932 Annual Meeting. The Council, therefore, adopted the policy of taking no action looking to the reduction of dues at this time.

Reductions in Expenses. As economy measures, the following

procedures were initiated for 1933–34. Transactions of only two Divisions are to be distributed per member; the *A.S.M.E. News*, suspended in 1933, and the Membership List, suspended in 1931, are not to be printed in 1934; only two meetings of the Society are to be held; inactive Local Sections and Professional Divisions and certain committees are to be temporarily suspended; traveling allowances are to be reduced; Council and Committee meetings for which mileage and expenses are paid by the Society are to be reduced; the Local Sections Delegates Conference is to be made up of one representative of each of the seven geographical areas of the country, each geographical group to have had its own conference prior to November 1, 1933; the new Student Branch plan is to be installed in only one additional area in 1933–34; no appropriation was made for campaigning for new members; representation on the ASA was reduced from two to one; and the work of the technical committees is to be curtailed.

American Engineering Council. The American Engineering Council is carrying on a highly worth-while work, especially in view of this time of depression. However, the Society requested that its representatives on American Engineering Council urge the adoption of a policy whereby the expenditures of the Council can be reduced to a minimum by a simplification in activities and a substantial reduction in the number of representatives of member organizations.

Library. The Standing Committee on Library and the Society's representatives on The Engineering Foundation were authorized to request The Engineering Foundation to furnish as much as practicable of the A.S.M.E. appropriation to the Library for the next fiscal year with the understanding that the Society waive its request for research aid for new projects.

Employment Service. The Council adopted a policy of urging the Employment Service to approach commercial rates and become self-supporting in normal times. Under present conditions it is the opinion that the rates should be slightly increased.

Engineering Index. The Engineering Index is to be discontinued on January 1, 1934, unless sufficient outside aid is received to remove the possibility of loss to the Society.

Balance Sheet. Every effort is to be made to increase the Society's cash, decrease inventory, reduce borrowings, and write off unpaid accounts and obsolete inventory. The schedule of income and expenses for next year appears in the Finance Committee's report.

Fiscal Policy. The Council also adopted eighteen detailed statements of policy for the guidance of the Finance Committee in the formulation of the budget and for the aid of the Council in administering the fiscal operations of the Society.

Program

(1) Steps are to be taken to upbuild the morale of our Society and to win the enthusiastic support of its members. To that end the aims, objectives, and ideals of our Society will be defined and broad policies for achieving them, enunciated. The Committee on Policies and Budget has this in process.

(2) A definite plan will be adopted to provide regular visits of Officers and Members of Council to Local Sections and Student Branches as funds permit.

(3) The new Student Branch plan is to be extended and further developed as funds permit.

(4) The plan to serve better the interests of our Junior Members is to be further developed to bridge the gap between the Student Member and full membership.

(5) A plan is to be devised to strengthen the Local Sections by bringing into their Executive Committees the outstanding members in each Section.

(6) The Local Sections Committee, assisted by the Meetings and Program Committee, is requested to devise a plan to elevate the character of the meetings of the Local Sections by sending prominent speakers to discuss timely subjects and thus increase interest in the Sections and the Society. To that end, part of the funds used for this should be considered as a part of the appropriations for the Sections visited.

(7) The Committee on Professional Divisions is asked to devise a plan to upbuild and strengthen the Professional Divisions as a means of binding our Society more closely together, increasing our Society's value to its members and increasing their interest in it. During 1933–34 new Divisions should not be launched. The present ones, however, should be encouraged to be more active, and inactive ones be temporarily suspended.

(8) The Local Sections Committee and the Professional Divisions Committee are requested to devise jointly a plan for promoting closer cooperation between these activities for the purpose of increasing the effectiveness and usefulness of each, separately and jointly.

(9) The Publications Committee is asked to give continuing attention that the reader interest in *Mechanical Engineering* be increased to augment its advertising value.

(10) A critical examination is to be made of all activities to determine the advisability of continuing them.

(11) Critical examination is to be made to determine if the activities of other societies and associations are being duplicated and, if so, that those activities be eliminated in our Society if possible. In case elimination does not at first appear feasible, steps should be taken to induce the other societies and associations to conduct those activities so as to permit elimination in our Society.

(12) The Committee organizations are to be reviewed for the purpose of simplifying them, and committees engaged in activities remote from mechanical engineering are to be discontinued.

(13) Steps are to be considered to make membership in the Society mean more to members by raising the professional status of our Society; consideration also is to be given to raising membership to a higher level by more strict entrance requirements.

(14) The Committee on Local Sections is requested to conduct a careful study of the reasons for the large number of members dropped for non-payment of dues.

(15) The committees responsible for Standardization and Safety are requested to give further consideration to the trade association movement with the view toward having the projects carried on by trade associations when feasible.

(16) The Finance Committee is to be charged with the specific duty of acting as a conservator of our Society's funds for the express purpose of preserving the soundness of our Society's financial structure, guarding against undue spending, and insuring the practice of rigid economy.

(17) The Council is requested to establish a Committee on Funds and Endowments, this Committee to be responsible for collecting such Funds.

(18) The American Engineering Council is to be interpreted to our members so that they may better understand its purpose and appreciate its value.

(19) Our Society's organization, management, and procedure is to be made more responsive to and governed more by changes in general business conditions.

(20) The Finance Committee is requested to consider the desirability of entering our investments on the balance sheet at market value instead of at cost.

(21) The Finance Committee is requested to consider the desirability of keeping accounts on a cash basis instead of on accrual basis, as at present.

Summary of Operations in 1932–33 as Shown by Committee Reports

Notwithstanding several drastic curtailments in activities and staff, the year just passed shows a deficit in Society operation. This deficit is largely due to the fact that dues from the members fell far below the most conservative estimate. The Finance Report which follows gives the matter in detail. It should have the careful study of every member.

Despite reductions in income for the current year, the general activities of the Society have been carried on with devotion and enthusiasm. The Annual Meeting in 1932 was a splendid success and the meeting in Chicago, bringing together as it did all of the engineering societies, has not been equaled by a meeting outside New York in many years. The number and quality of meetings held by the Sections, despite reduced appropriations, is highly creditable, and the large number of excellent papers that were secured as a result of the efforts of the Professional Divisions indicates that the Society is very much alive as a technical body.

The Library was obliged to function with a proportionate reduction in appropriation and yet had to meet a demand from seventeen per cent more readers and from some eighteen thousand inquirers by mail.

The excellent program for the development of Student Branches which was started in one area of the country during the previous year was extended to three additional areas (the New England, North Atlantic, and North Central States) during

the past year and will be extended still further to an additional area during the coming year.

The publications of the Society were necessarily curtailed. The Membership List was not published, the *A.S.M.E. News* was suspended, the number of papers that were published was reduced, and savings were made in the publication of the Record and Index by sending it to only those members who requested it. Further savings were made by issuing offset printed papers where the material could not be included in the reduced volume of Transactions and the provision of thousand-word abstracts instead of preprints for the Chicago meeting.

As an evidence of the virility of the Society, during the year the Membership Committee recommended 1670 new candidates for membership and 174 transfers to a higher grade. The comparative figures for the year before were 1123 and 179, and for the year before that were 1396 and 252. It will be apparent that even without concerted effort, the number of new members recommended for election in the Society has increased materially. While the major portion of this increase comes from Junior Members who transfer from student membership under the new plan, this is indeed an excellent showing. The accompanying table shows the actual changes in membership recorded up to September 30, 1933.

CHANGES IN MEMBERSHIP—OCTOBER 1, 1932, TO SEPTEMBER 30, 1933

	Membership		Increases			Decreases				Total Changes		
	Oct. 1, 1933	Oct. 1, 1932	Transferred to	Elected	Reinstated	Transferred from	Resigned	Dropped	Died	Increases	Decreases	Net change
Honorary Members	22	25	0	0	0	0	0	0	3	0	3	−3
Life Members	66	68	1	0	0	0	0	0	3	1	3	−2
Members	8,657	8,878	66	66	2	2	234	0	119	134	355	−221
Associates	515	564	1	4	0	1	45	0	8	5	54	−49
Associate-Members	4,123	4,150	70	48	0	22	96	0	27	118	145	−27
Juniors (20)	1,875	2,076	0	0	0	74	110	16	1	0	201	−201
Juniors (10)	4,942	4,318	0	688	4	24	39	0	5	692	68	+624
	20,200	20,079	138	806	6	123	524	16	166	950	829	+121

The technical committee activities have progressed also in spite of reduced financial support. Two new standards projects were initiated as were two new research projects. All of the Committees report well-attended, enthusiastic meetings in spite of the depression.

Other actions of an important administrative nature include the transfer of the supervision of the Max Toltz Loan Fund from the Awards Committee to the Committee on Relations With Colleges and the decision to defer temporarily the proposed revision of the Constitution and By-Laws to bring them up to date with current procedure. This was also deferred because of the work of the Committee on Policies and Budget which is reexamining the purposes and functions of the Society with the view to clarifying its aims.

The Individual Member

The Council and officers are aware of the responsibility of the Society to its individual members, particularly in these trying times. Always in the foreground of thought is consideration of what can be done for them. Their point-of-view is paramount and as the coming year unfolds, more and more attention will be given to it. This is regarded as the first duty of the Council and the officers.

Reports of Committees

Complete reports of committees follow. They are worthy of careful and discerning study by the members of the Society. In addition, this year there are appended reports on Joint Activities and on the Office of the Society.

Calvin W. Rice, *Secretary.*

Reports of Standing and Special Committees

FINANCE

The Society has passed through a year of strenuous effort in meeting the financial problems brought about by the general business depression. The situation was complicated by an unexpected shrinkage in income to an amount greatly below the conservative estimate against which the budget of expenditures was balanced. In spite of the heavy retrenchment in expenditures that had previously been made, a further drastic reduction during the year was demanded. To give the members the usual high quality of service under such conditions without an appreciable curtailment in activities taxed the resourcefulness of all spending agencies.

In order that the membership may be fully informed regarding the financial operations of the Society during this critical period, the annual financial statements for the past fiscal year ended September 30, 1933, are presented in much greater detail than has been customary in recent years. In addition to the usual statement of income and expenses, and balance sheet, there are given detailed statements of the direct expenses of Standing Committees, the appropriations to joint agencies, the expenses incurred in printing and distributing publications, the expenses of the office of the Society classified both by items and by departments, expenses of The Engineering Index, and the direct and indirect cost of all activities. A statement is also given of the changes in the surplus that were authorized by the Council. By presenting the financial transactions of the Society for the past year in such complete form, the Finance Committee has endeavored to answer all reasonable questions which may arise.

The books of account were audited at the close of the fiscal year by Haskins and Sells, a firm of certified public accountants of nationally recognized standing, which has for several years audited the accounts of the United Engineering Trustees, Inc., and other national engineering societies. The services of this firm were engaged owing to the regrettable death of William J. Struss, who had served the Society in this capacity for many years. The financial statements in this report were prepared from the annual report of the auditors.

Budget Reductions

The balanced budget, adopted by the Council at Bigwin in June, 1932, had to be revised downward twice during the year, due to the unanticipated shrinkage in income. The original budget of $543,500 was 16 per cent lower than the actual expenditures of $644,588.52 during the preceding fiscal year 1931–32. After four months' operation the Executive Committee was compelled to revise the budget in January, 1933, by authorizing a further reduction of 14 per cent, which brought it down to $465,500. The second revision was made by the Council at its meeting in Chicago in June, 1933, when an additional reduction of 8 per cent, to $429,400, was authorized. It was recognized at that time that a further reduction in expenditures would seriously affect major activities during the remainder of the year; furthermore, a large part of the appropriations for many activities had already been spent. An operating deficit at the close of the year was therefore anticipated.

Operating Income

The activities of the Society, and its service to the membership, are dependent upon two main sources of income—advertising and membership dues. Income from advertising is beyond the control of both the management and the membership. The payment of dues is, however, the responsibility of the membership. Both of these sources of income were seriously affected by the general business conditions.

Income from advertising for 1932–33 was 48 per cent lower than for the preceding year, as shown by the comparative statement of

income in Exhibit A. Even though this tremendous reduction in advertising income occurred, the Society would have enjoyed a surplus of approximately $70,000, instead of a deficit of $44,347.57, if all members had paid their 1933 dues. If, in addition, every member in arrears at the beginning of the year had paid the full amount of back dues owing to the Society, the total income would have exceeded the total expenses by approximately $181,000.

Early in 1932, the Council adopted the liberal policy of not dropping members who desired to retain their membership but were unable to pay their dues. The total number of members on the rolls of the Society October 1, 1933, was 20,200 as shown in the table of membership changes on page 20. At the beginning of this year, on October 1, 1932, 5,737 members owed the Society $110,867.36, for dues, of which amount $55,000.00 was set aside as a probable loss. The following tabulation shows the status of the membership on September 30, 1933:

Honorary Members		22
Members of More Than 35 Years' Standing		482
Members Paid in Full		10,445
Members With 1933 Dues Temporarily Suspended		760*
Members in Arrears:		
For 1933 Dues Only	3,112**	
For 1933 and Prior Years' Dues	5,379*	8,491
Total Membership, September 30, 1933		20,200

Upon recommendation of the Finance Committee, the Council considered it advisable to set up a reserve of $115,000.00 for the uncollected amount of 1933 dues, as shown in the income statement, Exhibit A, and to provide for the uncollected amount of prior years' dues by making a deduction of $49,317.89 from surplus, as shown in the surplus statement, Exhibit B. This action resulted in a very small amount of uncollected dues being carried over as a current asset on the balance sheet. As shown in Exhibit C, the asset of dues receivable amounts to only $12,101.56, which is considerably less than the amount which should be collectable.

Almost all of the Society's investments promptly paid the regular rate of interest when due. The total amount of interest and discount received was $14,546.85, which was $6,113.98 in excess of the interest and discount paid.

Operating Expenses

The operating expenses for all activities of the Society were reduced to a greater extent than the income, the percentage of reduction being 33 per cent from a total expense of $644,588.52 in 1931–32 to $432,848.99 in 1932–33.

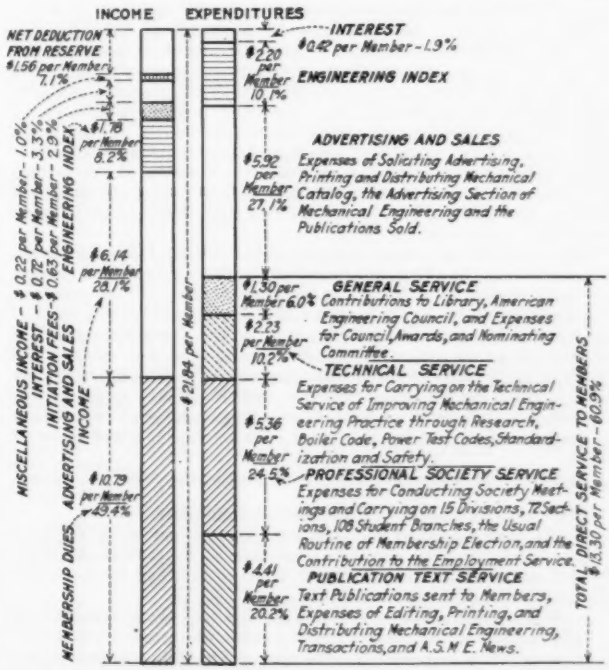
In the four major groups of expense the percentages of reductions as shown by Exhibit A were: Committee Expense, 21 per cent; Publications Printing and Distributing Expense, 42 per cent; Office Expense, 28 per cent; and Engineering Index Expense, 47 per cent.

For the convenience of those who wish to examine the expenditures in greater detail, the operating expenses are itemized in Schedules 1 to 7, inclusive. Direct appropriations to the joint activities and to Standing Committees are given in Schedule 1. The printing and distribution expenses of each publication of the Society are shown in Schedule 2. The expense of the office of the Society is classified in Schedule 3 according to departments with salaries separated from other expense items; and is itemized in Schedule 4 according to the purposes for which the expenditures were made. The total expense of the Engineering Index is itemized in Schedule 5. The direct and indirect cost of activities is shown in Schedule 6; and the total cost of activities is compared with the budget for 1933–34 in Schedule 7.

Deficit

Although the total operating expenses for the year exceeded the total operating income by $44,347.57, the net deduction from working surplus required for the current year's operations was $31,552.13, inasmuch as the income of $12,795.44 from initiation fees was not considered as a part of operating income but was credited directly to surplus. The primary purpose of building up the surplus during the period from 1924 to 1929 was to take care of such a situation as the Society has been in during this depression.

* Did not receive *Mechanical Engineering* and Transactions.
** Did not receive Transactions.



Surplus Changes

The surplus statement in Exhibit B was prepared by the auditors to show the changes made by action of the Council in writing down the current assets resulting from prior years' operations in addition to those changes resulting from operations in 1932–33.

The credits to surplus consist of $12,795.44, initiation fees; $15,000.00, reversal of reserve for depreciation of securities; and $2,456.62, the unused portion of the provision in 1931–32 for the expense of the Mechanical Catalog that year.

The deductions from surplus consist mainly of reduction in receivables and inventories, made for the purpose of clearing the current assets of questionable items that were considered to have doubtful cash value. The write-off of obsolete and inactive items in the inventories of supplies and publications for sale amounts to $78,660.48; the write-off of uncollected dues for prior years amounts to $49,317.89, as previously stated; the write-off of all unpaid accounts contracted for advertising space in *Mechanical Engineering* and Mechanical Catalog, for the purchase of publications, and for subscriptions to the Engineering Index card service, previous to October 1, 1932, from which there seemed to be but slight likelihood of settlements, amounts to $20,384.69; the write-off of obsolete and discarded office furniture and equipment, amounts to $6,984.74. Other items shown resulted in a total charge of $165,576.83 against surplus for prior years' operations, which, together with the deduction for the current year's deficit, brought the surplus down to $205,303.71.

A.S.M.E. INCOME AND EXPENDITURES PER MEMBER, 1932-1933

The following statement regarding the initiation fee reserve is quoted from the report of the auditors: "The Council passed resolutions requiring 50 per cent of initiation fees to be placed in the 'Reserve Fund,' commencing on October 1, 1922, and later adopted an amendment to the By-Laws requiring the entire amount of initiation fees to be deposited in the 'Reserve Account,' presumably commencing on October 1, 1924. If the foregoing actions were to be interpreted as requiring a specific reserve for the initiation fees received during the years involved, rather than a transfer to the Society's Reserve (Surplus) then the amount of such Initiation Fees Reserve at September 30, 1933, would be $258,794.92, based on information contained in the annual reports of the former auditors. The inclusion of such a reserve in the balance sheet would change the Surplus shown therein from $205,303.71 to a deficit of $53,491.21."

Balance Sheet

The final statement in this report is the balance sheet at September 30, 1933, as prepared by the auditors. The details of four accounts in the balance sheet are shown in the following schedules: Schedule 8, Securities Owned; Schedule 9, Trust Fund Securities; Schedule 10, Custodian Funds; and Schedule 11, Trust Fund Reserves.

In order to pay its obligations promptly and to improve the cash situation during the latter part of the year, the Society, like other going concerns, found it necessary to borrow money. Loans on short term notes were advanced by the bank upon the Society's securities as collateral. The bank loan amounted to $164,000.00 at the end of the year. The assessments for the Library, the Employment Service, and rent were paid by notes to the United Engineering Trustees, Inc., during the last nine months of the year. These notes, amounting to $16,353.27, were paid in full in October, 1933.

Because of the large reductions made in the current assets, it was considered inadvisable to increase the current operating deficit by a reduction in the deferred charge for the Fiftieth Anniversary. Likewise it was decided to postpone increasing the reserve for employees' retirement allowances.

Considering the present conditions, the financial position of the Society is sound. Inactive inventories and uncollectable accounts owing the Society have been written off and such large allowances have been made for unpaid dues that the current assets shown on the balance sheet represent a conservative figure. The debt has been reduced. The current assets exceed the current liabilities by $240,635.27. The deferred credit resulting from dues paid in advance exceeds the deferred charges by $11,899.49, and there is a previously accumulated reserve set aside from surplus of $23,432.07 for employees' retirement allowances. The investment in furniture and equipment has been written down to the present market value. The valuation of the Society's quarter interest in the Engineering Societies Building amounts to $496,948.48. The investments represented by securities are carried at cost upon recommendation of the auditors, since such a large portion are in real estate mortgage bonds for which there is no market value at present. However, the soundness of the securities is evidenced by the fact that the bank has accepted them as collateral and further by the fact that they yielded interest amounting to $13,081.19.

With expenditures cut to a minimum by a well-established program of economy, only one thing is needed for the Society to show a surplus each year instead of a deficit, to be clear of debt, and to increase, once more, its reserves. It is that which is vital to the well-being of any membership organization—the loyalty and prompt payment of dues by all its members. While our Society has not escaped the impact of the present economic disturbances, it is being guided safely through these trying times by the resourcefulness and devoted services of the officers, members of committees, and staff upon whom has rested directly the responsibility of administering the Society's affairs.

The Certificate submitted with the Report of the Auditors follows:

> The American Society of Mechanical Engineers:
>
> We have examined your accounts for the year ended September 30, 1933. The accounts receivable at September 30, 1933, and collections during the year, were not verified by confirmations obtained from the debtors.
>
> Subject to the above, it is our opinion that the accompanying balance sheet, and statements of income and expenses and surplus set forth, respectively, your financial condition at September 30, 1933, and the results of your operations for the year ended that date.
>
> [Signed] Haskins and Sells
>
> New York,
> November 24, 1933

Respectfully submitted,

Kingsley L. Martin, *Chairman* — Walter Rautenstrauch
John H. Lawrence, *Vice-Chairman* — D. Robert Yarnall

Initiation Fees (carried to Surplus)—See Exhibit B	$ 12,795.44	$ 16,288.33
Student Dues	5,667.10	1,158.00
Membership Dues (Less Allowance for Dues Uncollected at September 30, 1933, $115,000.00, September 30, 1932, $55,000.00)	212,289.41	261,137.28
Interest and Discount	14,546.85	16,168.57
Mechanical Engineering Advertising	43,464.10	103,757.32
Mechanical Catalog Advertising	41,213.35	60,807.47
A.S.M.E. News	178.00	802.00
Publication Sales	40,441.16	53,134.03
Engineering Index	35,965.62	63,552.17
Miscellaneous Sales	1,553.53	2,212.07
Contributions Unrestricted	2,845.00	
	$398,164.12	$562,728.91
Less: Bad Debts	1,229.83	2,427.10
Total Income	$396,934.29	$560,301.81
Expenses and Charges		
Committee Expense—See Schedule 1	$ 75,770.24	$ 96,523.86
Publication Expense (Printing and Distribution Only)—See Schedule 2	90,690.78	156,606.36
Office Expense—See Schedules 3 and 4	221,863.29	306,905.89
Engineering Index Expense—See Schedule 5	44,524.68	84,552.41
Total Expenses—See Schedules 6 and 7	$432,848.99	$644,588.52
Interest and Discount Charges	8,432.87	
Total Expenses and Charges	$441,281.86	
Net Loss for the Year (Carried to Surplus)—See Exhibit B	$ 44,347.57	

SCHEDULE 1. COMMITTEE EXPENSE

(Direct Appropriations Only)

	1932-33	1931-32
Council	$ 3,851.44	$ 6,221.91
Engineering Societies Library	8,925.24	10,297.98
American Engineering Council	12,694.96	17,506.65
Sections Committee Mileage	629.91	1,611.21
Sections Delegates Mileage	7,012.79	6,884.14
Sections Operation	15,799.76	23,103.99
Awards	203.57	569.53
Nominating Committee	649.54	897.26
Relations With Colleges—Mileage	471.56	
Research	205.00	300.00
American Standards Association	1,124.98	1,500.00
Divisions Meetings	2,431.15	5,827.73
Divisions Operation	320.72	2,064.47
Divisions Mileage		218.01
Society's Meetings	9,324.25	10,745.72
Engineering Societies Employment Service	8,169.93	6,708.69
Student Branches Operation	3,955.44	2,066.57
Total	$75,770.24	$96,523.86

SCHEDULE 2. PUBLICATIONS EXPENSE

(Printing and Distribution Only)

	1932-33	1931-32
Mechanical Engineering Text Pages	$24,110.06	$ 31,676.16
A.S.M.E. News	2,666.31	9,133.48
Transactions	22,863.83	45,591.20
Membership List		197.63
Mechanical Engineering Advertising Pages	9,416.55	22,836.73
Mechanical Catalog	15,989.11	21,783.92
Publications for Sale	15,644.92	25,387.24
Total	$90,690.78	$156,606.36

SCHEDULE 3. OFFICE EXPENSE*

(Classified by Departments)

	Salary Expense, 1932–33	Other Expense,** 1932–33	Total Expense, 1932–33	Expense Budget, 1933–34
General Department—General supervision, staff service to Council, Executive Committee, Special Committees of Council, Committees on Finance and Publications, central accounting, purchasing, stores, mail, addressograph, duplicating, files, clerical and stenographic	$ 56,844.46	$13,631.80	$ 70,476.26	$ 58,000.00
Field Department—Staff service for Sections, Branches, meetings, Divisions, membership, awards, Employment Service, Chicago and Tulsa Offices	31,053.69	6,224.07	37,277.76	32,000.00
Technical Department—Staff service for Committees on Boiler Code, Power Test Codes, Research, Safety, and Standardization	24,523.35	2,637.03	27,160.38	17,600.00
Editorial Department	23,649.49	791.10	24,440.59	21,000.00
Advertising Department	31,920.50	7,510.08	39,430.58	30,000.00
Publication Sales Department	5,528.46	3,818.62	9,347.08	9,300.00
Rent, Insurance, Depreciation		13,730.64	13,730.64	10,500.00
Relief and Contingencies				1,600.00
TOTAL	$173,519.95	$48,343.34	$221,863.29	$180,000.00

* See pages 49 and 50 for more complete description of duties and functions of the Office of the Society.
** Other Expense includes postage, printed matter, travel, telephone and telegraph, office supplies, stationery, maintenance and repair, and unclassified.

SCHEDULE 4. OFFICE EXPENSE

(Classified by Items)

	1932–33	1931–32
Salaries	$173,519.95	$232,088.79
Commissions		293.95
Postage	8,827.00	11,401.97
Printed Matter	7,862.99	9,457.06
Traveling	4,051.72	8,146.38
Collections	15.15	291.21
Telephone and Telegraph	4,952.52	6,085.55
Insurance	1,360.92	1,965.14
Office Supplies	3,521.57	6,991.14
Secretary's Emergency Fund	32.90	200.66
Rent	11,369.72	14,708.96
Stationery	1,547.50	2,297.34
Maintenance and Repair	573.42	1,101.13
Cost of Miscellaneous Sales	862.69	1,143.52
Depreciation of Furniture and Equipment	1,000.00	1,696.28
Unclassified	3,128.66	11,826.13
	$222,626.71	$309,695.21
Less: Receipts	763.42	2,789.32
TOTAL	$221,863.29	$306,905.89

SCHEDULE 5. ENGINEERING INDEX EXPENSE

	1932–33	1931–32
Salaries	$34,423.16	$ 58,049.11
Postage	1,372.89	3,403.23
Printed Matter	1,774.04	3,069.46
Traveling	1,572.02	3,817.34
Telephone and Telegraph	191.60	503.50
Insurance	53.37	260.78
Office Supplies	1,817.76	2,739.39
Rent	2,933.64	5,541.72
Stationery	90.64	263.62
Maintenance and Repair	167.50	38.52
Paper for Card Service	1,134.61	2,800.37
Distribution of Card Service	839.72	1,425.79
Cost of Annual Volumes Sold	14,498.41	15,719.54
Interest on Loan		6,403.18
Depreciation of Furniture and Equipment	300.00	588.36
Unclassified	355.32	1,962.50
	$61,524.68	$106,586.41
Less: Receipts	0.00	34.00
	$61,524.68	$106,552.41
Less: Accrued Editorial Charge to Annual Volume	17,000.00	22,000.00
TOTAL	$44,524.68	$ 84,552.41

SCHEDULE 6. DIRECT AND INDIRECT COST OF ACTIVITIES

(For the Fiscal Year Ended September 30, 1933)

	Direct Committee Expense	Direct Office Expense	Indirect Office Expense	Total Cost
General Service—Contributions to Library, American Engineering Council, and expenses of Council, Awards and Nominating Committees	$ 26,324.75			$ 26,324.75
Society Activities—Expenses for Society Meetings, Professional Divisions, Local Sections, Student Branches, Membership Election, and contributions to Employment Service	48,115.51	$ 37,277.76	$22,700.00	108,093.27
Technical Service—Expenses of Committees on Boiler Code, Power Test Codes, Research, Safety, and Standardization	1,329.98	27,160.38	16,600.00	45,090.36
Publication Text Service—Expenses of Editing, Printing, and Distributing Text Section of *Mechanical Engineering*, Transactions, and *A.S.M.E. News*	49,640.20	24,440.59	15,000.00	89,080.79
Advertising and Sales—Expenses of Soliciting Advertising, and Printing and Distributing Mechanical Catalog, Advertising Section of *Mechanical Engineering*, and Publications Sold	41,050.58	48,777.66	29,906.90	119,735.14
Engineering Index—Expenses of Editing, Printing, Soliciting and Distributing Card Service and Annual Volume		44,524.68		44,524.68
TOTAL	$166,461.02	$182,181.07	$84,206.90	$432,848.99

SCHEDULE 7. TOTAL COST OF ACTIVITIES

(Comparison of Costs for 1931–32 and 1932–33 With Budget for 1933–34)

	Budget, 1933–34	Actual, 1932–33	Actual, 1931–32
General Service	$ 14,000.00	$ 26,324.75	$ 35,493.33
Society Activities	94,000.00	108,093.27	150,769.97
Technical Service	29,600.00	45,090.36	55,356.48
Publications Text Service (Editorial, Printing, and Distribution)	74,400.00	89,080.79	142,573.54
Advertising and Sales (Soliciting, Printing, and Distribution)	102,047.00	119,735.14	175,842.79
Engineering Index (Editorial, Soliciting, Printing, and Distribution)		44,524.68	84,552.41
TOTAL	$314,047.00	$432,848.99	$644,588.52

EXHIBIT B

STATEMENT OF SURPLUS

For Fiscal Year Ended September 30, 1933

BALANCE, OCTOBER 1, 1932, PER SOCIETY'S ANNUAL REPORT.			$376,706.01
ADD ADJUSTMENTS IN PROPERTY FUND RESERVE TO SEPTEMBER 30, 1932			8,270.04
BALANCE, OCTOBER 1, 1932, AS ADJUSTED			$384,976.05
CREDITS			
Initiation fees		$12,795.44	
Reversal of reserve for depreciation of investments		15,000.00	
Unused portion of provision in prior year for expense of Mechanical Catalog		2,456.62	30,252.06
TOTAL			$415,228.11
CHARGES			
Net loss for the year, per exhibit A		$44,347.57	
Net write-down on account of obsolete and inactive items in inventories, applicable to prior years		78,660.48	
Write-off of, and provision for, prior years' receivables still uncollected, and related adjustments:			
Dues	$49,317.89		
All other	20,384.69	69,702.58	
Write-off of obsolete and discarded office furniture and fixtures, at depreciated values		6,984.74	
Cancelation on account of suspensions, resignations, deaths, etc., of dues billed in prior years		4,497.03	
Relief payments to former employees		4,292.00	
Excess transfer from Life Membership Fund to income in prior year		1,440.00	209,924.40
BALANCE, SEPTEMBER 30, 1933—SEE EXHIBIT C			$205,303.71

EXHIBIT C

BALANCE SHEET, SEPTEMBER 30, 1933

ASSETS

CURRENT ASSETS			
Cash			$ 16,222.09
Advance Receivable—Committee on Thermal Properties of Steam			15,000.00
Accounts Receivable (not verified by confirmations from debtors):			
Dues (less reserves for uncollected items)	$ 12,101.56		
Publications and Advertising	56,061.46		
Engineering Index	6,944.58		
Miscellaneous	250.80	75,358.40	
Inventories (not verified as to quantities):			
Publications for Sale	65,708.87		
Publications in Process	10,351.32		
Supplies	4,359.06	80,419.25	
Securities—At Cost; market value not obtainable ($264,250.00 face value deposited as collateral to notes payable at bank)—See Schedule 8		316,833.89	
TOTAL CURRENT ASSETS			$503,833.63
TRUST FUND INVESTMENTS—			
Securities—At Cost; market value not obtainable. See Schedule 9		166,127.16	
Uninvested Cash		5,700.16	
TOTAL TRUST FUND INVESTMENTS			171,827.32
PROPERTY FUND INVESTMENTS			
One-Fourth Interest in Real Estate and Other Assets of United Engineering Trustees, Inc., Exclusive of Trust Funds		496,948.48	
Equipment			
Office Furniture and Fixtures (depreciated value)		25,577.16	
Library Books		1.00	
Engineering Index		1.00	
TOTAL PROPERTY FUND INVESTMENTS			522,527.64
DEFERRED CHARGES			
Fiftieth Anniversary ($15,000.00 written off prior to October 1, 1931)		24,399.66	
Society Activities Applicable to Subsequent Years		1,135.46	
TOTAL DEFERRED CHARGES			25,535.12
TOTAL			$1,223,723.71

LIABILITIES

CURRENT LIABILITIES			
Notes Payable:			
Bank (See securities pledged, contra)	$164,000.00		
United Engineering Trustees, Inc	16,353.27	$180,353.27	
Accounts Payable		34,763.78	
Unfilled Commitments		18,687.31	
Custodian Funds—See Schedule 10		28,933.18	
Gift for Thurston Biography—Unexpended Portion		460.82	
TOTAL CURRENT LIABILITIES			$263,198.36
TRUST FUND RESERVES (balances as shown by books)—See Schedule 11			171,827.32
PROPERTY FUND RESERVE			522,527.64
RESERVE FOR EMPLOYEES' RETIREMENT ALLOWANCES			23,432.07
DEFERRED CREDIT—DUES PAID IN ADVANCE			37,434.61
SURPLUS, PER EXHIBIT B			205,303.71
TOTAL			$1,223,723.71

SCHEDULE 8: SECURITIES OWNED, SEPTEMBER 30, 1933

	Description	Maturity	Face Value	Cost
Railroad Bonds				
	Baltimore & Ohio Railroad Co. refunding and mortgage 5%	1996	$ 2,500.00	$ 2,473.75

MEETINGS AND PROGRAM

During the fiscal year, October 1, 1932, to September 30, 1933, only two Society meetings were held, namely, the Annual Meeting in New York, December 5 to 9, 1932, and the Semi-Annual Meeting in Chicago, June 25 to 30, 1933. As the general programs of both these meetings have been amply described in the publications of the Society, they will not be gone into here.

This year's work of the Committee on Meetings and Program has taken full cognizance of the difficult times which have affected our Society no less than they have others.

Need for the curtailment of expenses for meetings has been balanced against the need for continued improvement in the conduct and quality of technical sessions. By means of a questionnaire, valuable comments and criticisms were obtained upon the 1932 Annual Meeting. These have been recorded and have assisted greatly in future planning.

The Committee has cooperated fully with the spirit and purpose of the Special Committee on Policies and Budget. The final allotment of funds to the Meetings and Program Committee by the Council, amounting to $5500* for the fiscal year 1933–1934, will not be exceeded. Two meetings of the Society are contemplated during the coming year. These are the Annual Meeting in New York and the Semi-Annual Meeting, probably in Colorado.

A new subdivision of the work of the Committee has been made and specific responsibilities have been assigned to individual members. Under this plan a close coordination has been secured, and its effect at the Chicago Semi-Annual Meeting was generally beneficial.

One full meeting of the Committee was held in Chicago while the convention was in progress, in order to secure the full advantage of the observations of the committee members.

The policy of the Society with respect to the subject matter and treatment of technical papers was examined during the year, and as a result special important regulations were drafted and sent to all Professional Divisions.

The plan to eliminate the printing of papers in full for the Chicago meeting and to substitute abstracts was, in general, well received. Some of the Divisions which were especially desirous of having their papers printed in full, financed the expense through some of their own members. One case in point was that of the paper by Messrs. Wert, Cope, and Smith, on the design of pipe bends for steam lines, which could hardly have been understood without the complete text. The cost of publishing this paper was borne by the authors' company. The following authors arranged to preprint their own papers: B. D. Stevens, J. Jamieson, Temple Joyce, A. C. Jewett, Dr. H. D. Hubbard, H. R. Isenburger, J. E. Ridder, Cuneo Press, J. H. Taylor and E. O. Walters, R. M. Hardgrove, S. Timoshenko, Eugene Szepesi, Townsend Tinker, Ray Sorenson, E. K. Benedek, and R. F. Onsrud. Also several trade magazines cooperated splendidly by publishing other papers and in several cases supplied extra copies for discussers. The Symposium on Water Hammer was printed and the expense was underwritten by a group of engineers in the Hydraulic Division.

Instructions to presiding officers, authors, and discussers were revised during the year, and a special effort was made to point the technical sessions to higher standards.

As one economy measure, a new plan was introduced at Chicago, which required that participants in technical sessions, attending the authors' breakfasts and luncheons, should pay for their own meals. This change of Society policy was satisfactorily received.

In conclusion, the Committee wishes to report that its analysis of Society affairs in relation to present-day conditions makes it clear that its next year's activities shall, among other things, be especially directed to the energetic promotion of a deeper interest in the whole Society among those of its members not fortunate enough to be able to attend the regular, full Society meetings. There can be no question that the members attending such meetings have the opportunity to see the Society at work and are able to absorb quickly something of its spirit. They are proud to belong to the Society and to give their loyalty to it and to their fellow engineers, and to support the work of improving the status of the profession. This same sense of pride and usefulness in the upbuilding of the profession must be quickened among the men who cannot attend other than the regional or local meetings of their geographical groups.

Respectfully submitted,

J. W. Parker, *Chairman*
C. P. Bliss — E. C. Hutchinson
R. I. Rees — H. N. Davis.

* As compared with $9500 in 1932–1933.

PUBLICATIONS

Upon the Committee on Publications rests the responsibility for adding to the literature of engineering the most important contributions submitted to it through the Society's numerous committees and Professional Divisions. It is charged with the supervision of all of the Society's publications, which makes it the Society's largest single spending agency. And, because of advertising revenue accruing from the publications, the Committee in normal times is also the Society's largest income producer.

As the agency spending the greatest proportion of the Society's income, the Committee on Publications has the very serious obligation of making certain that its business is conducted wisely and with the greatest economy. As chief income producer, the Committee is in the position, in good times, of making it possible for the Society to finance many projects for the benefit of the members in particular and of the engineering profession in general. But, in periods of business stagnation, the severe reduction of the volume of revenue which the Committee can contribute to the Society's income forces the drastic curtailment of activities undertaken in better times. In the present emergency, this curtailment has extended to the very publications that produce the income as well as to the activities supported out of it, with the result that some of them, the Membership List and the *A.S.M.E. News*, have been suspended indefinitely and the Engineering Index faces suspension on January 1, 1934.

This dual role of spender and earner must be understood in order to appreciate the problems and responsibilities that the Committee on Publications has had to face during the last few years. While in 1929–1930 the income from the Committee's activities was 40 per cent greater than that from dues, in 1932–1933 it had shrunk to a point little more than 60 per cent of that from this other source.

In 1929–1930 income from publications more than paid the cost of publications—not one cent of a member's dues had to be used on the publications. Of the $11.80 average dues income per member in 1933, $3.79 had to be used on publications that in former years had been supported entirely by advertising. (Average dues equals receipts for dues divided by total number of members.)

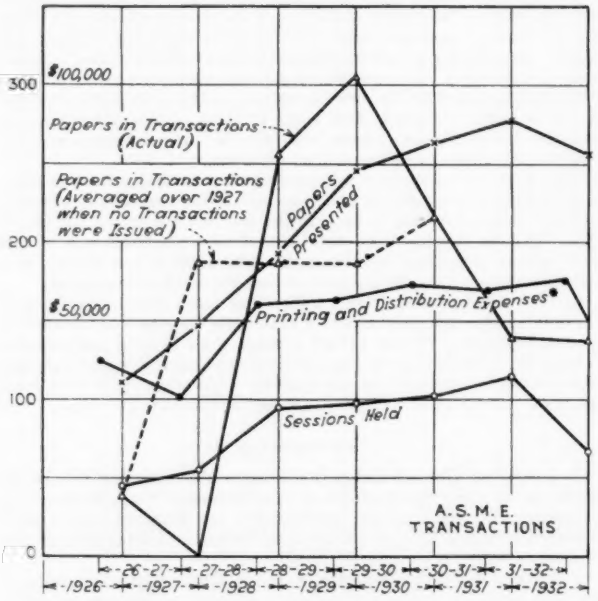
Transactions

As a result of Council action at Chicago, each member will, in the future, receive the Transactions of two instead of three Professional Divisions. Copies of papers published in the Transactions of other Divisions continue to be available upon request. This is an economy measure.

A source of increasing economy, so far as Transactions is concerned, has been found in methods of printing, adopted during the preceding year, and more extensively used since. Preprints and reports, not to be set in type, are reproduced by the photo-offset process in accordance with a standard style. Synopses, with a request blank, are published in *Mechanical Engineering*. Copies are preserved, cataloged, and indexed for the Record and Index.

The Record and Index is a section of the Transactions. Only 5500 copies of the 1932 Record and Index were printed as compared with 21,000 for 1931. The net saving to the Society of $2062 was made possible by distributing the copies only upon request, instead of to every member. In this procedure there was no reduction in service, because a notice was sent to each member with the request that he specify whether or not he wanted a copy.

In the interest of establishing a Society policy for papers to be presented by way of Transactions, and otherwise, the Publications Committee approved the following statement that originated with the Committee on Meetings and Program:



"The Constitution of The American Society of Mechanical Engineers mentions specifically as one of the objects of the Society the promotion of 'the art and science of mechanical engineering and the allied arts and sciences.' This gives wide scope to appropriate subjects for discussion.

"It should be a policy of the Society to accept papers for public presentation and publication on the basis of the merits of the individual paper as determined by a careful review of it by competent and responsible critics and in view of whatever related factors may be of importance at the time; and to open its forums and meetings for the discussion, under competent parliamentary supervision, of such appropriate subjects as can be intelligently and profitably treated. At the same time, the discussion of controversial subjects likely to arouse only fruitless argument and inconclusive debate should be controlled in the interest of economy of time and effort on the part of all concerned. Authority should be vested in the program-making agencies of the Society, in the chairmen who conduct the parliamentary procedure of every public meeting, and in the editor of publications, to enforce with firmness, tempered by a generous and understanding fairness, the spirit of this statement of policy, subject to the final ruling

of Council in cases where this authority is challenged as being improperly exercised."

The present scheme of Transactions was put into effect with the issue of the annual volume for 1928. Statistics of development are shown graphically in the accompanying chart. The change was designed to provide a means for distributing the much greater number of papers that were being presented as a result of the organization of the Professional Divisions. It was hoped that, *without increasing publication costs*, about 50 per cent more material could be published. Actually it was possible to print about 70 *per cent more material* than under the old scheme.

Differences in the fundamental points of view and states of technological and scientific development of the fields of interest represented by the Professional Divisions have naturally resulted in a variety of standards in judging technical papers. Those of the Divisions that are developing fields to which engineering has been only

*Estimated Expense, 1932-33, $29,000

DEVELOPMENT OF TRANSACTIONS, 1926–1932

recently applied are obliged to secure material of a descriptive character while others are presenting material of a highly technical nature or which is the result of valuable researches.

In 1928, 1929, and 1930, when funds were available, the Committee adopted the very liberal attitude of publishing in Transactions practically every paper recommended by the executive committees of the Divisions. This year, however, with almost three times as many papers recommended as there are funds out of which to pay for publication, the Committee has been forced to change this policy and publish only those papers that seem to be of permanent reference value. This means that Divisions and committees developing papers of this character are getting a greater volume of publications than are other Divisions, and it places an added responsibility on the Divisions to insist on high quality in the papers they recommend for publication.

When it established the Applied Mechanics Division, the Society provided a forum for advanced researchers and workers in this field and an outlet for the technical papers they produced. There are no other outlets for technical papers in applied mechanics—no papers published by societies or otherwise that render to engineers working in this field a service such as exists in the fields of power, machine-shop practice, railroads, iron and steel, aeronautics, and most of the others. This is true not only with respect to mechanical engineers interested in this subject, but for engineers of all types. No other engineering society has attempted to provide a forum and publication outlet for these men. The need is a very real one. No commercial publisher can undertake the task because of the relatively small number of men who would be potential subscribers and because their interests and buying power provide no profitable field for the advertiser.

Without the sponsorship and financial assistance of some group like the A.S.M.E., these engineers, whose original researches and mathematical studies in the field of applied mechanics provide the basis for fundamental engineering designs, and whose contributions are greatly enriching the literature for the immediate and permanent benefit of engineering designers, would be denied a necessary means by which they can exchange experience, make contacts with men of similar professional activities, and record the results of their work.

As a step toward providing this group with a periodical commensurate in usefulness and professional standing with the character of the work they are doing, the Committee on Publications has secured a separate post-office entry for the section of Transactions sponsored by the Division and now known as "Applied Mechanics." With the return of better times, the Division looks forward to developing this periodical into a broader and more valuable publication. In addition to papers presented at Division meetings, it is hoped to include other contributions, news of the men in the field and the work they are doing, reports on projects under way and contemplated in various laboratories, reviews of work and publications in other countries, book reviews, and similar features.

The program is an ambitious one, but it merits very serious consideration; the work done by this Division and its members is typical of what can be fostered only by professional societies because its publication is likely never to be commercially profitable. If engineering societies, in times of normal prosperity, cannot support activities of this sort, their right to be considered professional and educational bodies is justly questioned. It seems to us that they will fail to replenish the force that sustains them.

While the plans of the Applied Mechanics Division must be held temporarily in abeyance, awaiting the return of better times, they must receive attention at the earliest possible date. The Committee on Publications bespeaks the enthusiastic backing of members of the Society for this project, as well as for its policy of raising the standards of quality and value in all sections of the Transactions.

"MECHANICAL ENGINEERING"

It is a fact frequently commented upon that *Mechanical Engineering* now definitely aligns itself with the broader aspects of engineering. By far a majority of the comment has been favorable.

The Publications Committee is proud of the issues for this year. During the last few years the whole world has come to realize its regrettable ignorance concerning things social and economic. It is looking for help. Shall the mechanical engineer look to his Society? The Publications Committee thinks that he should, and has gladly endorsed the policy of a discerning editor which you now see put into practice in *Mechanical Engineering*.

Smaller than formerly, this magazine still contains 64 editorial pages. We have felt that fewer would not suffice; advertising revenue has enabled us to refrain from further reduction.

"A.S.M.E. NEWS"

To secure data upon which to base its decision in regard to suspending the *A.S.M.E. News*, the Committee canvassed the Local Sections, by means of a letter sent early in November, 1932, to Local Sections Delegates to the 1932 Annual Meeting Conference; and discussed the matter with the Employment Department, committees whose work might be affected, officers of the Society, and individual members.

A digest of the data convinced us that several of the services being rendered by the *News* could be discontinued, at least until the Society had improved its financial position; that the carrying on of other services could be transferred to *Mechanical Engineering;* and that still others could be conducted by special communications.

Accordingly, the recommendation was made to Council (December 5, 1932) that the *A.S.M.E. News* be indefinitely suspended.

Our formal communication to the Executive Committee of Council made the recommendation contingent upon the inclusion at no extra expense of the material transferred to *Mechanical Engineering;* no further publication of the necrology (except in Record and Index), personals, reports of Section meetings, material relating to Society organization and operation, and other material appearing regularly in the *News;* the transfer to *Mechanical Engineering* of only such material as would permit the maintenance of the existing high standards of quality, prestige, usefulness, and reader interest possessed by that publication.

The recommendation of the Publications Committee was adopted by the Council, and the *A.S.M.E. News* was discontinued with the publication of the December 22, 1932, issue. The saving for the balance of the fiscal year ending September 30, 1933, amounted to $5400. It is estimated that the saving for a full year would be approximately $8000.

Mechanical Catalog

Mechanical Catalog continues to reflect the general lack of business that prevailed up to the middle of the year. It must be remembered that the acceptance of contracts for the Catalog ceases about the middle of the year in order to allow time for editing, setting, proofreading, printing, and binding, to meet the established distribution date of September 30, a condition that prevented increased sales on account of the better business of the latter half of 1933.

Acquaintance on the part of the members of the Publications Committee with the personnel of the advertising sales force of the Society has convinced them that they know their work and that they have done as good a job as conditions would permit.

Membership List

No Membership List was printed during the year 1932–1933. It is the recommendation of the Committee that none be issued for 1933–1934. In addition to the need for economy it seems inadvisable to issue such a list at a time when there are so many changes in the addresses and business connections of members.

Engineering Index

At its meeting in Chicago, the Council voted to suspend the Engineering Index on January 1, 1934, unless sufficient subvention was received to relieve the Society from financial risk. In the meantime, all efforts possible are being made to secure the aid necessary to carry on this valuable agency.

The action looking toward the suspension of the Index was taken with deepest regret. When the Society, in 1919, purchased The Engineering Index from its former publisher, The Engineering Magazine, it exhibited a quality of aggressiveness and a sense of professional obligation that did justice to the high ideals which its founders had for its services to the profession. The maroon-bound volumes that are a familiar sight on the shelves of the best reference libraries will stand as a reminder to future generations of engineers that a serious business depression interrupted a service, the value of which cannot be estimated merely by the number of persons or organizations subscribing to it.

When the Index was established on a comprehensive basis in 1928, thorough studies had been made of the possibilities of developing it as a self-supporting venture. In 1930, with a total income in excess of $100,000, this condition was nearly approached. For the past two years, reductions in income have been effected more rapidly than corresponding reductions in expenses could be made and the Index is still not self-supporting. This loss has been a source of dissatisfaction to members of the Society and this, together with the necessity to sell the service at a high price, were the reasons for the action of the Council. In view of opposition to the Index, vigorously expressed by many members, speaking individually and through their Local Sections' representatives, the Committee on Publications, after having made reductions in operating expenses that would soon be reflected in the quality of the Index, was unwilling to continue its operation at a deficit. Inasmuch as it cannot be operated profitably during the business depression, the Index will be suspended on January 1, 1934, unless outside aid can be secured. Reductions in price of the service are absolutely essential if the Index is to have the widespread usage its value warrants. This cannot be done without outside aid, such as is received by Biological Abstracts and Chemical Abstracts, two comparable services. Every effort is being made to secure the aid necessary to make the Index of wider use and to carry it on without risk to the Society. Final decision will be reached before January 1, 1934.

Advisory Committee

During the year 1932–1933 the Committee presented to the Council a request that it approve the appointment of three advisory members. This request was granted, and the President appointed one from St. Louis, one from Blacksburg, Va., and one from San Francisco. In general, the functions of the advisory members are to comment on all actions of the Committee, to provide advice as requested on specific questions, to canvass the opinions of members of the Society about the publication policies and report to the Committee, and to fulfil any other functions that will aid the Committee in meeting its responsibility in the conduct of the diverse publication needs of the Society.

This plan is considered experimental, the term of appointment of the three members continuing until December, 1934, when the Committee will submit its conclusions and recommendations to the Council.

Budget for 1933–1934

The expenditures for printing and distribution of the publications of the Society for the past year and for the previous year, and the budget for next year are shown in the following table:

PUBLICATIONS INCOME BUDGET

	1933–1934
Mechanical Engineering Advertising	$ 42,000.00
Mechanical Catalog Advertising	40,000.00
Publication Sales	39,000.00
	$121,000.00
Less: Bad Debts	3,000.00
	$118,000.00

PUBLICATIONS EXPENSE BUDGET

(Printing and Distribution)

Mechanical Engineering Text Pages	$ 21,000.00
Transactions	19,000.00
Mechanical Engineering Advertising Pages	8,500.00
Mechanical Catalog	15,500.00
Publications for Sale	13,647.00
	$ 77,647.00

As discussed previously in this report, the volume of Transactions must be reduced if this budget is to be reached. The Transactions of two Divisions only will be issued to each member, instead of three as at the present time. The income from the publications is reduced seriously and the Committee is cooperating with the Council, the Executive Committee, and the Finance Committee in working to this scheme.

Conclusions

In conclusion we present the income and expense statement of Publications as prepared by the Finance Committee. In doing so we wish to emphasize that the amounts have to do with printing and distribution only.

Publications Income

	1932–1933	1931–1932
Mechanical Engineering Advertising	$ 43,464.10	$103,757.32
Mechanical Catalog Advertising	41,213.35	60,807.47
A.S.M.E. News	178.00	802.00
Publication Sales	40,441.16	53,134.03
	$125,296.61	$218,500.82
Less: Bad Debts	1,229.83	2,427.10
	$124,066.78	$216,073.72

Publications Expense

(Printing and Distribution)

Mechanical Engineering Text Pages	$ 24,110.06	$ 31,676.16
A.S.M.E. News	2,666.31	9,133.48
Transactions	22,863.83	45,591.20
Membership List	.....	197.63
Mechanical Engineering Advertising Pages	9,416.55	22,836.73
Mechanical Catalog	15,989.11	21,783.92
Publications for Sale	15,644.92	25,387.24
	$ 90,690.78	$156,606.36

Engineering Index

Income from Card Service and Annual Volumes	$35,965.62	$63,552.17
Expense (Editorial, Printing, Selling, and Distributing)	$44,524.68	$84,552.41

Respectfully submitted,

E. L. Ohle
Advisory Members.

LOCAL SECTIONS

Scope of Service

It has been urgently necessary for Local Sections to economize, even in the face of increased demands for service to the membership. Some activities, such as Registration of Engineers and the Economic Status of the Engineer, have been temporarily discontinued, in order that Sections may better apply their strength to problems such as the collection of funds for relief and the organization of unemployment committees, and committees to cooperate with Governmental agencies such as the Reconstruction Finance Corporation and the Public Works Administration. The Sections, too, have been urged to cooperate more fully with the Committees on Relations With Colleges, Professional Divisions, and Meetings and Program.

In order to effect economy of administration, the Committee has recommended and urged the combination of the St. Paul and Minneapolis Sections under one Section organization and title of "Twin Cities Section," with territory to cover a radius of sixty miles from the State Capitol.

Operation of Local Sections

The Local Sections of the Society deserve full credit for their loyal support and cooperation in carrying forward to fruition, full programs, in spite of the necessary curtailment of funds. In a number of cases, in order that Society prestige not suffer, Sections have carried on committed programs which have exceeded in cost the Sections' allotments, without calling upon the Society for additional funds. This has been accomplished in the interest of continuing the high standard of Section performance established in the past.

Meetings and Membership Chart

During the past fiscal year the Sections of the Society have held 394 meetings. The number of reported meetings held by each individual Section is shown in Table 1. This table also details the membership of the respective Sections on October 1, 1932, and October 1, 1933; the net increase or loss in membership; etc.

New Members

The potential possibilities of Society membership are big. But with business conditions so unsettled, no drive for new members has been undertaken. On the contrary, every effort has been put forth by Sections to hold and interest our present membership. With the improvement of business, however, the Committee feels some effort should be expended in an attempt to explore this potentially enormous field.

Prospective Sections

No new Sections were added to the rolls of the Society. In keeping with the policy laid down by the Committee on Policies and Budget, no effort has been made to interest members in the organization of new Sections.

There are still a few industrial areas in the United States where new Section possibilities seem to exist.

Measure of Sections' Operation

The Committee has undertaken the development of a Scale of Measure for Sections' Operation, in the effort to set a minimum standard of Section accomplishment. This has been made necessary by the temporary suspension of 14 Local Sections for lack of reported Section activity; and the question of reinstatement of these Sections. In the future, all Sections of the Society will be required to meet a definite minimum requirement of successful operation to continue on the active list of Sections.

Local Sections Visited by Committee

With improved health, William Lyle Dudley, of Seattle, Wash., has been able to resume his duties on the Committee, making desirable contacts with the Sections of Group VII. Due to curtailment of funds, however, the Committee visits have been substantially reduced, as compared to those of past years. It is the unified opinion of the Committee that means should be provided by the Society, not only for Local Section Committee member visits to the Sections, but visits by Council members as well. No other activity of the Society will do more to assist the Sections to operate successfully and to hold the interest of the membership. (See Table 2.)

Mid-West and Mid-Continent Offices

Under the budget set-up for 1933–1934, the Committee felt that it would be unwise to renew the present leases for these offices. Activity and contact, however, in these territories will be maintained.

The Mid-West Office continues to assist the Local Sections and Student Branches within its territory and to serve individual members in every possible way. The contacts afforded by this office accomplish a great deal in the development of professional consciousness and acquaintance with the problems of the profession, and help greatly in the increase of Society prestige.

The Mid-Continent Office has continued its efforts in organized investigation and reports on problems and developments in the oil industry. Public and membership interest in Society undertakings has been greatly increased by the operation of this office. Student activity has been fostered with good results; and assistance in unemployment relief has placed this office in equally as important a position in its territory, as the Mid-West office occupies in the Chicago area.

The Committee feels that these offices and operations should be continued for the welfare and up-building of the Society in these areas.

TABLE 1 MEMBERSHIP IN LOCAL SECTIONS, OCTOBER 1, 1933

Section	Total Membership 10/1/33	10/1/32	Increase or loss	1933 Dues paid	Dues part paid	Dues suspended	Dues unpaid	Basic membership for L.S. approp.	Meetings, 10/31-10/32

Membership in Society, October 1, 1933, 20,200.
Membership in Sections, October 1, 1933, 17,826.
Membership in Society, October 1, 1932, 20,057.
Membership in Sections, October 1, 1932, 18,155.

Cooperation With Special Committee on Policies and Budget

The Committee on Local Sections has done everything possible to maintain the Sections at best efficiency, despite curtailment of funds, and has cooperated in every way with the Special Committee on Policies and Budget. Realizing that the Local Sections form the links of the Society's chain, the Committee on Local Sections urges that at the very earliest possible moment, full and adequate financial assistance again be accorded the Sections.

In order to keep expenditures within the allowed budget, in connection with the next Delegates' Conference, there will be a series of Regional Conferences by Groups and only one Delegate will be sent from each Group to the Annual Meeting at New York. These Group Delegates will confer at New York with members of the Council and Professional Divisions. Substantial economy will thus be effected in the cost of the Section Delegates' Conference.

Cooperation With Student Branches

The Local Sections of the Society encourage in every way Student Branch activity. Realizing their important obligation to Student Branches, they have entered actively into the work. Many Sections have established Student Prizes, to win and hold undergraduate interest. The District Student Branch Conferences in the Groups where the new student policy is in force, were held under the auspices of Sections in these Groups. These Conferences do much to promote closer relationship between Section membership and Student Branches.

Cooperation With Professional Divisions

The cooperation of Local Sections with Professional Divisions has consistently been developed, co-relation of activities being increased by placing both activities under one administrative head.

The Sections have availed themselves of every opportunity for such inter-relationship of opportunities.

It will be seen that due to budget curtailment, these activities have likewise had to be substantially reduced. With increase of business and increase of Society activities, the Committee feels this cooperative effort should be fostered.

Tours and Transportation

The Committee on Local Sections arranged for reduced fares to the Annual, Semi-Annual, and other national gatherings of the Society during the year, thereby saving thousands of dollars to the membership.

In connection with the Chicago Meeting, the Century of Progress Exposition and other points of engineering interest in and about Chicago were made more easily accessible to the members through the efforts of the Mid-West Office and the Chicago Section of the Society.

Foreign Relations

For a number of years foreign relations have been handled under the supervision of the Local Sections Department because the actual help rendered foreign visitors is developed through the Local Sections themselves. Last year, as previously, many of the Local Sections cooperated by giving considerable time and attention to engineers from abroad. In spite of the general conditions there was a greater number of visitors than in the previous year. Forty-four visitors from twelve countries were received and assisted. Eight of these were students who had just been graduated from the engineering course from Liverpool University, England.

In addition, letters of introduction to foreign engineering and technical societies, as well as to specific plants, were given to a large number of members of the Society who made trips abroad.

Cooperation With Publications Committee

The Committee is so strongly of the opinion that a new membership list is needed, that it has urged the Publications Committee to endeavor to publish such a list for the year 1933–1934.

The Committee further urges that in view of the economic pressure on some members, a column of *Mechanical Engineering* be devoted to "Men Available" as previously published in the *A.S.M.E. News*.

Cooperation With Meetings and Program Committee

It has been suggested by the Committee, and recommended to the Meetings and Program Committee, that all papers for presentation by members at National Meetings, be first presented before Section or Professional Divisional Meetings. It is felt that both Sections programs and National programs would be helped by such a procedure.

Respectfully submitted,

J. M. Todd, *Chairman*
J. W. Haney — W. W. Macon
W. L. Dudley — R. E. W. Harrison.

* Annual Meeting.

PROFESSIONAL DIVISIONS

The Divisions have completed a year of most successful activity despite reduced appropriations. In order to support the great Society meeting at the Chicago Century of Progress in June, 1933, most of the Divisions provided comprehensive programs for that gathering and relinquished the privilege of holding separate Division meetings through the year. The result was a technical program for Chicago of fine quality and excellent diversity.

The study being conducted under the leadership of the Committee on Policies and Budget looking to a critical reexamination of the activities of the Society has met with the approval of the Committee on Professional Divisions, which is cooperating wholeheartedly. Some of the immediate problems relating to the Divisions are raised in this report.

The reports of individual Divisions appended are well worth careful study, as they demonstrate forcefully the fact that many individuals are giving of their time and effort, through the work of the Professional Divisions, in advancing the purposes of the Society.

Chicago Meeting

The holding of many technical sessions by the Divisions at the Chicago Meeting had the effect of consolidating the National Meetings of most Divisions. The resulting technical program was most excellent, equaling in extent and quality that of an Annual Meeting. However, curtailment in appropriations for publications brought about the need for issuing 1000-word abstracts in place of the usual reprints and made somewhat more difficult the problem of securing discussion in advance and of providing advance information to those attending the meeting. While there was much approval of the new scheme, because of the compactness of the book of abstracts there was some objection, which was relieved by various expedients. The trade press cooperated in some instances by printing papers in advance. Some authors provided preprints, and a few Divisions arranged the papers in pamphlet form for sale. This scheme of abstracts has been used by other societies with success and must, by reason of the lack of funds, be tried at the Annual Meeting in 1933. The Committee regards it as a necessary temporary expedient and believes it advisable to return to the scheme of preprints as soon as possible.

Other Meetings

Four meetings were held in addition to the Semi-Annual Meeting at Chicago and were successful in programs and attendance and were economically handled. These special meetings consisted of the following: Pacific Coast Applied Mechanics Meeting, January 20–21, in cooperation with California Institute of Technology and the Los Angeles Section; Air-Conditioning Conference sponsored by the Air Conditioning Committee of the Process Industries Group and the San Francisco Section, held February 9–10 at the University of California; National Lubrication Engineering Meeting, held at Pennsylvania State College, May 25–26, in cooperation with the College, the Central Pennsylvania Section, and the Lubrication Engineering Committee of the Petroleum Division; National Oil and Gas Power Meeting, held under the auspices of the Oil and Gas Power Division of the Society at Atlantic City, August 23–26.

Fundamental Problems

Present Organization and Relations With Other Societies. Are the Divisions properly organized to cover the technical developments in the field of mechanical engineering? This question is frequently raised, primarily because of the fact that some Divisions, as Textile and Petroleum, deal with a specific industry, while others, as Management and Machine Shop Practice, take up matters of interest to several industries. Various solutions have been advanced, such as consolidation of Divisions or turning over activities to related societies or associations that may be carrying on technical activities in fields of the individual Divisions.

In this connection there are some fundamentals we must keep clearly in mind. Our Divisions originate from demands for activity in given fields. New developments and new problems must arise in a changing technical civilization. Our members must turn to their Society for help in these developments and problems, and the groups having common interest in them must be provided with adequate forums for mutual discussion. Our organization should be flexible enough to provide for growth and rapid change. Furthermore, we must provide for interchange of experience and knowledge between the separate groups. Formal organizations must go on, and it is our policy to be continuously on the watch to bring about mutual understanding between the various groups both in the Society and outside. Committees that clear problems between Divisions have been organized, and close cooperation with other technical and industrial groups is actively fostered.

The Standing Committee and the Divisions are constantly alert as to these problems and the changes that may be required. At the present time, however, the Committee considers that our form of Division organization meets current needs as well as any other that may be suggested.

Reducing Registration in Divisions. As an economy measure the Council at the Chicago Meeting authorized the reduction from three to two as the number of Divisions in which a member may register. The present form of publication of Transactions by Division Sections was initiated in 1928 to serve our membership better by publishing more material. It was considered that many members of the Society would want and need only certain papers that the Society published, and that it would be wasteful to send them all the papers. Each member was permitted to select three Divisions from which he would automatically receive the papers published. If he wanted papers published in other Divisions he could get them without charge by requesting them when *Mechanical Engineering* announced that they were available. The reduction, now, from three to two merely means that a member will more often have to send in requests for papers, especially for those in the third Division that he has been receiving automatically. The Society still stands ready to furnish without charge to every member a copy of every paper published in the Society's Transactions.

Summary of Division Activities

The Aeronautic Division, during the present year, held its National Meeting as part of the Semi-Annual Meeting of the Society in Chicago, June 26 and 27, 1933, presenting twelve papers; assisted Local Sections in holding Aeronautic meetings in New York, Boston, and San Antonio; and held a session at the Annual Meeting.

In the latter part of 1932 there was organized a new aeronautical engineering society under the name of the Institute of Aeronautic Sciences. The first technical gathering of this new organization was held in New York, N. Y., on January 26, 1933, at Columbia University. The Aeronautic Division and the Society extended their greetings and offered their cooperation. The members of the Institute were invited to participate in the aeronautic program of the Chicago Meeting.

At the Chicago Meeting, the A.S.M.E. Special Committee on Aircraft Safety and Inspection, which was initiated by the Division, presented a further progress report. During the year the Society, at the request of the Aeronautic Division, recommended to the American Standards Association that the Aircraft Safety Code be revised.

For the year of 1934 the Aeronautic Division will hold its National Meeting on the Pacific Coast at the University of California.

The Applied Mechanics Division held its National Meeting in Chicago as part of the Semi-Annual Meeting of the Society, presenting twelve papers in joint sessions with the Structural Division of the American Society of Civil Engineers on Thursday and Friday of that week. Besides this, the Division held one session independently and two sessions on plasticity jointly with the Iron and Steel Division, making a total of seven sessions at the meeting in which the Division cooperated and for which it secured papers. At the 1932 Annual Meeting, the Division presented a symposium on working stresses which was unusually successful.

The Division held a Pacific Coast Applied Mechanics Meeting in cooperation with the Los Angeles Section and the California Institute of Technology at the Institute on January 20 and 21, 1933, at which nine papers were presented. The meeting was very successful, with about two hundred in attendance, and gave sufficient evidence of the need and advisability of occasional meetings on the Pacific Coast by this Division.

Several sessions are planned for the 1933 Annual Meeting, while for the coming year of 1934, the Division will actively cooperate in the International Congress of Applied Mechanics to be held in Cambridge, England, June, 1934. Cooperation in the summer meeting of the Society for the Promotion of Engineering Education at Cornell University is being considered.

The Division has six special subcommittees: Elasticity, Strength of Materials, Plasticity, Dynamics, Mechanics of Liquids and Gases, and Thermodynamics.

The Fuels Division held its National Meeting as part of the Semi-Annual Meeting of the Society in Chicago, presenting eight papers at four sessions. At the 1932 Annual Meeting the Division had two sessions, one of which was held jointly with the Iron and Steel Division, and it is sponsoring a session at the 1933 Annual Meeting. The Pure Air Committee has continued its activities. The work of its Subcommittee on Standards for Setting Heights has now been organized into a committee under the ASA. The special subcommittee of the Division on Boiler Furnace Explosions was disbanded, as there did not seem to be sufficient demand for specifications on explosion doors or information as to how to write such specifications.

The Hydraulic Division sponsored a splendid Water Hammer Symposium at the Chicago Meeting of the Society and also cooperated in two other sessions with the Power Division of the A.S.C.E. The Division sponsored two sessions at the 1932 Annual Meeting and is planning a water measurement symposium for the 1933 Annual Meeting.

Due to the decreased income of the Society, the Hydraulic Division's Water Hammer Committee took care of the publication in a separate pamphlet of the Water Hammer Symposium. This special committee not only did the splendid work of developing the symposium and coordinating the mathematical symbols but also underwrote the cost of publication.

For 1934 a Pacific Coast hydraulic meeting is being planned, to be held at Berkeley, California.

The Iron and Steel Division held three sessions at the 1932 Annual Meeting, one of which was in cooperation with the Fuels Division. At the Chicago Semi-Annual Meeting two sessions were held in cooperation with the Plasticity Committee of the Applied Mechanics Division. A joint meeting with the Pittsburgh Section and the Engineering Society of Western Pennsylvania was held in April, 1933. The Division some years ago initiated the Special Research Committee on Heavy-Duty Anti-Friction Bearings and this committee has now completed some very valuable research work and submitted its final report at the Chicago Meeting. The Division is planning further cooperation with the Plasticity Committee on deformation of metals. For the 1933 Annual Meeting, one session is planned and the Division will cooperate in the Heat Transfer Symposium.

The Machine Shop Practice Division held three sessions at the Chicago Semi-Annual Meeting and sponsored a similar number at the 1932 Annual Meeting. A representative program has been arranged for the 1933 Annual Meeting.

During the past year the Division has organized a Subcommittee on Welding, this committee to act jointly with the American Welding Society. In addition to sponsoring sessions on welding and initiating new activities in this field, this Committee is charged with the responsibility of keeping the members posted on the latest developments in welding.

Like the Welding Committee, the Subcommittee on Foundry Practice acts jointly with the American Foundrymen's Association.

This Subcommittee has continued its excellent activity and has sponsored sessions at all meetings.

The Division has a third Subcommittee on Machine Design which is developing its program of activity.

Divisional cooperation with the Special Research Committee on Cutting of Metals has successfully kept members informed on the latest developments in this field.

The Management Division sponsored two sessions at the Semi-Annual Meeting in Chicago and also cooperated in two sessions of the Econometric Society. At the 1932 Annual Meeting the Management Division sponsored three sessions and it will also sponsor several sessions at the 1933 Annual Meeting. During the last year, the Division has had a number of active subcommittees, among which are, (1) Waste Elimination Committee, which assisted in a Chicago Session; (2) Engineering Economics Committee, which sponsored sessions at the Annual Meeting; (3) the Society's Special Research Committee on Measures of Management, in cooperation with the Materials Handling Division, which is active in sponsoring papers each year; (4) the Job Shop Management Committee, which is continuing a survey it started last year; (5) the new Marketing Committee, which is working on a session for the coming Annual Meeting and has undertaken a survey to determine the present status of Marketing Research in Industry; and (6) a Special Metropolitan Section Committee of the Division, which sponsors informal evening management conferences in New York several times a month, during the fall, winter, and spring. There is also a Subcommittee on Maintenance which was not active during the year. The Engineering Economic Committee cooperated in the Third Annual Economic Conference for engineers held at the Stevens Institute of Technology Engineering Camp. The Division is represented on the International Management Institute and also on the new National Management Council, which was formed this year to coordinate management activities.

The Materials Handling Division sponsored at the 1932 Annual Meeting a joint session with the Railroad Division on materials handling on railroads and will also sponsor a session at the 1933 Annual Meeting. The Division organized a special Subcommittee on Foundry Handling with the American Foundrymen's Association and held a joint session at the American Foundrymen's Convention in Chicago, the Friday preceding the Semi-Annual Meeting. In January, the Division cooperated in two sessions held by the Materials Handling Institute at the National Road Building Congress in Detroit.

The Oil and Gas Power Division held its National Meeting at Atlantic City, N. J., August 23 to 26, presenting eleven technical papers and having an equipment exhibit in conjunction with the meeting. Preprints of the papers were made available at the meeting through the courtesy of a trade magazine. The Division had one session at the 1932 Annual Meeting and also will hold a session at the 1933 Annual Meeting. There is one special Subcommittee on Oil Engine Power Cost which presented its fifth yearly report at the Atlantic City Meeting. This report was for the year 1932 and covered 140 plants in comparison with 110 in the 1931 Cost Report. The Division formed a Subcommittee on Diesel Fuel Oil Problems which had several meetings during the year.

The Printing Industries Division held its National Meeting in Chicago as part of the Semi-Annual Meeting; presenting seven papers and including two informal discussions and one group conference. This Division each year conducts a forum for the discussion of the problems of the industry, to which all of the organizations and associations in the industry send delegates. Their Chicago sessions formed the Fourth Conference of the Technical Experts in the Printing Industry and were among the best attended of the Semi-Annual Meeting sessions. The proceedings of the meeting are being issued in a special pamphlet form by the Division. At the Chicago session a program of Cooperative Printing Research in America was presented by A. C. Jewett and received the endorsement of the meeting. For several years the Division has been encouraging the possibility of a printing research institute, which has resulted in the presentation at Chicago of this formal program. During the year the Division lost by death its Chairman, Floyd E. Wilder, who had been very active in organizing the work of the Division for the last few years. John Clyde Oswald was appointed chairman for the remainder of the year.

The Petroleum Division has a number of special subcommittees. Several of these are located at Tulsa, Okla. They are as follows.

The Fluid Flow Calculations Committee has started a series of tests on three separate operating crude-oil trunk lines of six, eight, and ten inches diameter.

The Subcommittee on Oil Metering Problems of the Special Research Committee on Fluid Meters has continued its work on the collection of data to determine the correctness of existing coefficients and correction factors for the flow of fluids of varying viscosities and temperatures through orifice plates, flow nozzles, and venturi throats at various velocities.

The Production Committee has completed the set-up and obtained some data on preliminary runs on the capacities of slush pumps handling mud fluids of various weights and at different pressures and velocities.

The Special Research Committee on Prime Movers for Rotary Drilling has completed its third study on the various types of prime movers for rotary drilling. The studies completed are the combination Gas-Electric Prime Mover, Steam Equipment for Rotary Drilling, and Electric Equipment for Rotary Drilling. The two studies that remain to be accomplished are Gas Engine and the Diesel Engine Prime Movers.

The Lubrication Engineering Committee held a National Meeting at Pennsylvania State College, May 25 and 26, in cooperation with the college, presenting nine papers. It was voted at the meeting to ask the A.S.M.E. to petition the American Standards Association to form a committee on the classification of industrial lubricants. Pending the formation of the committee by the ASA the Lubrication Engineering Committee will continue to gather information on classification of industrial lubricants. Another special committee was appointed to act as a clearing house on problems of application of lubrication. The Lubrication Engineering Committee sponsored one session at the 1932 Annual Meeting and will also sponsor one at the 1933 Annual Meeting.

The Petroleum Refining Committee this year issued a short test sheet to go with its Recommendations on Testing of Heat Exchange Equipment for Oil Refining Service. The committee is also cooperating with the Process Industries Committee in arranging the Heat Transfer Symposium for the coming Annual meeting. The Petroleum Utilization Committee sponsored a Metropolitan Section meeting.

The Process Industries Committee sponsored two sessions at the Chicago Meeting and has planned a Heat Transfer Symposium for the 1933 Annual Meeting. It has appointed a special Subcommittee on Heat Transfer Symposiums which it is anticipated will develop sessions for a number of meetings. Other Divisions and societies are cooperating in these Heat Transfer Symposiums. The Process Industries Committee was responsible for initiating the Society's Special Research Committee on Cotton-Seed-Oil Processing and a report on the work of the Committee was made at one of their sessions in Chicago.

The Subcommittee on Drying sponsored a Metropolitan Section meeting and the Pulverizing and Grinding Committee sponsored a session at Chicago.

The Committee on Air Conditioning sponsored a Pacific Coast Air Conditioning Meeting at San Francisco under the auspices of the San Francisco Section. The Section arranged for the printing of the papers in a special pamphlet form for sale. The Conference was very successful and attracted considerable interest.

The Power Division held two sessions at the last Annual Meeting, one on Industrial Power and one on Central Station Power, and three sessions at the Chicago Meeting. Sessions are also planned for the 1933 Annual Meeting. Besides this, several of the Society's special research committees in the power field hold sessions at the Semi-Annual and Annual Meetings, among these being Boiler Feedwater, Power Test Codes, and Steam Tables Research. The Division has a special Subcommittee on Industrial Power which holds a luncheon meeting during the Annual Meeting and at the 1932 meeting there were two reports presented, one on Power Plant Costs and Records, by W. W. Shoudy, and the other one on Power Plant Betterment, by D. M. Myers.

The Railroad Division held a research symposium of two sessions at the Semi-Annual Meeting at Chicago and is arranging to print the papers presented there in special pamphlet form. The research symposium was of unusual merit and attracted considerable attention. At the 1932 Annual Meeting the Division sponsored two sessions and cooperated in a third session with the Materials Handling Division. The Railroad Division organized a special Subcommittee for the Chicago District known as the Chicago Group. This group is composed of five members and a secretary. Its formation marks an important advance in the organization work of the Division, owing to the importance of Chicago as a railroad center. For the past year, the Executive Committee has been engaged in revising the organization and activities of the Division. A number of new and unique features have been incorporated into its organization, some of which are worthy of study and consideration by other Divisions of the Society.

The Textile Division held a session at the 1932 Annual Meeting and also sponsored an evening meeting in the Metropolitan Section. It also assists New England and Southern Sections in arranging textile

meetings. At the 1933 Annual Meeting a session and a luncheon meeting will be held.

The Wood Industries Division held its National Meeting as part of the Semi-Annual Meeting in Chicago and presented six papers. A Symposium on Wood Preservation which attracted considerable attention was held in the spring in New York. The papers of this Symposium are being prepared by the Division in pamphlet form for distribution.

The Wood Industries Division is planning the reorganization of two former Special Research Committees, one on Saws and Knives and the other on the Existing Supplies of Hardwood. It is the intention of the Division to have these carry on as subcommittees of the Division until such time as they may warrant being again organized as research committees. The Division also has a special survey research committee which is planning surveys of research problems.

Respectfully submitted,

P. T. Sowden, *Chairman*
C. B. Peck, *Vice-Chairman*
K. H. Condit
W. A. Shoudy
G. B. Pegram.

MEMBERSHIP

The Committee on Membership held twelve regular meetings and eleven by proxy during the fiscal year 1932–1933. In addition to special and miscellaneous matters placed before the Committee for consideration and recommendation to Council, the following applications were given attention in the transaction of the Committee's work.

Applications pending, October 1, 1932	255
Applications received during fiscal year 1932–1933	1757
Total applications handled during year 1932–1933	2012
Recommended for membership	1844
Transfers denied	1
Deferred	4
Cancelled	3
Incomplete	12
Applications pending, October 1, 1933	148
Total applications handled during year 1932–1933	2012

The 1844 recommended for membership were divided into the following grades:

Members	86
Transfers to Member	77
Associates	5
Transfers to Associate	2
Associate-Members	66
Transfers to Associate-Member	95
Transfer from Student Member to Associate-Member	1
Juniors	136
Transfers from Student Associate to Junior (R5-Rule 1)	379
Transfers from Student Member to Junior (R5-Rule 1)	997
Total recommended	1844
Total new members recommended	1670
Transfers (above Junior grade)	174
Total recommended	1844

During the fiscal year 1932–1933 the Membership Committee made the following recommendations:

Elections declared void	134
Resignations accepted	418

Respectfully submitted,

Hosea Webster, *Chairman*
O. E. Goldschmidt
H. A. Lardner
R. H. McLain
C. L. Davidson
H. W. Butler, *Advisory Member.*

CONSTITUTION AND BY-LAWS

Four meetings of the Committee held in December, 1932, were devoted to a study of the possibility of simplification of the By-Laws and Rules and to the consideration of suggestions the Committee had invited from the chairmen of the various committees and the staff, which indicated the advisability of a considerable number of changes. While the Committee found little opportunity for any material reduction in volume of the By-Laws and Rules, short of omissions that would leave some of the activities of the Society without definition and control, a complete revision is advisable in order to simplify and clarify the material, to improve the grouping of items, and to eliminate minor inconsistencies. The Committee has prepared a draft of the major part of the By-Laws and Rules in recommended form, but this draft cannot be completed until decisions are reached by those interested in a number of items.

In the meantime, the Executive Committee of Council, at its meeting on June 8, 1933, directed the Committee to discontinue its work on the proposed revision because of present conditions, and the Committee is therefore awaiting the pleasure of the Council before proceeding further.

During the year certain changes in the By-Laws and Rules have been presented to the Committee on Constitution and By-Laws for consideration. These amendments, approved by the Committee, are now before the Council for action, and include, first, a revision of the Code of Ethics; second, a change in the manner of electing delegates to the American Engineering Council by placing the choice of these delegates in the hands of the A.S.M.E. Council; third, a provision in the By-Laws and Rules for the Local Sections Delegates' Conference; and, fourth, a change in the wording regarding Life Membership payment.

Respectfully submitted,

T. C. McBride, *Chairman*
R. S. Neal
P. R. Faymonville
H. H. Snelling
J. A. Hall.

AWARDS

Faced once more with the impossible task of comparing practically incomparable papers for Society awards, the Committee on Awards took certain steps to have some of its duties handled more efficiently.

Papers submitted for the Student Awards were referred to the Committee on Relations With Colleges. This Committee accepted the responsibility because of its potentiality for improving its college contacts.

The Charles T. Main Award papers were referred to the Pure Air Committee because this year's subject was "Progress in the Prevention of Smoke and Atmospheric Pollution."

In order better to administer the Max Toltz Loan Fund, the Committee recommended to the Council that this responsibility be transferred to the Committee on Relations With Colleges. This was approved by the Executive Committee, September 22.

Dexter S. Kimball, past-president, was appointed to fill the unexpired term of D. B. Rushmore.

Announcement of all awards for the year 1933 will be made at the Annual Meeting in December.

Respectfully submitted,

K. H. Condit, *Chairman*
F. L. Eidmann
D. S. Kimball
W. L. Batt
R. C. H. Heck.

RELATIONS WITH COLLEGES

During the past college year the Committee on Relations With Colleges has extended the new plan of student membership into the New England, North Atlantic, and North Central States by personal visits to 48 engineering colleges. Without exception, the new plan has been adopted by the Student Branches. The result has been a student membership of 1900 in four out of seven divisions of the United States and four regional conferences—at Bethlehem, Birmingham, Chicago, and Worcester—with an average student attendance of more than 200 at each.

The support of the Student Branches and the membership total have been very gratifying to the Committee, particularly as college students have felt the depression severely. The dues from Student Members have been sufficient to balance the operating expenses of

the new plan within $43, which is less than one per cent of the budget. The Committee is confident that the student membership will carry its own division of the Society financially when all college Branches are under the new plan and economic conditions have improved. Even in the desperate financial situation of the past year an average of 30 students were enrolled in each of the 65 Student Branches functioning under the new plan. Of the approximately 1900 Student Members of the Society, composed of both Juniors and Seniors, and in some cases Sophomores, 1000 were transferred upon graduation to the grade of Junior. In view of the economic conditions the Council has extended the period during which these students may qualify in order to give them an opportunity to secure employment.

Under the new plan an engineering student attains regular membership in the Society, with the grade of Student Member, upon the approval of his application by the Council. Student Members receive *Mechanical Engineering* and other Society literature and hold their own conferences, at which they present their own papers. They are not only informed of engineering society affairs but taught active participation in them. The Committee on Relations With Colleges believes that this plan will annually introduce several thousand Junior Members to the Society as soon as it has been completely installed, and that these Junior Members will be prepared and anxious to take part in Society work.

This Committee appreciates the help of the Committee on Local Sections, which is not only fostering interest in the Student Members but making careful plans for retaining and developing their support as Juniors. The recommendation of the Committee on Policies and Budget, approved by the Council, that the student plan be extended as rapidly as financially possible, is an expression of confidence greatly appreciated by your Committee. The plan will be extended to the engineering colleges of Ohio, West Virginia, and Western Pennsylvania before the 1933 Annual Meeting.

The Committee has agreed to take over the responsibility for certain activities heretofore administered entirely by the Committee on Awards. These include the administration of the Max Toltz Loan Fund, which is available to engineering students, and the recommendation regarding the winners of papers submitted for the Student Awards.

Respectfully submitted,

D. B. Prentice, *Chairman*
E. F. Church, Jr. — E. W. O'Brien
W. L. Abbott — R. V. Wright.

EDUCATION AND TRAINING FOR THE INDUSTRIES

The reduction in the number of workers in industry during the past five years, particularly in the machine industries, brought about reductions in training programs for these industries. The sessions arranged for 1933 by the Committee were planned to give the present status of education for industry in various sections of this country, and to show the trend of such education. The subjects for these sessions were proposed by the Committee in 1932 under the chairmanship of Dean R. L. Sackett. One paper on the training of workers for industry in times of depression was also included. Following are the programs for the Semi-Annual Meeting and for the Annual Meeting.

Semi-Annual Meeting. "Education Within Industry in the Central States," by Robert H. Spahr, director, Instruction and Curriculum Development, General Motors Institute of Technology, Flint, Mich.; "Training Programs for Apprentices in Times of Depression," by John T. Faig, president of Departments, Ohio Mechanics Institute, Cincinnati, Ohio.

Annual Meeting. "Training Within Industry in the East," by Ovid W. Eshbach, American Telephone & Telegraph Co., New York, N. Y.; "Training Within Industry in the South," by Theodore S. Johnson, professor of industry, North Carolina State College of Agriculture and Engineering, Raleigh, N. C.

The Committee on Education and Training for the Industries confines its activities to sessions on training and education of non-college type for the industries, in order that its activities may not cross into the field of the Committee on Relations With Colleges. There is peculiar need for a forum for the presentation of education and training for the industries in our Society, and this our committee attempts to offer. In times of depression, training programs in many of the small and medium sized companies are altogether abandoned, or are reduced to skeleton organizations. When economic conditions improve, the personnel charged with the revival of the training program is frequently the reflection of the interest and enthusiasm of one of the executives of the plant, whose influence may be lost when he leaves the organization or when his increasing responsibilities leave little time for the problems of education and training.

Some years ago, when the volume of business was much larger, papers on this important subject were presented at many regional sessions, as well as at the Semi-Annual and Annual Meetings. More recently they have been offered only at these two meetings. However, many business organizations are daily losing some workers through death or retirement, and relatively few apprentices are being taken on, so that when business is again better, it is likely that a considerable dearth of workers will be experienced in some lines. We are therefore approaching a time when our Committee should become more active. It is wise for the Society to carry on with its program in education and training for the industries, so as to maintain the interest of specialists in these lines in the Society and to provide the opportunity for an exchange of ideas.

Respectfully submitted,

J. T. Faig, *Chairman* — S. S. Edmands
H. S. Falk — R. H. Spahr.
C. F. Bailey

LIBRARY

The Library Committee, as representatives of the Society upon the Library Board of the Engineering Societies Library, presents the following report.

The depression of the past year has brought no lessening of demands upon the library. On the contrary, unoccupied time and the need for information upon new lines of activity have brought members to it in larger numbers than before. Thirty-three thousand readers, seventeen per cent more than in the previous year, have visited it, and more than twelve thousand others have used it by mail. The readers have taxed the seating capacity on many days, although additional chairs were provided during the year.

Literary resources have also increased. Books and pamphlets to the number of 7800 were added, bringing the total up to 145,000.

The library has suffered severe financial restrictions during the year. Its budget has decreased from $54,500 in 1931 to $42,450 in the current year. This heavy reduction in the appropriation for its maintenance has necessitated drastic economies. To bring the cost of operation within the amount appropriated it has been necessary to reduce salaries, employ fewer workers, buy fewer books, and shorten the hours open. The Library Board has endeavored to meet this perplexing situation of increasing use and decreased funds in a way that will cause the least inconvenience to members.

If the library is to maintain its rank, as a place where all important periodicals and new books are to be found, additional funds are urgently needed. Increased use brings greater demands, which cannot be met unless funds for books and sufficient personnel to attend to inquirers are provided. It is earnestly hoped that ways may be found to enlarge the service given, and that any necessity for further curtailment of the work will be voided.

Respectfully submitted,

W. M. Keenan, *Chairman*
G. F. Bateman — G. F. Felker
E. P. Worden — Calvin W. Rice.

RESEARCH

The wisdom of the founders in providing that the encouragement of original research should be one of the principal objects of the Society has been fully demonstrated over the years, even these latter years of economic depression. Interest in the 25 projects sponsored by the A.S.M.E. has been sustained on the part of the engineering and industrial firms mostly concerned and especially on the part of the 450 members of the committees in charge of these problems.

During the year two new projects were authorized by the Council. The first of them was proposed by the A.S.M.E. Process Industries Committee and covers a study of the mechanical problems in conditioning, cooking, and pressing of cotton-seed meats. The second deals with methods of sampling pulverized fuel in moving gas streams. This latter project was endorsed by the A.S.M.E. Fuels Division, and while the difficulties of the problems involved are fully recognized, the Committee is receiving the full support of those members of the Society most interested. The A.S.M.E. Research Committee's part in the initiation and development of these research projects is of necessity limited to that of a helpful influence. The Committee members and the staff confer with the Special Committee members and give them the benefit of their years of experience in the organizing and financing of such activities.

The progress toward the completion of the study of the thermal properties of steam begun in 1921, has been steady during the year. The experimental work at the Massachusetts Institute of Technology and the Bureau of Standards has advanced satisfactorily so that January 1, 1934, has been set for the completion of this project. The Fluid Meters Committee has also been active. It has supplied the inspiration and some of the money for experimental work at the Ohio State University and the University of Oklahoma on flow coefficients for oil and gas measurement. The American Gas Association has cooperated in the first of these series of tests and the American Petroleum Institute is showing interest in them also. The important Part 3 of the Fluid Meters Report on Selection and Installation of Meters has been completed and will be published by the Society in December.

Business conditions notwithstanding, the Joint Research Committee on Boiler Feedwater Studies has been successful in financing two important researches closely related to the conditioning of boiler feedwater. One subcommittee has collected $5000 from industry this year and has an equal amount pledged next year for a two-year study of the alkalinity and sulphate relations in boiler water salines. The experimental work has been under way at the Bureau of Mines Non-Metallic Minerals Experiment Station, New Brunswick, N. J., since March. Another subcommittee has developed test methods for the determination of carbonates, hydroxides, and phosphates in boiler waters from experimental work at the University of Michigan. This study was financed by the Engineering Foundation* and the new methods are being published by the Society for trial by industry preliminary to their formulation as standard test procedures by the A.S.T.M. for referee and plant control purposes.

In the metallurgical field, the Special Research Committees on the Cutting of Metals, on Mechanical Springs, on Vessels Under External Pressure, and on the Effect of Temperature on the Properties of Metals have advanced their programs consistently. Progress reports on the experimental work and technical papers, prepared by members of the several committees and the research workers employed by the committees, have been presented at the meetings of the A.S.M.E. and other societies. Among the reports presented are (1) a code for the design and construction of unfired pressure vessels subjected to external pressure and (2) tentative test codes for short-time and long-time high-temperature tensile tests for metals.

Organization and Financing

The accumulated experience of the A.S.M.E. Research Committee, which has existed continuously over a period of 25 years, has shown that the Society can most effectively meet the needs of its membership in the field of research by sponsoring specific researches that are of broad interest to the engineering profession and industry, and that are especially suited to cooperative study. By virtue of its prestige, impartial character, and freedom from commercial influence, the Society is continuously demonstrating its ability to promote industrial cooperation in the solution of common problems. It is able to exert a coordinating influence and to prevent unnecessary duplication of effort.

This sponsorship of cooperative research by the Society carries with it certain obligations; there are implied obligations of service to the special committees, contributed funds must be held and carefully administered so that contributors receive full value for their money, and the provisions of the contracts entered into by the special committees with laboratories and research workers must be fulfilled.

As in the past, this year the Standing Committee on Research continued to assist the various Special Committees with their plans for financing their projects. The small grant of $300 which the Council made this year was used to aid three committees to carry on. It was possible, however, for the Committee to secure six grants from the Engineering Foundation, totaling $8000, for a corresponding number of Special Committees sponsored by the Society. This financial assistance has prompted industry to contribute, as in the past, from three to four times the total expenditure of the Society for this activity. This year the amount raised from outside sources was $40,500.

Employment

A fair number of jobs and highly technical training are provided the research workers employed through the practice of the committees in placing experimental programs in university and institutional laboratories. During the past year 25 men have been at work, full or part time, at the following laboratories: Bureau of Standards at Washington and Columbus, Bureau of Mines at Pittsburgh and New Brunswick, Battelle Memorial Institute, the Universities of Illinois, Michigan, Ohio, Oklahoma, and Tennessee, Carnegie Institute of Technology, Purdue University, and the Massachusetts Institute of Technology.

Publications

One tangible return to the members of the Society from its activity in the field of cooperative engineering research is represented by the reports and papers contributed by the committees to the technical sessions and the publications of the Society. Approximately twenty-five separate articles amounting to some 120 printed pages of original technical material were contributed during the past year to *Mechanical Engineering*, the Transactions, and the technical press. These cover problems in many of the specialized fields of mechanical engineering. In addition, reports and papers amounting to 400 typewritten manuscript pages were produced by the committees, some of which will be published if the necessary funds are available.

The texts of the following special publications were completed and will be published in pamphlet form during the first few months of the new fiscal year: Fluid Meters Report, Part 3, on "Selection and Installation," a group of reports on the "Determination of Carbonate, Hydroxide, and Phosphate in Boiler Waters," and collected "Research Reports and Papers for 1933." The "Report of Tests on Electrical Equipment for Drilling Rotary-Drilled Oil Wells" was issued in April.

International Cooperation

The amount of correspondence and the exchange of reports, and personal contacts, with members of committees of sister societies abroad, have been as in other years. The most important societies participating this year in this exchange are the Institution of Mechanical Engineers and the Department of Scientific and Industrial Research of Great Britain, the Société des Ingénieurs Civils de France, and the Verein deutscher Ingenieure. To Laurence V. Benét, managing director of Hotchkiss and Co., Paris, is due the credit for the development of our research relations with the French engineers, and he has promoted these relations during the past year. A prominent visitor was Dr. Ing. Friedrich Schwerd of the Technische Hochschule, Hannover, Germany, who presented a paper on his metal cutting research work at the 1933 Semi-Annual Meeting at the invitation of the Special Research Committee on Cutting of Metals.

The following two committees were discharged within the period of this report since they had served their purposes: the Special Research Committee on Existing Supplies of Hardwoods and the Special Research Committee on Methods and Apparatus for Noise Measurement.

Special and Joint Committee Reports

Lubrication, A. E. Flowers, Chairman. The Committee has selected a group of 14 original papers on lubrication, many of which are out of print or difficult to obtain, and has prepared abstracts of them. It is the Special Committee's recommendation that these be combined and published with a bibliography of two or three hundred important references on lubrication which it has collected.

Fluid Meters, R. J. S. Pigott, Chairman. Fluid Meters Report, Part 3 on Selection and Installation was completed and will be published in December, 1933, for sale by the Society. A revision of Part 1 on Theory and Application which will greatly broaden its scope, is under way.

The joint A.G.A.-A.S.M.E. subcommittee is analyzing the results of its test program, conducted by Prof. S. R. Beitler at Ohio State University, from which it expects to clear up existing discrepancies in the values of orifice coefficients for gas measurement. The American Petroleum Institute may cooperate in the sponsorship of the resulting handbook.

Tests at the University of Oklahoma under Prof. W. H. Carson to determine the accuracy of existing coefficients and correction factors for the flow of oil through orifice plates, flow nozzles, and venturi tubes have been hampered somewhat during the year by the proposed movement of the Engineering College from Norman to the State Agricultural and Mechanical College, at Stillwater.

Thermal Properties of Steam, Alex Dow, Chairman. At the Massachusetts Institute of Technology, Dr. F. G. Keyes completed the correlation of specific volume data obtained from his experimental work and has nearly completed that on compressed liquids. He is engaged in the measurement of the constant temperature and Joule-Thompson coefficients and the comparison of the Kelvin with the platinum resistance temperature scale. The establishment of this relation is necessary in order to provide a basis for the correlation of the experimental data.

The saturated liquid and vapor measurements at the Bureau of Standards under Dr. N. S. Osborne are to be completed and correlated by January 1, 1934. This will complete the experimental pro-

* The A.S.M.E. is represented on The Engineering Foundation and also upon the Division of Engineering and Industrial Research of the National Research Council. For the reports of these representatives see pages 45 and 47.

gram which has been financed by the Committee since 1921 at a total cost of $175,000 at three laboratories.

Dr. J. Havlicek presented the results of three years' valuable work at the Masaryk Academy of Work, Czechoslovakia, to the Committee's 1932 Annual Meeting session. It included nearly 800 measurements of the enthalpy of compressed water and superheated steam over a wide range of temperature and pressure. Work at M.I.T. and the Bureau of Standards was also reported on at this session.

It is hoped that economic conditions will permit the holding of the Third International Steam Tables Conference next year in the United States as was planned for this year. Much new data have been collected by the research workers here and abroad which should make it possible to narrow considerably the present tolerances of the international skeleton tables.

Strength of Gear Teeth, R. E. Flanders, Chairman. The investigation of the surface fatigue limits under wear and dynamic loading for materials used in the manufacture of helical gears has occupied the attention of this Committee during the year. Prof. Earle Buckingham and graduate students at the Massachusetts Institute of Technology employed the Lewis Gear Testing Machine owned by the Committee for this purpose. Lack of funds has hampered progress.

Cutting of Metals, F. C. Spencer, Chairman. The Subcommittee on Metal Cutting Materials under the chairmanship of Coleman Sellers, 3d, reports that the further introduction and development of shop practice in the use of cemented carbide cutting tools has been greatly retarded by the present business conditions. Nevertheless, the Subcommittee has kept the members of the Society informed of progress in this field through papers it sponsored at the 1932 Annual and 1933 Semi-Annual Meetings.

Another subcommittee, under the chairmanship of King Hathaway, has been successful in collecting and correlating a large volume of published and unpublished data on (1) speeds and feeds in machine operations, (2) choice of tool steels, and (3) heat treatment and grinding of tools. It is the purpose of this Subcommittee to develop material for a series of practical handbooks for the shop based on the principles advanced by F. W. Taylor, Carl G. Barth, and others but applied to modern tool and work materials.

In December, 1932, C. J. Oxford and Prof. O. W. Boston presented a final report of the Subcommittee on Cutting Fluids on experiments conducted for the Committee at the University of Michigan.

Mechanical Springs, J. R. Townsend, Chairman. Dr. D. J. McAdam, at the Bureau of Standards, is completing an extensive report summarizing the present state of the knowledge of the fatigue characteristics of spring materials. A section of this report was presented as a paper for general discussion at the 1933 Semi-Annual Meeting of the Society and it is planned to publish the complete report shortly.

Business conditions have slowed up the tests on fatigue life of helical and wire springs conducted by several cooperating industrial laboratories for the subcommittees under the chairmanships of C. T. Edgerton and F. P. Zimmerli.

Prof. M. F. Sayre at Union College has completed his report on the elastic behavior of spring materials and will present it at the 1933 Annual Meeting in December.

Effect of Temperature on Properties of Metals (Joint Committee with the American Society for Testing Materials), H. J. French, Chairman. Tentative test codes for short-time and long-time high-temperature tensile tests were completed and submitted to the sponsor societies for publication in June, 1933.

Results obtained from the experimental programs financed by the Committee at the University of Illinois under Prof. H. F. Moore and at Battelle Memorial Institute under Dr. H. W. Gillett will be reported at the 1933 Annual Meeting. Comparisons of creep and fatigue characteristics of cast and wrought 18:8 chromium-nickel steels at temperatures up to 1200 F will be available then. Business conditions have practically halted similar studies that were being carried on by cooperating industrial laboratories.

A subcommittee on which are represented the American Petroleum Institute, the American Association of Steel Manufacturers, and the Joint Committee was organized and is studying problems relating to high-temperature applications of metals in oil refineries.

The Committee assists in the review and abstracting of current high-temperature literature which is published monthly in *Metals and Alloys*.

Condenser Tubes, A. E. White, Chairman. During the past year this Committee has continued to encourage studies in certain central-station plants and to collect and report industrial experience in fighting condenser-tube deterioration. A report and two papers were presented at the 1932 Annual Meeting last December.

Boiler Feedwater Studies (Joint Committee with the American Boiler Manufacturers Association, American Railway Engineering Association, American Society for Testing Materials, American Water Works Association, and Edison Electric Institute), S. T. Powell, Chairman. A subcommittee under the chairmanship of C. H. Fellows has completed within the year the development of test methods for the determination of carbonates, hydroxides, phosphates, and sulphates in boiler waters. These test methods are the result of experimental work conducted at the University of Michigan and financed by a grant from the Engineering Foundation. They are to be given preliminary publication by the A.S.M.E. and when they have proved their reliability they are to be recommended to A.S.T.M. Committee D-19 as the bases for preparing standard referee and plant control test procedures.

With the aid of funds supplied by the Joint Committee, Prof. C. W. Foulk has continued his experiments at Ohio State University on priming and foaming of boiler waters. He presented a report at the 1933 Semi-Annual Meeting of the Society on the effect of suspended solids in promoting foam.

During the year, a subcommittee under the chairmanship of J. H. Walker has raised more than $5000 and has pledges of an additional amount from industry for a two-year study of alkalinity and sulphate relations in boiler water salines. The experimental work is progressing satisfactorily at the Bureau of Mines Non-Metallic Minerals Experiment Station, New Brunswick, N. J., and a preliminary report will be made at the 1933 Annual Meeting.

Boiler Furnace Refractories, W. A. Carter, Chairman. Again this year the study of the principal components of the slag refractory system has been continued at the Bureau of Standards Ceramic Station, Columbus, Ohio, under T. A. Klinefelter. Due to a lack of funds the Committee was obliged to withdraw financial support from this experimental program about the middle of the year, but the Bureau is continuing the work at its own expense. A progress report is in preparation.

Elevators, M. H. Christopherson, Chairman. Lack of funds compelled this Committee also to stop its buffer test program at the National Bureau of Standards on March first. However, the extensive equipment will be kept intact and studies of undercar safeties will be undertaken when business conditions improve. The Committee has continued to meet throughout the year.

Strength of Vessels Under External Pressure, W. D. Halsey, Chairman. A draft of a proposed code for the design and construction of unfired vessels subjected to external pressure was completed by the Committee. It will be recalled that this project was originally proposed by the A.S.M.E. Boiler Code Committee. So, within a few weeks, this tentative proposed code will be submitted to the A.S.M.E. Boiler Code Committee for review. This proposal applies only to the three main types of vessels in wide use and operated under external pressures not in excess of 500 lb per sq in. and temperatures not in excess of 700 F.

Absorption of Radiant Heat in Boiler Furnaces, W. J. Wohlenberg, Chairman. Considerable data on the measurement of furnace temperatures has been made available to the Committee during the year by twelve central stations. A report is being compiled by an engineer under the direction of the chairman at Yale University.

Velocity Measurement of Fluid Flow, W. F. Durand, Chairman. As teaching duties have permitted, Professors H. E. Hartig and H. B. Wilcox at the University of Minnesota have continued the development and testing of their methods of utilizing sound waves for the measurement of velocity of fluid flow.

Measures of Management, W. E. Freeland, Chairman. The Committee has continued its activity of collecting and reporting information on management research going on throughout the country. It is in touch with ten such projects under way in industry and universities. Prof. E. D. Smith and L. C. Lichty of Yale will report the results of their investigations of the human aspects of technological development at the Committee's session during the 1933 Annual Meeting. A round table conference will also be held at which Dr. Shewhart of the Bell Telephone Laboratories will discuss developments in the control of quality and its practical significance to the inspection function in manufacture.

Diesel Fuel Oil Specifications, L. H. Morrison, Chairman. Owing to the Government economy program, the tests to discover the effect of variations in the viscosity and Conradson carbon of fuel oils on Diesel engine operation have proceeded slowly at the U. S. Submarine Base, New London, Conn. However, the laboratories of several cooperating oil companies and engine manufacturers have investigated the ignitability of fuel oil in a new type of experimental engine.

Wire Rope, W. H. Fulweiler, Chairman. The Bureau of Standards completed tests on 150 samples of worn wire rope contributed by building operators, the mining industry, the U. S. Navy Bureau of Construction and Repair, the Panama Canal, etc. Funds to cover these tests were made available by the Engineering Foundation. The preliminary report indicates that a definite relation exists between wear and the number of broken wires in a rope and its remain-

ing strength. It is expected that this report will be published about the first of next year. The tests are being continued.

Heavy Duty Anti-Friction Bearings, W. Trinks, Chairman. The program which the Committee laid out for itself in 1929 was brought to a successful completion during the year within the limit of funds contributed by industry—which in the three years of the investigation amounted to more than $7500.

A paper on "Strength of Roll Necks," summarizing the work of the preceding year, was presented by the Committee at the 1932 Annual Meeting. The Ninth Progress Report, "Comparative Study of Various Types of Roll Neck Bearings," and the Tenth Progress Report (final), "Roll Neck Bearings," were completed during the present year and distributed to committee members and financial subscribers. An abstract of the final report was presented at the 1933 Semi-Annual Meeting in Chicago, and the entire report is now being revised for publication and sale by the Society.

While the Committee plans no further experimental work at present, it will continue to function as a clearing house for information on rolling and roll neck bearings. An investigation of plastic deformation is also being considered in cooperation with the Plasticity Committee of the Applied Mechanics Division.

Removal of Ash as Molten Slag From Powdered-Coal Furnaces, K. M. Irwin, Chairman. Samples of coal, slag, and fly ash received from twelve stations have been analyzed at the Bureau of Mines Experiment Station in Pittsburgh, Pa., cone fusions made, and flow temperature determined in air in the electric furnace. Cone fusion values are important for operators to know, as they indicate the probable qualities of slag which coals will give that have not been previously tried in slag tap furnaces.

A study has been nearly completed on the effect of the state of oxidation of the iron in slags on the flow temperature. The ratio of silica to alumina is another variable affecting flow temperature that has been studied.

The fluxing effect of some materials—principally limestone—as dependent on the state of the iron in the slag as fixed by the reducing effect of the furnace atmosphere is to be studied. The principles of absorption of fly ash on a molten slag surface are also to be briefly investigated.

The Committee presented a progress report at the 1932 Annual Meeting and will present another at the 1933 Annual Meeting of the Society.

Automatic Oil Pipe Line Pumping Stations, W. G. Heltzel, Chairman. Economic conditions have temporarily halted the research program of this Committee, but the same personnel is functioning in the way of holding meetings on subjects of vital interest to the pipe line industry just now. A pipe line symposium on Air Compressor Explosions in Diesel Engine Driven Pumping Stations was held in Tulsa on May 12, and a pipe line conference for the purpose of arriving at a suitable formula for the calculation of fluid flow in pipes on May 13, 1933. The Committee is at work on a report on the Economic Analysis and Costs of Pipe Line Pumping Stations. When finances permit, the Committee expects to improve its experimental station on the basis of the experience gained in field stations that were built with it as a model.

Rotary Drilling of Oil Wells, D. L. Trax, Chairman. At the University of Oklahoma, Prof. W. H. Carson made tests on an experimental set-up of boilers and slush pumps, such as are used in steam rotary drilling, and collected data for an addition to the Committee's Steam Rotary Drilling report published by the Society last year.

An investigation of the performance and efficiency of a gas-electric type of prime mover while employed in the drilling of a rotary-drilled oil well was made. The data are now being computed and compiled in the form of a report similar to the one on Steam Rotary Drilling.

The "Report of Tests on Electrical Equipment for Drilling Rotary-Drilled Oil Wells," supplementing the previous report for Steam Equipment, was published in April, 1933, by the Society.

Critical Pressure Steam Boilers, A. A. Potter, Chairman. A report was presented, at the 1932 Annual Meeting, covering enthalpy determinations made on steam at high pressures and temperatures in the experimental boiler. The results were in line with the Keenan and new German steam tables.

Tests with water and steam were conducted to secure data on friction losses during flow in pipes of various sizes and at a wide range of pressures and temperatures. Friction factors with cold water and saturated steam were consistent and reproducible; but great variations in friction factors were obtained with superheated steam. The cause for these variations is now being investigated and is apparently related to the condition of the feedwater. Head losses through valves will also be studied. In connection with this study use is made of an X-ray tube as a manometer and with unusually fine results.

Sampling Pulverized Fuel in Moving Gas Streams, J. C. Hardigg, Chairman. This project was organized at a meeting held during the 1932 Annual Meeting of the Society. The Committee is investigating the possibility of developing a satisfactory standard method for sampling pulverized fuels in a moving gas stream and for checking the efficiency of pulverizing equipment. Various methods now in use for sampling are being tested and compared with the hope that a generally satisfactory test method may be evolved.

Cotton Seed Processing. At its meeting on December 9, 1932, the Council approved the organization of this committee to study the mechanical problems in conditioning, cooking, and pressing cotton-seed meats. The project is centered at the University of Tennessee under Prof. W. R. Woolrich, and is moving forward slowly. A progress report was presented at the 1933 Semi-Annual Meeting in Chicago, the substance of which was published in the trade press. The Tri-States Cotton Oil Mill Superintendents Association has subscribed $500 and the University of Tennessee $675 toward the experimental program. A grant of $500 during 1933 was secured by the Society from The Engineering Foundation to support the study.

The following two Committees were inactive due to business conditions: the Special Research Committee on Worm Gears and the Joint S.A.E.-A.S.M.E. Committee on Diesel Fuel Combustion.

Respectfully submitted,

W. H. Fulweiler, *Chairman*
A. D. Bailey — D. B. Bullard
G. M. Eaton — C. R. Richards.

STANDARDIZATION

Notwithstanding the economic conditions which have prevailed during the year, satisfactory progress has been made by many of the committees, and the committee organization has grown somewhat. In all, 31 large sectional committees have been at work on as many separate projects under the procedure of the American Standards Association.* These include one new project, the sponsorship for which was accepted in May, 1933. These committees have subdivided themselves into 265 subcommittees and subgroups in order that the work assigned to them might be carried forward more promptly and effectively. The total number of members of these committees is now 1145, of which 412 are members of the A.S.M.E. During the year the Society was represented on 28 additional standards committees by 41 of its members. A total of 50 standards committee meetings were held within the twelve month period.

The broad nature of the Society's technical committee activity in the field of standardization is indicated by the nature of the several projects which have made the most significant progress toward completion during the year. The greatest interest has centered around the revision and extension of two American Tentative Standards originally completed and published in 1927, the standard for "Steel Flanged Fittings and Companion Flanges" and the standard for "Wrench Head Bolts and Nuts and Wrench Openings." On the other hand, the most general interest of the membership at large was shown in the two standards for "Engineering and Scientific Charts for Lantern Slides" and "Abbreviations for Scientific and Engineering Terms." The first of these projects grew out of recommendations of the A.S.M.E. Meetings Committee for the improvement of the form of lantern slides used in the Society's meetings to illustrate technical papers and committee reports. The chairman of the Committee was W. A. Shewhart. The second is part of a larger project set up for the standardization of letter symbols for use in technical publications of all kinds and was led by George A. Stetson, editor of A.S.M.E. publications. All four of these standards are now available in pamphlet form.

The list of standards completed includes also a number which are of special interest to certain branches of mechanical engineering. They are "Gear Materials and Blanks," "Shaft Couplings," "Spur Gear Tooth Form," and standards on several types of ball bearings.

Two projects which, though not completed, have been advanced well along toward completion by the energetic work of their committees are: (1) Code for Pressure Piping, E. B. Ricketts, chairman, and (2) Drawings and Drafting Room Practice, F. DeR. Furman, chairman of Sectional Committee, who was assisted in the editing of the standard by T. E. French.

The new project for which the Society was named sponsor, the Unification of Rules for the Dimensioning of Furnaces for Burning Solid Fuel, grew out of the necessity of burning fuels with higher efficiency and without the production of smoke. It was proposed by the Pure Air Committee.

Under the American Standards Association's procedure it is con-

* The A.S.M.E. has two representatives on the ASA. For their report see page 45.

venient to indicate the present status of the several projects for which the Society holds sponsorship or joint sponsorship by classifying them under the following seven heads which represent definite steps in that procedure: (1) Committee Organization, (2) Development of Proposal by Subcommittee, (3) Distribution of Tentative Proposal to Industry for Criticism and Comment, (4) Review of Comments by Subcommittee, (5) Revised Proposal Before Sectional Committee, (6) Proposed Standard Before Sponsor Bodies, and (7) Approval by ASA and Publication in Pamphlet Form.

This care and deliberation in the development of these standards has been found desirable and necessary since the designation "American Standard" implies general acceptance by all interested groups forming the branch of industry affected by the standard.

(1) Committee Organization

Classification and Designation of Surface Qualities, C. G. Mettler, Temporary Chairman. The organization meeting of the Sectional Committee on Classification and Designation of Surface Qualities was held in New York on December 9, 1932. Officers were elected for the Committee and five subcommittees organized to prepare draft standards covering: (1) Surfaces Produced by Tools and Abrasives, J. Cetrule, temporary chairman, (2) Surfaces Produced by Mold, Die, Rolls or Any Other Means of Deforming Materials, E. F. Cone, temporary chairman, (3) Coated Surfaces, V. W. Todd, temporary chairman, (4) Symbols for Indicating Surface Quality on Drawings, T. G. Crawford, chairman, and (5) Ways, Means, and Apparatus for Measuring Quality of Surface, R. T. Kent, temporary chairman.

Subcommittees Nos. 4 and 5 held their first meetings in Chicago during the Semi-Annual Meeting of the Society, June 26–30, 1933. A tentative proposal on Symbols for Indicating Surface Quality on Drawings is now in the hands of the members of Subcommittee No. 4 for review.

Unification of Rules for the Dimensioning of Furnaces for Burning Solid Fuel, C. W. Bronson, Temporary Chairman. Acting on a resolution passed at a conference called by the A.S.M.E. Pure Air Committee in December, 1932, the A.S.M.E. Standardization Committee recommended to the Council of the Society in March, 1933, that a project on standard setting heights of small boilers be initiated under the procedure of the American Standards Association. Favorable action was taken by the Council of the A.S.M.E. and the Mechanical Standards Advisory Council, and on March 29, 1933, the A.S.M.E. requested the ASA to authorize the organization of such a project and offered its services as sponsor or joint sponsor.

The ASA in turn approved the initiation of the project and assigned sponsorship to the A.S.M.E. in May. Letters inviting 21 national associations to appoint official representatives to the Committee were immediately issued, and the organization meeting of the Committee was held on June 26, 1933, in Chicago. At this time the temporary officers of the Committee were elected and five subcommittees appointed: No. 1 on Scope, No. 2 on Combustion and Design, No. 3 on Warm Air Furnaces, No. 4 on Steel Heating Boilers (internally and externally fired), and No. 5 on Cast Iron Boilers.

(2) Development of Proposal by Subcommittee

Ammonia Flanges and Fittings, W. R. Kremer, Chairman. The proposed American Standard for Ammonia Fittings was formally approved by Subcommittee No. 1 on Cast Iron Flanges and Flanged Fittings for release to industry for criticism and comment. It is now being set in type to provide the necessary copies for this distribution.

Center to Face Dimensions of Ferrous Flanged Valves, F. H. Morehead, Chairman. During this year Subcommittee No. 5 on Face to Face Dimensions of Ferrous Flanged Valves developed a proposed standard for Center to Face Dimensions of Ferrous Flanged Valves for various pressures. This proposal will be distributed to industry in the near future for criticism and comment.

Materials and Stresses, A. M. Houser, Chairman. A series of adjusted pressure ratings for steel fittings when used at temperatures other than the rated temperature of 750 F was developed by Subcommittee No. 4 on Materials and Stresses. Final approval and publication of this table is delayed pending the modification of certain of the ratings to permit the use of the table in oil refinery practice.

Port Openings. The work on the revision of Port Openings for the 125 lb cast iron flanged fittings, sizes 14 to 24 in., which was assigned to Subcommittee No. 9 with W. W. Hubbard as chairman, has been discontinued. This action was taken upon the recommendation of the chairman, who reported after meetings of his Committee and a canvass of the industry that there was no pressing need for the changes proposed.

The four preceding projects are being developed by subcommittees of the Sectional Committee on Pipe Flanges and Fittings, of which C. P. Bliss is chairman.

Taper Pipe Threads, S. B. Terry, Chairman. During this year Subcommittee No. 2 on Taper Pipe Threads completed the revision of pamphlet B2-1919, which outlines the Taper Pipe Thread Standard with the exception of one or two points concerning gages which are still in question. It is expected that these will be settled shortly, and that the revision will then be submitted to the Sectional Committee for approval. This project comes within the scope of the Sectional Committee on Standardization of Pipe Threads.

Screw Threads, R. E. Flanders, Chairman. The Sectional Committee met in January, 1933, and at that time all details incidental to the revision of the Screw Thread Standard (B1a-1924) were thoroughly reviewed. This work is now under way, and the principal departures from the original standard are: (1) addition of three new series, 8, 12, and 16 pitch, (2) fixing of pitches for sizes 3 to 4 in., inclusive, and (3) revision of minor diameters of nuts. The combined work of Subcommittee No. 2, C. W. Bettcher, chairman, and Subcommittee No. 3, R. E. Flanders, acting chairman, is represented in the revision.

Screw Thread Survey, R. E. Flanders, Chairman. The report of the survey written by Earle Buckingham was discussed at the January, 1933, Sectional Committee meeting, and two copies were subsequently circulated to the members of the Committee for review prior to final editing and publication.

Acme Threads, Earle Buckingham, Chairman. Subcommittee No. 4 on Acme Threads has prepared a proposal covering the several types of Acme threads in more common industrial use. It is anticipated that this proposal will soon be duplicated for transmittal to the members of the Subcommittee and to industry in general for criticism and comment.

Lag Screw Threads, George Case, Chairman. On recommendation of its chairman, Subcommittee No. 6 on Lag Screws was discharged at the January, 1933, Sectional Committee meeting.

The four preceding items are parts of the work for which the Sectional Committee on Standardization and Unification of Screw Threads, R. E. Flanders, chairman, is responsible.

Gage Sizes, H. B. Reynolds, Chairman. In the preparation of its report Subcommittee No. 3 on Gage Sizes and Mounting Dimensions, issued a request in April, 1933, to a number of manufacturers of gages of the bourdon type for information concerning their present practice. A considerable amount of data which has been received by the Committee will be used as a basis for drafting its tentative report.

Accuracy and Test Methods for Pressure Gages, O. J. Hodge, Chairman. This Subcommittee completed a draft of its proposed report in February, 1933. However, since certain information seemed to be necessary to complete this section of the proposed standard on pressure and vacuum gages, a questionnaire was sent to a number of manufacturers in June, 1933, together with a copy of the tentative report. Replies are still being received to this inquiry.

Plain and Lock Washers, C. W. Squier, Chairman. Subcommittee No. 1 on Plain Washers developed a tentative standard for plain punched steel and cast washers with round holes, copies of which were distributed to the members of the Subcommittee in October, 1932. The replies to this distribution indicated that while the proposed sizes and proportions were agreeable to practically all of the large users, they were not entirely acceptable to the majority of manufacturers. On the basis of the replies received, a further study is being made in an effort to establish a logical compromise between the two principal points of view represented on the Committee.

Cast Iron Soil Pipe and Fittings, J. J. Crotty, Chairman. Splendid progress has been made during the year in the development of the proposed American Standard for Cast Iron Soil Pipe and Fittings. The Subcommittee responsible for this work held three meetings during the year, one of which was a three-day meeting, and completed a draft of the proposed standard, numbering some 45 pages, which has been released recently by the Subcommittee for distribution to industry for criticism and comment. Chairman Crotty presented the proposed standard for information and discussion at the annual meeting of the American Society of Sanitary Engineering, co-sponsor for this project, which was held in Chicago during the week of August 5.

Traps, A. R. McGonegal, Chairman. A tentative report on plumbing traps was received in August from Subcommittee No. 5 on Traps. It will now be duplicated for general distribution to industry for criticism and comment.

These two projects, together with a number of others in the same field, constitute the work undertaken by the Sectional Committee on the Standardization of Plumbing Equipment, of which W. C. Groeniger is chairman.

Machine Tapers, F. S. Blackall, Jr., Chairman. The Technical Committee met on December 6, 1932, and at this time the Steep

Taper proposal was referred back to Mr. Bouvier's Subgroup for further investigation of the patent situation and additional tests.

The Slow Taper proposal also was referred back to A. H. Lyon's Subgroup for minor changes with the recommendation that subsequently it be set up in draft form for final review by Technical Committee No. 3 and transmittal to the Sectional Committee for letter ballot vote. The revised draft has now been submitted by the Subgroup and is ready for duplication and distribution to the Technical Committee for review.

Other Projects in Course of Development. While no specific progress has been reported for the following projects during the past year they are being actively developed by the several committees concerned:

Machine Pins
Graphic Presentation
Malleable Iron Steel and Brass Seat Unions
Allowances and Tolerances for Cylindrical Parts and Limit Gages (Revision of standard approved and published in 1925)
Small Tools: Circular Forming Tools and Holders; Splines and Splined Shafts; Electric Welding Dies and Electrode Holders; Milling Machine Tables; Multiple Spindle Drilling Heads; Nomenclature
Revision of 125 Lb and 250 Lb Cast Iron Screwed Fittings
Leather Belting
Foundry Equipment
Stock Sizes, Shapes, and Lengths for Hot and Cold Finished Iron and Steel Bars
Wood Screw Threads
Inspection of Gears

(3) Distribution of Tentative Proposals to Industry for Criticism and Comment

Speeds of Machinery, A. E. Hall, Chairman. The Sectional Committee on Standardization of Speeds of Machinery released the proposed American Standard for Machine Speeds for distribution to industry for criticism and comment, and this proposal was mailed to 376 firms and individuals in April, 1933. The replies received are now being sent to the Committee for its consideration and further action. This project gained considerable publicity through an article in the April, 1933, issue of *Mechanical Engineering* and an editorial in the June, 1933, issue of *Power Engineering*.

Welding Neck Flanges, C. H. Haupt, Chairman. A special Subgroup of Subcommittee No. 3 on Steel Flanges and Flanged Fittings has been responsible for the development of a proposed American Standard for Welding Neck Flanges. This proposal was sent to industry in May, 1933, and the replies received from this distribution are now being correlated for transmittal to the subgroup for its review. This project is one of the many activities undertaken by the Sectional Committee on Pipe Flanges and Fittings, of which C. P. Bliss is chairman.

(4) Review of Comments by Subcommittee

Drawings and Drafting Room Practice, F. DeR. Furman, Chairman. Upon revision of the several sections of the proposed American Standard for Drawings and Drafting Room Practice by their respective subcommittees after review by industry, they were turned over to the Editing Committee, of which T. E. French is chairman. Professor French completed the editorial work during the past winter, and after preliminary review by the members of a special subcommittee of the Sectional Committee, this proposed American Standard will be submitted to the entire committee membership for vote on approval by letter ballot.

Code for Pressure Piping, E. B. Ricketts, Chairman. The sections of the Code for Pressure Piping covering (*a*) Power Piping, (*b*) Gas and Air Piping Systems, (*c*) Oil Piping, (*d*) District Heating Piping, and (*e*) Fabrication Details, have been completed by their respective subcommittees, edited, and released by the Editing Committee. Under the direction of Chairman Ricketts these sections are now being combined and unified and an extensive index is being developed. This work, however, is practically completed, and in the near future copies of the entire code will be prepared in quantity for distribution to the membership of the Sectional Committee for consideration prior to a meeting to be held in December at which final action will be taken.

Brass Fittings for Flared Copper Tubes, F. L. Riggin, Chairman. This Subcommittee of the Sectional Committee on Plumbing Equipment, of which W. C. Groeniger is chairman, completed a revision of its proposed standard on Brass Fittings for Flared Copper Tubes based on the comments received from the distribution of copies of the standard to industry in August, 1932. The proposed standard is now ready for discussion and approval by the Sectional Committee.

Wrought Iron and Wrought Steel Pipe and Tubing, H. H. Morgan, Chairman. During the present year Subcommittees Nos. 2 and 3 on Pipe and Tubing for Low and High Temperature Service, respectively, have been cooperating in the preparation of the proposed standard for Wrought Iron and Wrought Steel Pipe. In February, 1933, proof copies of the proposed standard were sent by Chairman J. J. Shuman of Subcommittee No. 2 to industry for criticism and comment. On March 8, 1933, the two subcommittees held a joint meeting in New York at which the 120 replies received were discussed and recommendations were made for the necessary revisions. At this same meeting Chairman Tanner of Subcommittee No. 3 presented a tentative proposal covering the specific application of this proposal to the 150, 300, 400, 600, 900, and 1500 lb steel flange standards.

In June, 1933, the Sectional Committee met in Chicago and at this meeting revised page proofs of the proposed standard for Wrought Iron and Wrought Steel Pipe and also a revised draft of the table showing wall thicknesses of wrought steel pipe for working pressures of 150, 250, 300, 400, 600, 900, and 1500 lb at 750 F were discussed in detail and were referred back to their respective subcommittees for certain additional refinements.

Socket Head Cap and Set Screws, Herman Koester, Chairman. This Subcommittee submitted the proposed American Standard for Socket Type Set and Cap Screws to industry for criticism and comment in March, 1933. The suggestions received as a result of this distribution are now in the hands of the chairman of the Committee and it is anticipated that the final draft will be ready for submittal to the Sectional Committee on the Standardization of Bolt, Nut, and Rivet Proportions in October.

Large Rivets, J. E. Kiernan, Chairman. The proposed American Standard for Large Rivets is still in the hands of Subcommittee No. 1 of the Sectional Committee on Bolt, Nut, and Rivet Proportions. This proposal was completed last fall with the exception of some further consideration by the manufacturers of the high-button-head shape of rivet head and the addition of dimensions and tolerances for rivet sets. Since that time the data on the sets have been accumulated and the manufacturers have conducted considerable research on the modification of their manufacturing processes or the design necessary in order to make the production of the high-button-head type of rivet commercially feasible. With these two remaining points apparently on the way toward completion, the submission of this standard for approval by the Sectional Committee is expected in the near future.

Lock Washers, C. H. Loutrel, Chairman. The work of Subcommittee No. 2 on Lock Washers has not progressed appreciably during the current year, principally on account of the present economic conditions. At the Committee's last meeting, which was held in April, 1932, substantial agreement was reached in the Committee on all the differences then existing as a result of replies received from industry. It is accordingly expected that some progress toward completion of the work will be made at an early date.

Pressure and Vacuum Gages, M. D. Engle, Chairman. Subcommittee No. 2 on Definitions, C. F. Schwep, chairman, held a meeting on December 6, 1932, at which revisions to its preliminary proposal covering Definitions for Pressure and Vacuum Gages, Dial Type, were completed. Copies of this proposal were distributed broadly for criticism and comment to industry in March, 1933. The replies received are now being reviewed by the Subcommittee for the purpose of making final revisions, after which the report will be submitted to the Sectional Committee for approval.

Spindle Noses and Collets, J. E. Lovely, Chairman. In October, 1932, Subgroup No. 4 of Technical Committee No. 4 on Spindle Noses met and recommended that the March, 1931, draft of the Spindle Nose proposal be adopted by the single and multiple spindle automatic lathe groups and the turret lathe group of the N.M.T.B.A. This recommendation has since been adopted by these groups, but no dates for the application of the standard designs to stock equipment have been set.

Jig Bushings, C. E. Rundorff, Chairman. In November, 1932, a revised draft of the proposed standard for Jig Bushings was distributed to industry for criticism and comment. The 145 replies received were abstracted and sent in February to all members of this Technical Committee for their review. On the basis of the comments received as a result of this distribution, a further revised draft is now being prepared for final approval by the Technical Committee.

Chucks and Chuck Jaws, J. E. Lovely, Chairman. During this year little progress was made in this project due to the economic conditions. It is expected that the work will develop rapidly, however, just as soon as conditions improve.

Punch and Die Sets, Sidney Diamant, Chairman. The Technical Committee held a meeting in December, 1932, and recommended that the proposed standard for Punch and Die Sets be revised in accor-

dance with the recommendations of a special subgroup of which W. C. Mueller was Chairman. These recommendations were based on the replies received as a result of the distribution of the proposal to industry in June, 1932.

On June 5, 1933, a meeting of Subgroup No. 3 on Details of Design and Editing was held and further progress was made toward the preparation of the proposed standard to comply with the criticisms received from industry.

The Technical Committees handling the preceding four projects are responsible to the Sectional Committee on the Standardization of Small Tools and Machine Tool Elements, C. W. Spicer, chairman.

(5) Revised Proposal Before Sectional Committee

Screw Threads for Hose Couplings, H. W. Bearce, Chairman. In October, 1932, the Sectional Committee on Standardization of Screw Threads for Hose Couplings met in New York and agreed upon a rearrangement of Table 1, the principal table of the proposed standard for Screw Threads for Hose Couplings. The Committee further authorized the addition of two tables giving complete detail dimensions for the thread form. In December, 1932, a revised draft of the standard was submitted to the members of the Sectional Committee for vote by letter ballot, but the returns from this ballot indicated considerable disagreement over the form of Table 1. In January, 1933, A. O. Boniface sent out a questionnaire to certain members of the committee in an effort to obtain a consensus of opinion on certain definite points in question. This was followed in April, 1933, by the distribution of a further revised draft of Table 1 in an effort to crystallize the ideas which had been put forth as a result of the first distribution of the standard and Mr. Boniface's questionnaire.

A study of all of the replies received in reply to these three mailings and a survey of the views of several manufacturers and dealers in New York was made by the A.S.M.E. staff and another draft of Table 1 was prepared in June and discussed with several members of the Committee in New York, Chicago, and Washington. This draft with some slight alterations was approved by Chairman Bearce in August for submittal to the members of the Sectional Committee for their formal consideration and vote by letter ballot.

Shafting. C. M. Chapman, Chairman. The revision of the standards for stock keys was completed by the Sectional Committee and submitted in October, 1932, to its membership for vote by letter ballot. The result of this vote was 15 for and 1 against. The reason given for this negative vote was that the branch of industry casting this vote does not approve the addition of the $^{5}/_{16}$ in. key now proposed by the Committee. After considerable correspondence between Chairman Chapman and the representative of that industry, a compromise was agreed upon whereby both the $^{1}/_{4}$ and $^{5}/_{16}$ in. sizes would be shown for the $1^{1}/_{4}$ in. shaft. This compromise proposal was submitted to the members of the Sectional Committee in August of this year and was approved by a vote of 14 to 2. It is altogether likely, however, that a unanimous agreement will be reached within the very near future, at which time the proposed revision will be ready for submittal to the Society as sponsor and to the American Standards Association for approval and designation as an American Standard.

Twist Drills. At the December 8, 1932, meeting of the Sectional Committee on Small Tools and Machine Tool Elements the proposed standard for Drill Sizes was discussed at length. As a result of this discussion, at least four members of the Committee each conducted a separate and independent thorough study of the entire situation, in his own plant. As a result of this further study, suggestions were made as to certain minor changes which would further simplify the list of Drill Sizes under discussion. This list, as amended, was adopted by mail ballot by the Technical Committee, and later by the Sectional Committee on Small Tools and Machine Tool Elements, and is now ready for approval of the sponsors.

(6) Proposed Standard Before Sponsor Bodies

Ball and Roller Bearings, F. W. Gurney, Chairman. In January, 1933, the Sectional Committee completed an extension of the tables for the light, medium, and heavy series of angular contact ball bearings contained in the American Standard for Ball and Roller Bearings approved and published in 1930.

A new table covering adapter sleeve bearings was also developed and approved by the Sectional Committee. These additions were submitted to the sponsor bodies in January, 1933, by the Committee. The S.A.E. approved the new sections at its meeting held during that month and the A.S.M.E. gave its approval on May 22, 1933.

A proposed standard for Taper Roller Bearings was presented by the Sectional Committee in August, 1933, to the two sponsor bodies for approval and transmission to the American Standards Association for designation as an American Standard. Action is now being taken by the S.A.E. and the A.S.M.E.

(7) Approval by ASA and Publication in Pamphlet Form

The following eight standards were approved as American Standards by the ASA during the past twelve months. The first six of them were published by the Society within the year and it is interesting to note that already a total of 4300 copies of the six have been sold.

Shaft Couplings, developed by A.S.M.E. Committee on Shaft Couplings, D. J. McCormack, Chairman.

Spur Gear Tooth Form, developed by Subcommittee No. 4, H. J. Eberhardt, Chairman, of the Sectional Committee on the Standardization of Gears, B. F. Waterman, Chairman.

Steel Flanges and Flanged Fittings, developed by Subcommittee No. 3 of the Sectional Committee on Standardization of Pipe Flanges and Fittings, C. P. Bliss, Chairman.

Wrench Head Bolts and Nuts, developed by Subcommittee No. 2, H. A. Spanagel, Chairman of the Sectional Committee on Standardization of Bolt, Nut, and Rivet Proportions.

Engineering and Scientific Charts for Lantern Slides, developed by Subcommittee No. 4, W. A. Shewhart, Chairman, of the Sectional Committee on Standards for Graphic Presentation, E. F. DuBrul, Chairman.

Abbreviations for Scientific and Engineering Terms, developed by Subcommittee No. 9, G. A. Stetson, Chairman, of the Sectional Committee on Standardization of Scientific and Engineering Symbols and Abbreviations, J. F. Meyer, Chairman.

Gear Materials and Blanks, developed by Subcommittee No. 8, T. D. Lynch, Chairman, of the Sectional Committee on the Standardization of Gears, B. F. Waterman, Chairman.

Ball Bearings, developed by Sectional Committee on Standardization of Ball and Roller Bearings, F. W. Gurney, Chairman.

Respectfully submitted,

W. S. Monroe, *Chairman*
Earle Buckingham — Alfred Iddles
C. W. Spicer — L. A. Cornelius.

POWER TEST CODES

The Committee on Centrifugal and Turbo-Compressors and Blowers, A. T. Brown, Chairman, and the Committee on Instruments and Apparatus, C. F. Hirshfeld, Chairman, have held the center of the stage during the past year in the A.S.M.E. Power Test Codes activity.

The proposed standard Test Code for Centrifugal Compressors, Exhausters, and Fans was completed during the fall of 1932, so it was scheduled for a public hearing at the time of the Annual Meeting of the Society, December, 1932. The discussion at this hearing indicated that Part 1 on Compressors and Exhausters was generally satisfactory to industry in the form presented. The addition of a few minor paragraphs was proposed. This hearing, however, developed considerable disagreement over Part 2 on Fans, since the test procedure advocated therein differed somewhat from that required by the test code which was prepared in 1923 by a joint committee of the American Society of Heating and Ventilating Engineers and the National Association of Fan Manufacturers. At the close of the discussion a motion was passed recommending to the Power Test Codes Committee that the fan part of the proposed A.S.M.E. Code be not printed at this time and that a new committee be appointed consisting of members of the American Society of Heating and Ventilating Engineers, the National Association of Fan Manufacturers, and The American Society of Mechanical Engineers, to produce a test code for fans which will be generally acceptable.

However, the members of Committee No. 10 and the Main Committee were convinced that it would be a serious mistake to publish a fan code which would be entirely independent of the compressor code. Not only are the problems involved in the testing of the two classes of apparatus similar fundamentally, but often it will be difficult to distinguish between the two classes of apparatus. It was accordingly decided to make the fan code Part 2 of the combined code, rather than a completely independent publication. The Main Committee endorsed this plan of procedure and authorized Committee No. 10 to develop its test code in two parts, i.e., Part 1 on Compressors and Exhausters and Part 2 on Fans. It is understood that while these parts will be first published separately, they will later be made available as one pamphlet.

Prof. M. C. Stuart, of Lehigh University, who has been named chairman of the new Subcommittee on Fans, has presented a plan of procedure which is approved by the Main Committee and which calls for the setting up in the Packard Laboratory at Lehigh University of a neutral proving ground for the demonstration of apparatus and code procedures in the development of fan testing.

In November, 1932, the members of Committee No. 10 met with the members of the A.S.M.E. Special Research Committee on Fluid Meters, R. J. S. Pigott, chairman, and the P.T.C. Committee No. 19 on Instruments and Apparatus to consider certain objections which the Fluid Meters Committee had raised to the section of the Code dealing with the measurement of volume by the use of the flow nozzle and the formulas and constants to be employed in the corresponding computations. The methods endorsed by Committee No. 10 are taken from Instruments and Apparatus, Part 5 on Measurement of Quantity of Materials, proposed Section 4 on Flow Measurement With Orifices, Flow Nozzles, and Venturi Tubes. At this conference, it was agreed finally (1) that the material so far developed by Committee No. 10 was satisfactory for its purpose, (2) that the forms of the equations employed were not in conflict with the principles laid down by the Fluid Meters Committee, and (3) that, while the conference recognized the immediate need on the part of Committee No. 10 for the methods of measurement and formulas which it had developed, the A.S.M.E. Special Research Committee on Fluid Meters was encouraged to investigate the relative merits of the venturi, the diaphragm, the orifice, and the flow nozzle for the measurement of gas flow in square and round ducts. Under the direction of the Research Committee on Fluid Meters, a subcommittee reviewed the section on flow measurement for the purpose of suggesting changes and additions to make these rules more generally applicable. Its report is now in the hands of the Chairman of the Committee on Instruments and Apparatus, No. 19.

While these negotiations were in progress, the Main Committee received communications from the International Standards Association and the British Compressed Air Society urging the adoption of the proposal of the I.S.A. Committee, which in effect is the V.D.I. form of nozzle with slight modifications in the test procedure over that recommended by our sister society.

Committee No. 19 is now studying carefully the details of design of nozzle and rules for use prepared by (1) its subcommittee on Flow Measurement, (2) the special subcommittee of the A.S.M.E. Special Research Committee on Fluid Meters, and (3) the I.S.A. Committee on the Measurement of Fluid Flow.

Work completed by Committee No. 19 during the year just closed includes the following five sections which were approved for publication, namely, Part 3, Temperature Measurement—Chapter 8 on Optical Pyrometers; Part 4 on Head Measuring Apparatus; Part 6 on Electrical Measurements; and Part 21, Leakage Measurement—Chapter 2 on Boiler and Piping Leakage and Chapter 3 on Steam Engine Leakage.

A draft of the proposed revision of the Test Code for Reciprocating Steam Engines was reviewed by the members of Committee No. 5, A. G. Christie, chairman, and certain members of the Main Committee. Important omissions were pointed out which have since been supplied. The final draft of the proposed revision of the Test Code for Reciprocating Steam Engines is now in shape for submission to the Main Committee.

At a meeting which was held in New York in January, 1933, Committee No. 6 on Steam Turbines, C. H. Berry, chairman, discussed the preliminary draft of the first revision of the Test Code for Steam Turbines. Many changes in this draft were suggested, and several items were referred to the members present for detailed study and report. The proposed redraft of the Code differs from the existing code in several respects: (*a*) It covers bleeder and mixed-pressure turbines; (*b*) It permits the use of orifices, nozzles, etc., for the measurement of steam flow, with certain qualifications concerning expected accuracy; (*c*) It permits the determination of exhaust pressure by thermometer for condensing turbines, with certain precautions; (*d*) It permits the use of electric resistance thermometers and thermocouples for measuring temperatures; and (*e*) The methods of making corrections have been more clearly set forth and have been extended to cover bleeder and mixed-pressure turbines. The proposed draft also conforms to the standard form recently adopted for all of the A.S.M.E. Power Test Codes.

Committee No. 3 on Fuels, W. J. Wohlenberg, chairman, has been reviewing the preliminary draft of the Test Code for Gaseous Fuels. Certain constructive criticisms of this draft have been received from the American Chemical Society through the secretary of its Gas and Fuel Division and are under consideration. Standard methods for determining the heating value of gas, especially the gases with heating value of 1000 Btu per cu ft or more, will also be recognized in the proposed code.

Committee No. 12 on Condensers, Water-Heating and Cooling Equipment, Geo. A. Orrok, chairman, is revising the Test Code for Steam Condensing Apparatus. It has also made progress in the development of a suitable method for determining the cleanliness factor of condenser tubes which is now to be incorporated in this test code. The subject of the cleanliness factor was thoroughly and fully discussed at a meeting of the A.S.M.E. Metropolitan Section in November, 1932, when a paper was presented entitled "A Test Method for Determining the Quantitative Effect of Tube Fouling on Condenser Performance," by P. H. Hardie and W. S. Cooper, of the Brooklyn Edison Company. Several methods of measuring the condenser cleanliness factor were described and data on several tests were presented showing the practicability of obtaining a specific value for the degree of tube fouling existing at the time of test.

The following committees held regularly called meetings during the past twelve months: Main Committee, four meetings—October, December, May, and June; Committee No. 6 on Steam Turbines; Committee No. 10 on Centrifugal and Turbo-Compressors and Blowers; Committee No. 11 on Complete Steam Power Plants; and Committee No. 18 on Hydraulic Power Plants.

A résumé of the progress which has been made during the past year in the preparation of the various parts and chapters of Instruments and Apparatus is as follows: The completion of Part 3, Temperature Measurement—Chapter 8 on Optical Pyrometers was reported in the November, 1932, issue of *Mechanical Engineering;* Part 10 on Flue and Exhaust Gas Analyses in the November, 1932, issue; and Part 14 on Linear Measurements in the July, 1933, issue. The development of the following parts and chapters has progressed appreciably within the past year: Part 2, Pressure Measurement—Chapter 2 on Static and Total Pressure, Static Holes and Tubes, Impact Tubes, and Chapter 3 on Pipes for Pressure Measurement; Part 3, Temperature Measurement—Chapter 2 on Radiation Pyrometers; Part 10 on Flue and Exhaust Gas Analyses; Part 15 on Measurement of Surface Areas; and Part 20 on Smoke-Density Determinations.

The question of a change of date of the meetings of the Main Committee on Power Test Codes was discussed at some length during the year. It was decided, however, that there shall be a December meeting during Annual Meeting week, since this annual meeting, to which all members of the Individual Committees are invited, offers an excellent opportunity for an interchange of ideas and information relative to the advancement of the work. A questionnaire was prepared and sent out to the members of the Main Committee and the chairmen of Individual Committees to ascertain their views on this question of meeting dates. A tabulation of the replies received indicates that the majority of members favor the holding of three meetings a year on the first Monday of the months of October, December, and April.

International Cooperation. Through membership in the U. S. National Committee of the International Electrotechnical Commission,* the Society, and for it the Main Committee on Power Test Codes, has been actively engaged in assisting to bring about international agreements on acceptance tests for steam turbines and internal-combustion engines. The Secretariat for the Advisory Committees on Steam Turbines, Internal-Combustion Engines, and Hydraulic Turbines is held by the United States National Committee of the I.E.C. The Society was represented this year on this Committee by Harvey N. Davis, Francis Hodgkinson, and Ely C. Hutchinson, with C. Harold Berry and Paul Diserens serving as alternates.

I.E.C. Internal-Combustion Engines. During the past year preliminary negotiations were completed which resulted in the scheduling of a meeting in the United States in September of Advisory Committee No. 19 on the Testing of Internal-Combustion Engines. However, due to the unsettled economic conditions throughout the world the cancelation of this meeting was deemed advisable.

The first meeting of this international committee, which was held in Stockholm in July, 1930, was attended by official delegates from Czechoslovakia, France, Germany, Great Britain, Italy, Sweden, and the United States of America. After reviewing the documents which had been presented by the several national committees, the Committee devoted its efforts to the preparation of a standard specification and information form which, when completed, will be available for use when international tenders or estimates are desired. Good progress had been made toward the completion of this document, Part I, the Specification, of the I.E.C. Publication on Internal-Combustion Engines, by correspondence since that meeting, and it was hoped that definite agreements might have been reached concerning it had a meeting been held this year.

The Secretariat had prepared also a rewritten document for Part II, Rules for Acceptance Tests, based on the comments and opinions of the several National Committees, which was to have been discussed at the September meeting. At Stockholm the U. S. National Committee had presented a proposal for these rules. The shortness of time, however, did not permit its detailed study at that time.

---

* The A.S.M.E. has three representatives on the U. S. National Committee of the International Electrotechnical Commission. For their report see page 47.

That proposal was based primarily on the A.S.M.E. Test Code for Internal-Combustion Engines.

SAFETY

Consistently throughout the year in its dealings with the working committees of the Society, the Safety Committee has maintained that the prevention of industrial accidents is essentially a problem of management and is, therefore, of direct interest to the members of the A.S.M.E. Our Society is frequently referred to as the "Society of the Industries" and, since it includes within its membership men in all positions of authority from the senior executive down to the junior engineer by whom accident prevention measures are and must be administered, the importance of this activity is obvious.

The Committee holds that industrial, or, more properly, occupational accidents, can be prevented. The evidence in support of that statement is so ample that its truth cannot be doubted by any one familiar with the facts. Accidents do not happen. They are caused and their causes are removable. It is estimated that not more than 2 per cent of industrial accidents can properly be considered as not preventable. Out of the remaining 98 per cent of preventable accidents, perhaps 10 per cent can be charged to physical hazards or causes, whereas fully 88 per cent are chargeable to supervisory causes. Both of these causes are within the sphere of management. It is estimated that 15,000 persons were killed by occupational accidents in the United States in 1932, and that in addition there were 1,200,000 non-fatal injuries, of which about 45,000 resulted in permanent disability and 1,155,000 in temporary disability.

A new feature was introduced into the 1932 Annual Meeting at the suggestion and through the enterprise of the Safety Committee. Under its auspices a lecture entitled "Conservation an Essential in Industrial Recovery" was given by H. W. Heinrich, assistant superintendent, Engineering and Inspection Division, Travelers Insurance Company, on the afternoon of Wednesday, December 7, of the 1932 Annual Meeting Week.

While the past year has not recorded any unusual progress on the part of the five sectional committees handling safety code projects for which the A.S.M.E. is sponsor or joint sponsor, definite advances have been made by some. These advances and the present status of the committees are covered in the paragraphs which follow.

Aircraft Safety. The special committee on aircraft safety and inspection of the A.S.M.E. Aeronautic Division has been at work during the year in preparing a revision of the tentative draft of the proposed "Inspection Manual for Maintenance of Conventional Aircraft" originally distributed for criticism and comment in May, 1932. At the 1933 Semi-Annual Meeting of the Society held in Chicago, Jerome Lederer, chairman of the Committee, presented a paper which outlined the present need for the Manual and the nature of its contents in general.

In January, 1933, acting on the recommendation of the A.S.M.E. Safety Committee and the A.S.M.E. Aeronautic Division, the Society requested the American Standards Association that steps be taken to bring about the revision of the present Aeronautic Safety Code originally approved and published in 1925. This recommendation was made in the belief that progress and safety in aeronautics are now being sacrificed because of a lack of unity in the present regulations for inspection, operation, and maintenance. The recommendation of the Society was placed before the Society of Automotive Engineers, sponsor for this project, by the ASA.

Safety Code for Elevators, Sullivan W. Jones, Chairman. The Sectional Committee on a Safety Code for Elevators held a meeting in March, 1933. At this meeting a tentative draft of the Elevator Inspectors' Handbook, prepared by Subcommittee No. 2, K. H. Colahan, chairman, was reviewed and discussed in detail. The resulting suggestions for changes and additions were of such a nature that the Committee considered it necessary to refer this draft back to the Subcommittee for revision.

Consideration was given also at the meeting to certain changes proposed by the Subcommittee on Elevator Research, Interpretations, and Recommendations in the American Standard "Safety Code for Elevators" published in July, 1931. This latter Subcommittee, under the Chairmanship of M. H. Christopherson, held four meetings during the year, in November, 1932, January, 1933, March, 1933, and September, 1933. Under the direction of the Committee tests on several types of elevator buffers have continued to be carried on at the National Bureau of Standards for several manufacturers of elevators.

Safety Code for Cranes, Derricks, and Hoists, J. C. Wheat, Chairman. The last section of the proposed Safety Code for Cranes, Derricks, and Hoists was completed during the year by Subcommittee No. 4 on Miscellaneous Equipment for Cranes and Hoists (including Slings, Chains and Hooks, Wire Rope and Attachments, Sheaves and Pulleys), L. W. Hopkins, chairman, and distributed to the Subcommittee members in February, 1933.

Safety Code for Machinery for Compressing Air, H. D. Edwards, Chairman. As no progress had been reported by the Committee, the continuance of the preparation of this code was discussed at the October 17, 1932, meeting of the Standing Committee on Safety. W. M. Graff expressed the opinion that the work should certainly not be dropped, but suggested that possibly with a revision of the Committee's scope progress could be made. The Standing Committee approved his recommendation and a revised scope will presently be submitted to the ASA.

Society Representation on Safety Code Committees. During the year the Committee has prepared recommendations for the presidential appointments of representatives of the Society on the three following safety committees: Safety Code for Specifications and Methods of Test for Safety Glass; Safety Code for Exhaust Systems; and Safety Code for Work Under Compressed Air. This brings the total of the safety code committees on which the Society has official representation to 32.

Respectfully submitted,

H. W. Mowery, *Chairman*
T. A. Walsh, Jr.
M. H. Christopherson
W. M. Graff
H. H. Judson.

PROFESSIONAL CONDUCT

The Committee is pleased to report that few cases of unprofessional conduct on the part of members of the Society have come up for consideration this year.

Last year the Committee redrafted the Code of Ethics of the Society to meet certain criticisms. The new Code is now before the Council for final approval.

During recent months, there has been tremendous activity in the formulation of trade and industrial codes to control our industrial reconstruction. The time seems particularly opportune for a reconsideration of a joint Code of Ethics for all of the national engineering societies. Such a joint code was under consideration about twelve years ago, but was not adopted by all the national societies. The Committee recommends to the Council that the president of the Society be authorized to suggest to the other national societies that the preparation of a joint code is timely and desirable in order to standardize the rules governing the conduct of all engineers.

Respectfully submitted,

A. G. Christie, *Chairman*
H. S. Philbrick
C. G. Spencer
E. R. Fish
J. H. Herron.

BOILER CODE

During 1932–1933 the Committee held nine regular meetings and several Executive Committee meetings, which were devoted to interpretations of the various sections of the Code and to the formulation of revisions and addenda thereto.

At the request of the U. S. Navy Department the Committee reviewed the U. S. Navy Specifications for Machinery in so far as the proposed new rules for welding were concerned. A conference was held at Annapolis and in Washington with representatives of the Bureau of Engineering of the U. S. Navy Department, the American Welding Society, and the Boiler Code Committee to discuss tentative changes and additions for inclusion in the specifications. The representatives of the Bureau of Engineering were highly appreciative of the cooperation. In response to an invitation extended by the Boiler

Code Committee the Officer-in-Charge of the Specifications Section of the Design Division of the Bureau of Engineering was appointed by the Bureau as a representative to attend the Committee meetings. Commander C. S. Gillette, who took an active part in the conference, is the present Officer-in-Charge. This appointment places the Boiler Code Committee in touch with the experience and practice of the Navy Department. It was arranged that the Commandant of the Navy Yard, New York, should designate an officer of the rank of Commander or of higher rank to attend the meetings of the Committee when it is impossible for the Bureau's representative to be present and report to the Bureau.

The Committee reports the passage in Congress of a Bill to amend sections of the Revised Statutes, as amended, relating to the construction and inspection of boilers, unfired pressure vessels, and appurtenances thereof, which provides for the revision of the present Steamboat Inspection Rules by empowering the Board of Supervising Inspectors to prescribe formulas, rules, and regulations. This Board has cooperated actively with the Boiler Code Committee for many years and has designated a representative to attend all of its meetings.

The Committee was requested by the National Board of Boiler and Pressure Vessel Inspectors to review a set of rules for repairs by fusion welding of boilers and other pressure vessels. These rules were considered at several regular meetings of the Boiler Code Committee and also by the Executive Committee, and a number of revisions were proposed which were approved by the National Board. The National Board was advised that the rules as amended are consistent with the rules in the Boiler Code for welded construction of new boilers and should give safe results.

The X-ray requirements for power boilers and unfired pressure vessels were revised as a result of experience and the development of new X-ray technique. One of the important changes was increasing the maximum wall thickness for X-raying power boilers and unfired pressure vessels to 4¼ in.

Under conditions where tubes were subjected to a high temperature the limiting creep stress became an important factor. As a result, it was necessary to provide for a weldable material with a higher creep stress value, and Specifications S-17 for Lap-Welded and Seamless Steel and Lap-Welded Iron Boiler Tubes were revised to conform with A.S.T.M. Specifications A83-32T.

The Committee is giving consideration to the use of alloy steels for both riveted and welded construction of unfired pressure vessels which are not as yet provided for in the Material Specifications Section of the Code. It is also giving consideration to carbon steels of higher tensile strength suitable for fusion welding.

Revisions were made in Specifications S-1, S-5, S-6, S-7, and S-18 to indicate that steel made by the electric furnace process will be acceptable under the Code on an equal basis with open-hearth steel.

As stated in the Annual Report for the fiscal year ending 1932, revised rules for the reinforcement of openings were incorporated in the Code. As a result of many questions in regard thereto, and to help in understanding and applying the rules, the Committee prepared and published in *Mechanical Engineering* a statement showing their derivation, which is now available in reprint form.

The Committee has made numerous revisions and additions to the various sections of its Code as a result of suggestions from manufacturers, inspectors, users, and others. These revisions were formally adopted by the Council on July 26, 1933, and distributed in pink-colored addenda sheets. 1933 Editions of the Power Boiler Code and the suggested Rules for Care of Power Boilers in Service were published in which were incorporated all revisions issued to date.

A new Subcommittee of the Boiler Code Committee on Special Design was appointed, consisting of D. B. Wesstrom, chairman, W. L. Bowler, R. E. Cecil, Paul Diserens, H. E. Rockefeller, W. H. Rowand, and F. S. G. Williams.

At the request of the Boiler Code Committee, the Council appointed F. W. Dean and Prof. E. F. Miller honorary members of the Committee. It is with deep regret that the Committee reports the death of Professor Miller on June 12, 1933. William Ferguson was appointed a member of the Subcommittee on Rules for Inspection.

Respectfully submitted,

F. R. Low, *Chairman*	A. M. Greene, Jr.
D. S. Jacobus, *Vice-Chairman*	F. B. Howell
C. W. Obert, *Honorary Secretary*	J. O. Leech
H. E. Aldrich	M. F. Moore
W. H. Boehm	I. E. Moultrop
R. E. Cecil	C. O. Myers
F. S. Clark	H. B. Oatley
W. F. Durand	James Partington
E. R. Fish	C. L. Warwick
V. M. Frost	A. C. Weigel
C. E. Gorton	H. LeRoy Whitney

ECONOMIC STATUS OF THE ENGINEER

In 1931 this Committee rendered two reports, one on the Earnings of Mechanical Engineers in 1930 and the other a recommendation for the establishment of a joint agency of engineering bodies through which the general status of the engineering profession could be improved.

The general economic situation has made it undesirable for the Committee to take active steps during the present emergency. The Committee, however, is holding itself in readiness for action, and its findings on previous occasions will be of tremendous value within the next year or so when general industry comes out of the depression and engineers are in greater demand.

As a result of the action of this Committee, the Engineers' Council for Professional Development,* which was organized in temporary form on October 3, 1932, has developed a charter and rules of procedure which have been adopted by the seven constituent bodies. It is expected that the formal organization of ECPD will be perfected early in October, 1933.

Respectfully submitted,

C. F. Hirshfeld, *Chairman*	H. B. Oatley
D. S. Kimball	H. L. Whittemore
C. N. Lauer	W. E. Wickenden
J. M. Todd, D. B. Prentice	*Ex-Officio.*

REGISTRATION OF ENGINEERS

The Committee on Registration of Engineers submitted to the Council at the last Annual Meeting the recommendation that the Society approve the adopting of the Model Law for the Registration of Professional Engineers and Land Surveyors by any state or municipality desiring to enact an engineering registration law. The Committee did not ask the Council to approve the principle of registration of engineers. The Council approved the recommendation of the Committee.

The Legislature of the State of New York passed a law during its last session rectifying the wrong which had been done to the engineering profession a few years ago. Engineers are now on the same level with architects as far as the filing of building plans is concerned.

The Committee again calls to the attention of the membership of the Society the necessity of engineers' knowing about the requirements of the registration laws. A member should consult with a competent authority in his state if he has any doubt about his standing to carry on professional work. Engineers must realize that the laws are on the statute books of many states and even though failure to register may result in no immediate difficulty, the lack of a license may be a bar to promotion to a position of greater responsibility. In some states it is becoming more difficult each year to obtain a license.

Respectfully submitted,

J. H. Lawrence, *Chairman*	C. F. Hirshfeld
D. S. Kimball	V. M. Palmer
Paul Doty	J. M. Todd.

Joint Activities

Reports for the year 1932–1933 were also presented to the Council by representatives of the Society on a number of joint activities. Reference to some of these will be found in the Report of the Council and others are presented or summarized in the following pages.

AMERICAN ASSOCIATION FOR THE ADVANCEMENT OF SCIENCE

SECTION M, ENGINEERING

The American Society of Mechanical Engineers, in cooperation with other engineering societies, participates in the conduct of Section M, Engineering, of the American Association for the Advancement of Science.

* For report of A.S.M.E. representatives on Engineers' Council for Professional Development, page 46.

During the fiscal year starting October 1, 1932, Section M held two meetings—one at Atlantic City and one at Chicago. The session at Atlantic City was given over to a joint discussion with Section K, Economics and Social Sciences, of a number of important economic problems. The papers presented were published in a separate book and received widespread attention.

The Chicago meeting of the American Association for the Advancement of Science immediately preceded Engineering Week. The meetings of Section M were held during Engineering Week. In view of the comprehensive technical program at Chicago, under the auspices of some twenty-eight engineering societies, Section M conducted only one session, at which a paper was presented by A. P. M. Fleming, of Manchester, England, on "The Industrial Developments of the Century." Section M participated in the general planning of the meeting, however, provided the liaison between Engineering Week and Science Week, and aided by securing the participation of several distinguished engineers and scientists from other countries.

During July, 1933, N. H. Heck, who had served as secretary of Section M for seven years, retired, and his position is to be taken up by Vannevar Bush, dean of the Massachusetts Institute of Technology.

Plans for the meeting of Section M in Boston, in connection with the A.A.A.S. meeting during the week of December 27 to January 2, are already under way.

Respectfully submitted,

W. S. Monroe, *A.S.M.E. Representative.*

AMERICAN STANDARDS ASSOCIATION*

Without doubt the most important event of the year for the American Standards Association is the transfer to it of the standardization activities and code work of the following five divisions of the Federal Government: Division of Trade Standards, Division of Specifications, Division of Simplified Practice, the Building Code and Plumbing Code work of the Building and Housing Division, and Safety Codes. While the direct reason for these transfers was the need for economy of Government expenditures, it is believed by many to be partly the result of natural trends in industry. The functions of these several groups will be absorbed by the ASA staff as fast as it is physically possible and the finances of the Association will permit. The July issue of the ASA monthly publication, "Industrial Standardization," was a joint publication with the "Commercial Standards Monthly." Howard A. Coonley, president of the ASA, and the members of his Board of Directors are taking steps which they hope will lead to the adequate financing of this enlarged activity of the ASA.

The standard having the most general interest among those approved during the year was an American Standard Practice for the Inch-Millimeter Conversion Factor for Industrial Use. By securing the approval of technical societies and industry on the ratio of 25.4 mm to the inch, the ASA has helped to clarify a very confused situation where slightly different equivalents had been in use. It is especially significant that this agreement was reached in the general conference which was called for this purpose without a dissenting vote.

The Annual Joint Meeting of the ASA Board of Directors and the Standards Council was held in New York on November 30, 1932. At this meeting the election of President Coonley and the reelection of C. M. Chapman as chairman of the Standards Council, were announced. Both men are members of the A.S.M.E. and the latter is one of its two representatives on the Standards Council.

The mid-year meeting of the Standards Council was not held in June, but throughout the year it has continued to function with the assistance of the staff by correspondence. Eleven new projects have been proposed during the twelve months, and within the same period forty-one completed standards were approved, receiving the designation "American Standard." These additions bring the total number of standards approved by the ASA up to 245, of which 58 are in the mechanical field.

The Year Book of the Association issued in May reports the number of member-bodies cooperating with the ASA as 28 societies and associations and 9 Federal Government departments. To these are added 245 firms and individuals who maintain memberships. It should be kept clearly in mind, however, that the number of organizations officially cooperating with the Association is far greater than the number of member-bodies. They total approximately six hundred.

Respectfully submitted,

C. M. Chapman
K. H. Condit } *A.S.M.E. Representatives.*

* See report of A.S.M.E. Standing Committee on Standardization, page 38, for projects for which the Society is a sponsor.

AMERICAN ENGINEERING COUNCIL

Most important meetings of the Assembly and Administrative Board of the American Engineering Council were held in Washington January 13 and 14, 1933. A complete record of these meetings is contained in the minutes which have been filed at the Society's office for reference. There follows a list of the most important matters which claimed the attention of these great engineering conferences, attended by 49 representative engineers from all parts of the United States:

Report of Committee on Water Resources and Control
Report of Committee on Membership and Representation
Report of Committee on Engineering Features of the Public Domain
Report of Committee on Government Expenditures
Report of Committee on Public Affairs (including consideration of various bills before Congress)
Report of Engineers Committee on Economic Balance
Consideration of Resolution on Technocracy.

In addition to this Annual Meeting, attention should be called to the work of the American Engineering Council which goes on uninterruptedly day by day.

(1) The A.E.C. has never had a busier year. The last Congress proposed and enacted legislation which will give entirely new direction to social, economic, and industrial trends of the nation. The A.E.C. has been closely identified with this movement.

(2) The A.E.C. has concerned itself with the new governmental agencies—National Industrial Recovery Administration, Federal Emergency Administration of Public Works, Tennessee Valley Authority, and Agricultural Adjustment Administration. Our Washington office is constantly in touch with these agencies, aiding them in every possible direction, submitting to them the names of qualified engineers, advising with them as to policies.

(3) Through the activity of the A.E.C., there has recently been secured from the $3,300,000 public works fund, seven or eight million dollars for geodetic and topographic surveys.

(4) Washington is the busy center of national activity today. Probably never in the history of the American Engineering Council has it been able to render greater or more direct service to the profession than during these last months.

(5) Some of our members have wondered whether the change from a Hoover to a Roosevelt Administration would change the influence of the A.E.C.; our Washington office is enjoying direct and influential contacts with the Roosevelt Administration.

THE ENGINEERING FOUNDATION

The Engineering Foundation Board is a body of representatives of the four Founder Societies associated for the purpose of fostering research and the application of the sciences through engineering, and of performing other functions, under its deeds of gift and charter, "for the good of mankind." It has an endowment of approximately $880,000 which is held by the United Engineering Trustees, Inc., as trustee for the Founder Societies. It functions chiefly in assisting, by the appropriation of funds or otherwise, specific researches organized and directed by the Founder Societies.

The Engineering Foundation Board has held three meetings, and

its Executive Committee three meetings, in New York during the period from October 1, 1932, to October 1, 1933.

There follows a review of noteworthy activities during the year:

(1) *Founder Society Projects.** Within the calendar year 1932, an amount of $26,500 was appropriated to the Founder Societies to aid certain specific projects. An additional $9000 was appropriated for special projects relating to engineering education, a preliminary study of the industrial system, and the Personnel Research Federation.

The budget for the calendar year 1933 totals $49,900, of which $6000 is set aside as reserve for contingencies, and $3262.50 is unappropriated. The remaining amount, $40,637.50, is broken up into $12,937.50 for administration, office, and publication expenses, and $27,700 for research projects. This latter amount is apportioned as follows:

A.S.C.E.	$7,200
A.I.M.E.	7,000
A.S.M.E.	8,500
A.I.E.E.	2,000
Engineering education	500
Summer school for engineering teachers	1,000
Personnel Research Federation	500
Transport research	1,000
Total	$27,700

(2) *The Engineering Societies Library.* The Engineering Societies Library reported an expected deficit of $4000 for the year 1933. Portions of this deficit may be made up from certain sources, but for the remainder no other source than the Foundation is in sight. Mr. Yarnall reported for the representatives of the A.S.M.E. that the Society would consent to diverting $1000 from its appropriation to the research committees to the Library. The Executive Committee of the Foundation was instructed to work out the problem of providing for the Library such portion of its expected deficit for the current year as cannot be provided for by other sources than the Foundation.

(3) *New Platform.* Consideration was given to the possibility of revising the Foundation's Program of Action adopted in 1925. A special committee submitted a new program intended to increase the usefulness of the Foundation to the advancement of the engineering profession and the good of mankind. A large conference held in May, 1933, and attended by the Foundation Board and representatives of the Founder Societies, discussed the matter at length and expressed varied opinions that ranged from favoring concentration on engineering research to calling for inclusion of other kinds of activities. The proposed new platform is now being studied by the Foundation's Executive Committee for report at the October meeting of the Board. It is understood that any basic change in policy or procedure would be submitted first to the Founder Societies for approval.

(4) *Courses for Disengaged Engineers.* On the initiation of the Engineering Foundation, advanced study courses were provided for disengaged engineers in the Engineering Societies Building from January through May. Certain colleges in the New York and New Jersey area laid out the courses and the teaching was done by professors from these colleges, unemployed teachers and engineers. The Professional Engineers Committee on Unemployment financed the project. More than 600 engineers took the courses, which were considered very helpful.

(5) *Basic Study of the Industrial System.* Conferences between the representatives of A.E.C. and Engineering Foundation on the financing of a joint study of economic balance continued during the first half of the year. It was finally decided that the financing of such an investigation at the present time would not be successful.

(6) *Publications.* A pamphlet entitled "Engineering: A Career—A Culture," prepared by a special committee headed by H. N. Davis, was published and 100,000 copies were distributed through libraries, schools, etc.

It was decided to discontinue the publication of "Research Narratives."

The final report of the arch dam investigation sponsored by the A.S.C.E. was published and the committee discharged.

Respectfully submitted,

D. Robert Yarnall
E. R. Fish
A. E. White
A.S.M.E. Representatives.

* See report of A.S.M.E. Standing Committee on Research, page 35, on projects toward the support of which The Engineering Foundation has contributed.

ENGINEERS' COUNCIL FOR PROFESSIONAL DEVELOPMENT

The Engineers' Council for Professional Development is a direct outgrowth of the work of the Committee on the Economic Status of the Engineer.* Following the recommendations of the latter committee, the A.S.M.E. issued invitations to certain other organizations to appoint representatives to meet and discuss the advisability and means of joint action leading toward the professional development of the engineer.

Out of this invitation there developed a meeting on April 14, 1932, at which a general plan was evolved for the inauguration of a joint body consisting of representatives of the following organizations:

American Society of Civil Engineers
American Institute of Mining and Metallurgical Engineers
The American Society of Mechanical Engineers
American Institute of Electrical Engineers
American Institute of Chemical Engineers
Society for the Promotion of Engineering Education
National Council of State Boards of Engineering Examiners.

The idea was to include not only engineering societies as representative of what may be called the professional aspects of the engineer's life, but also bodies representing the educational and legal aspects. The name suggested for this joint body was Engineers' Council for Professional Development.

All seven of the organizations named acted favorably on the recommendations of this joint committee and authorized the organization of such a Council with three members from each of the cooperating bodies. At a meeting held in October, 1932, the Council was organized with a temporary set of officers, a constitution and program were adopted for submission to the parent bodies, and working subcommittees were appointed so that there might be no delay in starting what is believed to be a most important move on the part of the engineering profession.

All the cooperating bodies have now accepted the recommendations of the Engineers' Council with respect to its composition, its constitution, and its program for the immediate future. It is therefore a going concern at the present time.

This Council has defined itself as "**** a conference of engineering bodies organized to enhance the professional status of the engineer through the cooperative support of those national organizations directly representing the professional, technical, educational, and legislative phases of an engineer's life."

It has stated its objective as: "**** the enhancement of the professional status of the engineer. To this end it aims to coordinate and promote efforts and aspirations directed toward higher professional standards of education and practice, greater solidarity of the profession, and greater effectiveness in dealing with technical, social, and economic problems."

The Engineers' Council has already appointed four working subcommittees and these are organized and working. Their names, chairmen, and tentative statements of their immediate objectives are:

(1) Committee on Student Selection and Guidance; chairman, R. L. Sackett, dean, College of Engineering, Pennsylvania State College. This committee "shall report to ECPD means for the educational and vocational orientation of young men with respect to the responsibilities and opportunities of engineers in order that only those may seek entrance to the profession who have the high quality, aptitude, and capacity which are required of its members."

(2) Committee on Engineering Schools; chairman, Karl T. Compton, president, Massachusetts Institute of Technology. This committee "shall report to ECPD means for bringing about cooperation between the engineering profession and the engineering schools. As an immediate step, the committee shall report criteria for colleges of engineering which will insure to their graduates a sound educational foundation for the practice of engineering."

(3) Committee on Professional Training; chairman, R. I. Rees, assistant vice-president, American Telephone and Telegraph Company. This committee shall report to ECPD plans for the further personal and professional development of young engineering graduates, and also of those without formal scholastic training.

(4) Committee on Professional Recognition; chairman, Conrad N. Lauer, president, Philadelphia Gas Works. This committee shall report to ECPD methods whereby those engineers who have met suitable standards may receive corresponding professional recognition.

The character of the men who have accepted the chairmanship of these committees and who are now actively engaged in producing

* See report of Committee, page 44.

results through those committees speaks for itself. There can be no doubt of the value of the plans of the Engineers' Council when such men will devote large fractions of their time to its purposes. These men all realize that the time has arrived at which the engineer begins to assume a different place in the social structure and additional and more important responsibilities than those he has carried heretofore. They also realize that it is necessary that he prepare himself properly for such responsibilities and that he provide means within the profession for maintaining such standards of professional ability and ethics as shall be required under these new conditions.

The Engineers' Council for Professional Development has a huge and important task before it. This task can be accomplished satisfactorily only if it has the whole-hearted cooperation of the bodies represented on it, the individual members of those bodies, and all other engineers throughout the country.

Respectfully submitted,

C. F. Hirshfeld
J. H. Lawrence
W. E. Wickenden
A.S.M.E. Representatives.

INTERNATIONAL ELECTROTECHNICAL COMMISSION

U.S. NATIONAL COMMITTEE

In 1924 the first World Power Conference, held in London, requested the International Electrotechnical Commission to take up actively the development of international agreements relative to test codes or specifications for prime movers. Prior to that time committees in Great Britain, Switzerland, Germany, and the United States had been at work developing national codes for water turbines, steam turbines, internal-combustion engines, etc. In February, 1925, the U.S. National Committee of the I.E.C. invited The American Society of Mechanical Engineers to accept membership, recognizing the A.S.M.E. Committee on Power Test Codes* as the authoritive group in the United States on the testing of prime movers and other auxiliary apparatus. This invitation was accepted and the Society through its representatives on the U.S. National Committee has since taken an active part in the international conferences on this subject.

In December, 1931, with the completion of the organization of the Electrical Standards Committee, the U.S. National Committee of the I.E.C. became identical in personnel with the E.S.C., plus three representatives of the A.S.M.E. and certain individuals appointed by the Committee. By this reorganization all the national bodies having interest in the work of the I.E.C. are directly represented on the international committee, and the work of the U.S. National Committee of the I.E.C. is closely associated with that of the American Standards Association.

The U.S. National Committee of the I.E.C. functions as Secretariat for Advisory Committees No. 1 on Nomenclature, No. 4 on Hydraulic Turbines, No. 5 on Steam Turbines, No. 14 on Rating of Rivers, and No. 19 on Internal-Combustion Engines. During the year preparations had been made for meetings in the United States of Advisory Committees No. 1 on Nomenclature, No. 2 on Rating of Electrical Machinery, No. 5 on Steam Turbines, and No. 19 on Internal-Combustion Engines, but due to the unsettled conditions generally, these plans have been abandoned indefinitely. It is expected, however, that wherever possible the programs of these committees will be carried on by correspondence until meetings can again be scheduled, although it is recognized that the work of Advisory Committees No. 5 on Steam Turbines and No. 19 on Internal-Combustion Engines, has reached a point where little more can be accomplished without international advisory committee meetings.

Respectfully submitted,

H. N. Davis
E. C. Hutchinson
Francis Hodgkinson
A.S.M.E. Representatives.

NATIONAL MANAGEMENT COUNCIL

Under the leadership of Harry A. Hopf there has been brought into being a joint body known as the National Management Council. The purpose is to bring into one fellowship all of the societies working in the management field, in order that their efforts may be coordinated and constructive work planned and carried through to realization.

The organization meeting was held on June 8, 1933, at which time officers were elected. The Constitution and By-Laws of the National Management Council had previously been ratified by seven management organizations, including The American Society of Mechanical Engineers for its Management Division.

Too short a time has elapsed to show definite results from this new management group. One responsibility, however, has been taken over, that of organizing and planning for International Management Congresses, a task formerly exercised by the International Management Congress Committee.

Respectfully submitted,

L. P. Alford
H. V. Coes
F. E. Raymond
A.S.M.E. Representatives.

NATIONAL RESEARCH COUNCIL

DIVISION OF ENGINEERING AND INDUSTRIAL RESEARCH

The purpose of the Division is to encourage, initiate, organize, and coordinate fundamental research in the field of industry and to serve as a clearing house for research information of service to industry.

It is one of eleven Divisions of the National Research Council, which is a cooperative organization for scientific and technical men of America, most of whom are representatives of the major scientific and technical societies. The administrative expenses of the National Research Council are largely paid from an endowment, but the actual research projects sponsored by the Division are financed by interested industries or from other sources in a manner similar to the A.S.M.E. system of research sponsorship.

The Division of Engineering is made up of five representatives of the four Founder Societies* and of representatives from the A.S.R.E., A.S.T.M., A.S.S.T., A.S.H.&V.E., I.E.S., W.S.E., S.A.E., and A.W.S. Charles F. Kettering, vice-president and general director of research, General Motors Corporation, is chairman of the Division this year.

Projects

Electrical Insulation. The Committee on Electrical Insulation held its annual meeting in connection with the Baltimore Regional Convention of the A.I.E.E. There were several sessions devoted to papers on progress in installation research, problems in connection with high voltage cables, etc. These papers and reports were published in several issues of *Electrical Engineering.*

Welding. A conference on Fundamental Welding Research was held during the Annual Meeting of the American Welding Society, at Buffalo, in October, 1932. A comprehensive list of fundamental research problems in the welding field that need solution has been compiled by the Fundamental Research Committee of the American Bureau of Welding and published in the December, 1932, issue of the *Journal* of the American Welding Society. Forty investigations are now under way in the various institutions of the country. Reports were submitted during the year by a number of these investigators.

At the meeting of the American Bureau of Welding in April, 1933, progress reports were presented by the Committee on Welding Wire Specifications, which has practically completed a new set of specifications for welding wire. A new investigation on structural steel welding was promulgated, and investigation on the impact resistance of welded joints is under way. The final report of the Welded Rail Joint Committee was published in September, 1932, and its 350 pages summarize the results of a ten-year program of investigation.

Highways. At the Twelfth Annual Meeting of the Highway Research Board in Washington, December, 1932, thirty papers and reports were presented dealing with factors of highway management and automobile design from the point of view of road performance as well as highway construction and maintenance. Two books were published covering these reports and the results of the special investigations. The special project on "Best Laying Methods," has been actively prosecuted during the year and two new projects were organized, one on "Roadside Development" and the other, "Use of High Elastic Limit Steel as Concrete Reinforcement."

Heat Transmission. This Committee is bringing to completion the preparation of a critical digest of information on heat trans-

* See report of Committee, page 41.

* See report of A.S.M.E. Standing Committee on Research, page 35.

mission. A comprehensive treatise on the several types of heat transmission, based on considerable unpublished information, as well as a critical examination of the literature, was prepared by the committee under the supervision of W. H. McAdams, of M.I.T., and published in book form in December, 1932, by the McGraw-Hill Book Company. A book on heat insulation is now in preparation.

University Relations

A plan for regional conferences was inaugurated in July, 1932, for the study of university research facilities and research capacities of the engineering research personnel of all universities in the country. The sum of $4600 has been made available for the conduct of a national survey of these resources. The purpose of this survey is to carefully catalog not only the physical facilities but also the various capacities of these universities to do research. Conferences will be held in suitably located centers in each of eight geographical districts. The first conference, which was held in Chicago in April, 1933, was a considerable success, and the next will be held in New York in October, 1933.

Surveys

A number of surveys initiated early in the year were continued. An analysis of the research expenditures in the chemical industry appeared in the August, 1932, issue of *Chemical and Industrial Engineering Chemistry*, which indicated the relative amount spent on research for 1931 as compared with 1929; the comparison of research programs with size of companies; and the change in trends in emphasis of research programs. Similar reports were published covering the food, metals, and machinery industries.

Addresses

A number of addresses by officers of the Divisions were presented before appropriate groups representing executives, trade associations, and technical societies. Aid is being given to several trade associations in organizing cooperative research programs.

Conclusions

A thorough examination of the accomplishments of the Division during the past fourteen years has led to the conclusion that there is a place for the Division which is not being filled by any other existing organization. This field may be briefly divided into three main divisions. First, the administration of research projects of national scope involving several branches of engineering or science; second, promotion and stimulation of research in universities, trade associations, and private companies; and third, maintenance of a central clearing house for research information in the industries which support research through the maintenance of about 1600 industrial research laboratories.

Respectfully submitted,

D. S. Jacobus, *Vice-Chairman*
W. D. Ennis
F. M. Farmer
G. W. Lewis
Albert Kingsbury
W. R. Webster
Calvin W. Rice, *Ex-Officio*

A.S.M.E. Representatives.

UNITED ENGINEERING TRUSTEES, INC.

On the initiative of senior national societies of engineers this corporation was granted a special charter by the State of New York for "the advancement of the engineering arts and sciences in all their branches, and to maintain a free public engineering library.... It shall have power to take real and personal property and to use, maintain, occupy, lease, mortgage, and convey the same."

Its Founder Societies are the American Society of Civil Engineers, American Institute of Mining and Metallurgical Engineers, The American Society of Mechanical Engineers, and American Institute of Electrical Engineers. For them it holds and administers the Engineering Societies Building and Library, and several funds. It has three departments, Administrative, Library, and The Engineering Foundation, the last devoting its energies mostly to research. It may create other departments at the direction or with the approval of the Founder Societies.

The financial resources of the corporation are payments made by the Founder and Associate societies for the use of offices and meeting halls in the building and for the support of the Engineering Societies Library, income from endowment and other funds, and special contributions. The funds include endowments for the Library ($224,500) and the Foundation ($883,000) and a depreciation and renewal fund ($317,800) for the building, which with the land cost $2,000,000. The depreciation and renewal fund is increased each year by the addition of its own income and a stipulated allotment from other sources, and against it are charged major repairs.

The book value of the securities owned for all funds is	$1,394,355.40
and the market value as of Dec. 31, 1932, is	1,102,741.88
Shrinkage, 21 per cent	$ 291,613.52

Total annual income from all sources would be, for normal conditions, $246,300, divided as follows:

From endowment funds	$ 53,000
From Founder Societies	60,000
All other sources	78,300
Estimated income 1933	191,300
Reduction of income due to depression	55,000
Total income, normal years	$246,300

The corporation's annual expenditures, and those of its departments, in *recent normal* business times, are compared below with the budget for 1933:

	Normal annual expense	Budget for 1933
(1) Salaries and wages for operating building	$46,200	$41,000
(2) Electric current, steam heating, and supplies for operating building	42,000	33,500
(3) Depreciation and renewal allotment for building	12,000	.....
(4) Telephone expense—private branch exchange for building tenants	15,400	13,500
(5) Bookkeeping, auditing, secretarial, financial, legal, and other services and insurance	18,400	14,100
(6) Operating cost Engineering Societies Library	68,800	53,000
(7) The Engineering Foundation		
(a) Administrative expense	4,200	4,100
(b) Promotion of research	6,300	5,100
(c) Allotment of Engineering Foundation income to all projects (part from previous unexpended balance)	33,000	31,500
Total expenditures	$246,300	$195,800

The difference between the 1933 estimated income of $191,300 and the budget of $195,800, or $4500, is more than offset by certain items of income from investments, classified as doubtful as a precaution of extreme conservatism at the time the income was estimated, but on which substantial payments have been received.

The corporation is administered by a Board of twelve Trustees, three appointed by each Founder Society for three-year terms. The Board elects from its members a president and two vice-presidents; also a treasurer, an assistant treasurer, and a secretary, who need not be members. The Board appoints the following standing committees: Finance, House, Memorials, and American Engineers' Memorial, the last an international body connected with the war memorial at Louvain.

Its executive officer is the secretary (part-time). It has a clerical, mechanical, and janitorial staff totaling 34.

The Library is managed by a board of 21 members, including the secretaries of the four Founder Societies, and is operated by a director with a staff of library and clerical assistants, totaling 24.

The Engineering Foundation has a board of 16 members elected by the Board of Trustees. It has a director, a stenographer-secretary, and a junior clerk, a total of 3, all on part time.

The Coordination Committee of the Engineering Societies and its subcommittees have been active. Under date of May 1 a report was submitted to the Founder Societies and United Engineering Trustees, Inc., suggesting certain actions and inquiring whether the Coordination Committee should proceed with its studies. Action by the Board of Trustees was deferred pending action by the Founder Societies.

The Library financial needs have had repeated consideration on account of the decrease in contributions by the Founder Societies enforced by severe reductions of their incomes. Even the reduced budget, it developed, could not be fully met because of a deficit caused by falling off of the business of the Library's service departments and the expectation of failure to receive income from certain investments of endowment funds. The Engineering Foundation has underwritten this deficit. In June the Trustees appointed a Library Fund Committee, having for members the chairman and the vice-chairman of the Library Board, and a Trustee, on the request of the chairman of the Library Board. This committee is seeking new contributions toward the deficit and the endowment of the Library.

Financial Matters. The Finance Committee has held meetings at least monthly and some additional meetings. The budget for the year was drawn on the basis of reduced income, and salaries have

been cut and other decreases of expenditures made to meet the conditions. The American Society of Mechanical Engineers was forced to request deferment of payment of part of its obligations to United Engineering Trustees, Inc., until October and is giving its notes monthly for the amounts deferred. To meet this situation, the Trustees are borrowing from the depreciation and renewal fund until payment shall have been received from the A.S.M.E.

The Trustees appointed the firm of Wood Struthers & Co. its financial advisers about the first of the year and has found the service very helpful in the administration of the various investments.

A number of sales and reinvestments of securities have been made from time to time under the guidance of the investment adviser and the treasurer, in order to improve the soundness of the portfolio and insurance income.

Bank accounts were moved in March from the National City Bank to the Bankers Trust Company. Current payments of income to the Library and the Foundation were reduced because of doubt as to receipt of interest and dividends from a small number of investments. To date the full amount has been received from the questioned railroad securities and approximately 50 per cent of the interest due on mortgages on real estate.

If any of the members of the A.S.M.E. are interested in further details, they can be secured by addressing United Engineering Trustees, Inc., 29 West 39th Street, New York, and asking for a copy of "History, Charter and By-Laws" or for any of the reports and leaflets pertaining to the Library and the Foundation.

Respectfully submitted,

W. L. Batt
E. R. Fish
Harold V. Coes,
President, U.E.T.
} *A.S.M.E. Representatives.*

JOINT AWARDS

The A.S.M.E. participates in a number of joint awards. The following paragraphs give the purpose of these awards, the organizations represented upon the boards of award, the names of A.S.M.E. representatives for 1932–1933, and the awards made between October 1, 1932, and September 30, 1933.

John Fritz Medal, for notable scientific or industrial achievement; A.S.C.E., A.I.M.E., A.S.M.E., A.I.E.E.; W. L. Abbott, R. V. Wright, C. N. Lauer, A. A. Potter; award for 1933 to Daniel C. Jacklin, April 20, 1933.

Herbert Hoover Medal, for distinguished public service; A.S.C.E., A.I.M.E., A.S.M.E., A.I.E.E.; D. S. Kimball, Ambrose Swasey, Calvin W. Rice; no award.

Washington Award, for advancing human progress through engineering; A.S.C.E., A.I.M.E., A.S.M.E., A.I.E.E., Western Society of Engineers; W. I. Westervelt, G. F. Gebhardt; no award.

Daniel Guggenheim Medal, for notable achievement in advancement of aeronautics; A.S.M.E., S.A.E., Canada, England, France, Germany, Holland, Italy, Japan; G. W. Lewis, H. I. Cone, P. H. Adams, E. E. Aldrin; award for 1932 to Juan de la Cierva, June 28, 1933; award for 1933 to Jerome C. Hunsaker, August 31, 1933.

Gantt Gold Medal, for distinguished achievement in industrial management as a service to the community; Institute of Management, Management Division of A.S.M.E.; R. A. Wentworth, J. W. Nickerson, J. W. Roe; award for 1932 to Henry S. Dennison, June 30, 1933.

Alfred Noble Prize, for most meritorious technical paper published by participating Societies; A.S.C.E., A.I.M.E., A.S.M.E., A.I.E.E., Western Society of Engineers; H. L. Seward; award for 1932 to Frank M. Starr, January 23, 1933.

OTHER REPORTS

Reports for the year 1932–1933 were also received from the following organizations on which the A.S.M.E. is represented as indicated. These reports are on file at the headquarters of the Society and will be embodied in the report of the Secretary to the A.S.M.E. Council on December 4, 1933.

American Bureau of Welding, James Partington
International Management Congress Committee, L. P. Alford, W. L. Batt, Calvin W. Rice
Joseph A. Holmes Safety Association, O. P. Hood
Professional Engineers' Committee on Unemployment, W. A. Shoudy, Calvin W. Rice, H. N. Davis, H. V. Coes, W. W. Macon, A. H. Meyer, Walter Rautenstrauch, R. I. Rees
State Councils of Professional Engineers, Paul Doty, J. A. Hall, B. M. Brigman.

Service Rendered by the Office of the Society

The number and diversity of the activities of the Society are summarized in the Report of the Council and detailed in the Reports of Society Committees and Joint Activities. These are the reports of those appointed to bring to accomplishment the purposes of the members of the Society. The Office of the Society in turn, under the direction of the Secretary, carries out the policies and procedures laid down by the Council and Committees. The duties of the Office, therefore, are as numerous and as varied as are the activities of the Society.

The Office, then, serves the Council, its Executive Committee, and all standing and special committees and representatives on joint activities. It keeps all records, handles correspondence, arranges for meetings, assists the Council and Committees in their reports, and prepares material for publication.

Moreover, as national headquarters of the Society, not only the members but also an ever-increasing number of other individuals and organizations, both of the United States and from abroad, look to it for assistance and advice in many ways. Requests for information and help in matters of import to the entire profession, come to the Society from the four corners of the world.

In other words, the Office of the Society not only performs the regular duties connected with many committee activities but also acts as a service bureau for the members, and on behalf of the members, as a service bureau to the public, in so far as facilities and resources permit.

The Reports of Standing Committees show how their activities have been curtailed. Fewer meetings, reduction of volume of published material, and some curtailment of technical committee work, have reduced the volume of the work of the Office. But certain curtailments, such as the holding of fewer committee meetings, have added to, rather than subtracted from, the work of the Office; because progress once made in committee meetings is now attained through correspondence handled by the staff for the committees. Nevertheless, changes in office methods for the purpose of saving time as well as money, have been made, thereby permitting the accomplishment of effective work in spite of a decreased staff.

A reduction of 26 per cent in the operating expenses of the Society was made during the past year, 1932–33, from a budgeted allowance of $545,500.00 at the beginning of the year to an actual expenditure of $432,848.99. This has been largely accomplished by reducing the number of persons on the staff and by reducing salaries. Since October, 1931, the number of persons on the staff has been reduced from 107 to 68. This is exclusive of the Engineering Index employees, the number of which has been reduced from 36 to 18 since 1931. The percentages of reductions in salary rates from the high point of 1929–30 ranged from 40 per cent for those in supervisory positions to 22 per cent for those in lowest positions. As the result of the reductions both in the number of employees and in the salary rates, the total salary expense has been reduced 42 per cent, from $282,283.45 in 1929–30 to $173,519.95 in 1932–33.

The Office is organized in six departments as follows:

(1) *Supervision and General.* Calvin W. Rice, Secretary, and C. E. Davies, Executive Secretary, supervise the office operations and the staff service that is rendered to the Council, Executive Committee, other special committees of the Council, and the Committees on Finance, Publications, Constitution and By-Laws, and Professional Conduct.

General (J. E. Hannum, Office Manager). Includes accounting, incoming and outgoing mail, addressograph, stenographic, filing, stores, shipping, and other routine services.

Number of employees*—28.

* The number of employees is as of September 30, 1933.

1932-1933* Expenditures, $70,476.26; 1933-34 Budget, $58,000.00.

(2) *Field* (Ernest Hartford, Assistant Secretary). Provides service required in the operation of the meetings of the Society, the 16 Professional Divisions, 72 Local Sections, 108 Student Branches, the Committee on Awards, the Employment Service, and related matters.

Number of employees—10 in New York, 1 in Chicago, 1 in Tulsa.

1932-33 Expenditures, $37,277.76; 1933-34 Budget, $32,000.00.

(3) *Technical Committees* (C. B. LePage, Assistant Secretary). Provides service for the 439 Committees and subcommittees engaged under the general leadership of the Committees on Standardization, Research, Safety, Power Test Codes, and Boiler Code.

Number of employees—7.

1932-33 Expenditures, $27,160.38; 1933-34 Budget, $17,600.00.

(4) *Editorial* (George A. Stetson, Editor). Edits and publishes *Mechanical Engineering* text pages, Transactions, and the papers provided in the off-set process in lieu of printed papers. Material equivalent to 2600 Transactions size pages was handled in 1932-33.

Number of employees—6 (2 additional part-time).

1932-33 Expenditures, $24,440.59; 1933-34 Budget, $21,000.00.

(5) *Advertising and Sales* (Frederick Lask, Advertising Manager).

(*a*) Secures and publishes advertising in *Mechanical Engineering* and the Mechanical Catalog.

Number of employees—11.

1932-33 Expenditures, $39,430.58 (1932-33 Advertising income, $84,855.45); 1933-34 Budget, $30,000.00.

(*b*) Handles sale and distribution of codes, standards, reports, and special publications sold by the Society.

Number of employees—4.

1932-33 Expenditures, $9,347.08 (1932-33 Sales Income, $40,441.16); 1933-34 Budget, $9,300.00.

(6) *Engineering Index* (J. E. Hannum, Editor, F. Y. Stewart, Sales Manager). Edits, publishes, and sells the daily and weekly card service and the annual volume of The Engineering Index, which involves the annual preparation and printing of more than 40,000 descriptive references to information published in some 2000 current technical publications in 20 languages and received from 40 countries.

Number of employees—18.

1932-33 Expenditures, $44,524.68; no budget for 1933-34.

In addition to these budgeted allowances for 1933–34, $12,100.00 has been appropriated for rent, insurance, depreciation of furniture and equipment, relief, and contingencies, making the total budgeted allowance $180,000.00 as compared with an actual expenditure for 1932–33 of $221,863.29, exclusive of The Engineering Index.

CALVIN W. RICE, *Secretary.*

* Tabulation of Salaries, and other expenses for all office departments appears as Schedule 3 in Report of Finance Committee, page 23.

Reports of Meetings

THE annual reports of the Meetings and Program and Professional Divisions Committees, elsewhere in this issue, summarize the meetings of the Society and of its Professional Divisions for the fiscal year.

The Semi-Annual Meeting, held at Chicago, June 25–30, 1933, during Engineering Week of the Century of Progress Exposition, was reported in the August, 1933, issue of *Mechanical Engineering*, pages 481–485. The program as presented was substantially the same as the advance program printed in the June, 1933, issue of *Mechanical Engineering*, pages 393–400.

The Annual Meeting, held at New York, December 4–8, 1933, will be reported in the January, 1934, issue of *Mechanical Engineering*. The advance program was printed in the November issue, pages 713–720, and the final program differed from it only slightly.

Of the four meetings sponsored by Professional Divisions, or Groups, three have been reported in *Mechanical Engineering*.

An Air-Conditioning Conference was held by the San Francisco Section at the University of California, Berkeley, February 9–10, 1933, with the cooperation of the Air Conditioning Committee of the Process Industries Group. This conference was reported in *Mechanical Engineering*, April, 1933, page 272. Titles and authors of the papers presented are given in the report, and the papers themselves have been published in book form.

The July, 1933, issue of *Mechanical Engineering*, page 463, contains an account of the National Lubrication Engineering Meeting held at Pennsylvania State College, May 25–26, by the Lubrication Engineering Committee of the Petroleum Division in cooperation with the Central Pennsylvania Section and Pennsylvania State College. The proceedings of this conference have since been published as Technical Bulletin No. 18 of the School of Engineering of the college. A review of this bulletin to be published in the February, 1934, issue of *Mechanical Engineering* contains the titles of the papers presented and the names of their authors.

In the October, 1933, issue of *Mechanical Engineering*, pages 655–656, will be found an account of the National Oil and Gas Power Meeting, held at Atlantic City, N. J., August 23–26, 1933, under the auspices of the Oil and Gas Power Division. The account contains the titles of papers presented and names of authors.

The Applied Mechanics Division held a Pacific Coast meeting on January 20–21, 1933, with the cooperation of the Los Angeles Section and the California Institute of Technology at the Institute in Pasadena. The following papers were presented:

Fluid Mechanics

A New Apparatus for the Determination of the Size Distribution of Particles of Fine Powders, R. T. Knapp

The Determination of Viscosity by the U-Tube Method, E. D. Howe

The Measurement of Viscosities of Liquids Saturated With Gases at High Pressure, B. H. Sage

Viscosity of Oils at High Temperatures, F. L. Maker

Problems Related to Earthquakes

On the Problem of Earthquake Resistant Construction, R. R. Martel

Calculation of the Effect of Earthquakes on Buildings, M. Biot

Vibration of Continuous Frames, W. Porush

Vibrations of Buildings, P. Byerly

Water Pressures on a Tank During a Simulated Earthquake, L. M. Hoskins and L. S. Jacobsen

Design of the Pine Canyon Dam With Reference to Earthquake Stresses, S. B. Morris and C. E. Pearce

General Lecture

The Modern Revival of Applied Mechanics, Dr. Theodor von Karman

Fluid Mechanics

An Application of Theoretical Hydrodynamics to Pumps and Turbines, G. Wislicenus

A Criterion for the Instability of Laminar Velocity Profiles, W. Tollmien

The Water Jet Pump, M. P. O'Brien and J. E. Gosline

The Turbulent Mixing of Two Jets of Different Velocities, A. M. Kuethe

Experiments on Fluid Resistance of Ultra-Rough Surfaces, R. G. Folsom

Theory of Viscosity and Turbulence Pumps, A. Hollander

Vibrations of Mechanical Systems

Some Factors Which Affect the Vibration of a Single "Spring-Mass" System, M. Asimow

Variation of Harmonic Components of Exciting Force (and Torque), due to the Gaseous Pressure, in an Internal Combustion Reciprocating Engine of the Constant Volume Type With Conditions of Operation, L. M. K. Boelter

Periodic Forces Due to the Reciprocating Masses in V-Type Engines, C. J. Vogt

Vibration Characteristics of Automobile Headlamps and Methods of Test Employed to Predict Mechanical Performance, D. O. Rusk

Elasticity

Graphical Integration of Differential Equations, L. H. Donnell

The Ultimate Strength of Thin Sheets in Compression, E. E. Sechler

Effect of Shear Deflection on Axially Loaded Beams, A. S. Niles

Effect of "Creep" on Working Stresses as Applied to Steel for High-Temperature Pressure Vessels, F. L. Maker.

Necrology

ASHEL CYRUS ABELL (1884–1933)

Ashel Cyrus Abell, head of the department of mechanical engineering at The State College of Washington, Pullman, Wash., died suddenly on January 1, 1933. Professor Abell had been at the college since he went there as a student in 1907. He received a B.S. degree in mechanical engineering in 1912 and an M.S. in 1929. He joined the teaching staff as instructor in shop practice and after successive advancements became head of the mechanical engineering department in 1930. His teaching specialties were steam power heating and ventilation.

Professor Abell was born at Arkona, Ontario, Canada, on February 4, 1884. He was a machinist apprentice from 1900 to 1902 at the Waters Engine Works Company, Brantford, Ont., and from then until the fall of 1905 at the Canadian Locomotive Company, Kingston, Ont. During the next two years he was in charge of the motor department of the Canada Cycle & Motor Co., in Toronto, directing the construction of automobile engines, and for the first six months of 1907 was engaged in testing automatic screw machines for the Cleveland Automatic Screw Machine Company, Cleveland, Ohio.

Professor Abell became an associate of the A.S.M.E. in 1918. He was chairman of the Inland Empire Section at the time of his death. He belonged to several fraternal organizations, including the Masonic and Theta Xi.

EDGAR E. ARISON (1873–1933)

Edgar E. Arison, president of The Harrington Emerson Counselors, Indianapolis, Ind., died on April 22, 1933.

Mr. Arison was born on March 4, 1873, in Monongahela, Pa., the son of William Henry and Elizabeth (Coulter) Arison. After attending the United States Naval Academy at Annapolis, Md., he spent several years in civil, mining, and railway engineering with McKinney and Smith, Pittsburgh, Pa., and the Baltimore & Ohio R.R.

For ten years beginning in 1894 Mr. Arison was connected with The Carborundum Company, Niagara Falls, N.Y., engaged in general operating, administrative, and sales work. In 1904 and 1905 he was with The Ozone Vanillin Company, of Niagara Falls.

Mr. Arison became associated with Harrington Emerson in 1905, while Emerson was applying his principles of efficiency to the problems of the Atchison, Topeka & Santa Fe R.R. He continued to work with him until 1918, becoming vice-president, in 1910, of The Emerson Engineers. From 1918 to 1920 he was chief of the Western Division of the U.S. Army Ordnance, advancing from the rank of major to that of colonel. He had been president of The Harrington Emerson Counselors since 1926.

Mr. Arison became a member of the A.S.M.E. in 1916. He was a Presbyterian and a Mason.

Surviving Mr. Arison are his widow, Marie Wallace (Rae) Arison, whom he married in 1899, and four children, Mrs. Margaret Feldon, Wilmette, Ill., Lt. Rae E. Arison, U.S. Naval Academy, and Mrs. Ethel Heiberger and Alan Arison, Evanston, Ill.

THEODORE PROSPÈRE ARTAUD (1876–1933)

Theodore Prospère Artaud, who had been in ill health for about two years, died on August 5, 1933. Prior to his illness he was associated with the National Park Planning Commission in the extension of the system of parks in Washington, D.C.

Mr. Artaud was born on April 29, 1876, at Jackson, Miss. His early education was secured at the Passy School, Paris, and Colliere's, in Washington. He then attended Rock Hill College, Ellicott City, Md., for three years and Harvard University, receiving A.B. and M.S. degrees from the latter in 1895 and 1897.

From 1898 to 1900 Mr. Artaud served in the Infantry of the U.S. Army, and during the next two years taught mathematics and drawing at the University School, Baltimore, Md. In 1903 he entered the employ of the Hudson Companies, New York, with which he was connected in various capacities, leading to that of purchasing agent, until 1908, when he was made assistant to the vice-president and purchasing agent of the Hudson & Manhattan R.R. In 1912 he took on additional responsibilities as superintendent of the Hudson & Manhattan Terminal in New York and the following year was given the office of assistant general manager of the company.

Mr. Artaud terminated his connection with the Hudson & Manhattan R.R. in 1915 and since then had been located in Washington. For the greater part of the time he was connected with the Interstate Commerce Commission, in charge of land appraisal work, for some years executive assistant of the Bureau of Valuation. In 1929 and 1930 he was vice-president, and director of research, of the National Association of Owners of Railroad & Public Utilities Securities.

Mr. Artaud became an associate of the A.S.M.E. in 1907. He is survived by a brother, Major Frank E. Artaud, Hapeville, Ga.

JOHANNES IMMANUEL ASTROM (1873–1933)

Johannes Immanuel Astrom, whose death occurred on August 15, 1933, was born at Helsingfors, Finland, on March 9, 1873, the son of F. A. and Marie (Klein) Astrom. His ancestors were sea captains of Swedish descent, but naturalized in Finland.

Mr. Astrom secured his M.E. degree from the technical university at Helsingfors in 1896 and soon afterward came to the United States. He found employment as a draftsman with the Nordberg Manufacturing Company, Milwaukee, Wis., and remained with that company until 1908, except for short periods as draftsman with the E. P. Allis Co., Milwaukee, in 1897, C. H. Bradley, Jr. & Co., Pittsburgh, in 1898, and the Westinghouse Machine Company, East Pittsburgh, 1899, and as mechanical engineer at a shipyard in Helsingfors from November, 1900, to July, 1902. He held the position of designer when he finally left the Nordberg Manufacturing Company in 1908 to become chief engineer and vice-president of the Fort Wayne Engineering & Manufacturing Co., Fort Wayne, Ind., where he remained for 18 years. Since 1926 he had engaged in consulting work and since 1929 had also been chief engineer and general manager of the Water Refining Company at Fort Wayne.

Mr. Astrom held a number of patents covering improvements in pumps and related apparatus, such as water softeners, filters, etc.

Mr. Astrom became a junior member of the A.S.M.E. in 1900 and a member three years later.

AUGUSTUS BAINBRIDGE (1863–1932)

Augustus Bainbridge, whose death occurred on December 23, 1932, was born at Swindon, England, on December 7, 1863. His early education was secured in Sicily and at the Netherfield Academy, England, and he later attended the Liverpool School of Science, receiving a certificate for passing the government examinations upon the completion of his studies there, which continued for about ten years, beginning in 1880. During this period he worked in Liverpool for Messrs. Fawcett Preston & Co., drafting parts for marine, hydraulic, and sugar crushing machinery, etc., and for Messrs. John Jones & Sons, designing machinery for passenger and cargo steamers, dredges, boilers, and other equipment. He continued with these companies until 1898, when he became connected with the Palmers Shipbuilding & Dry Dock Co., Ltd., Jarrow-on-Tyne, England. After four years there in charge of design of propelling machinery and equipment for different types of vessels, he went into business for himself, having purchased a small general engineering shop at Newcastle-on-Tyne. He handled repair and construction work not only in the marine field but also in connection with refrigerating, ore crushing, and other plants.

In 1906 Mr. Bainbridge came to the United States, where he was employed for the first six years by the Newport News Shipbuilding & Dry Dock Co., Newport News, Va. He specialized on cylinder design but also worked on other features of a number of naval and merchant vessels. From 1912 to 1917 he was acting chief draftsman in the Machinery Division at the Charleston Navy Yard, and since then had held a similar position at the Brooklyn Navy Yard.

Mr. Bainbridge became a member of the A.S.M.E. in 1923.

LEIGH KNOWLTON BAKER (1894–1933)

Leigh Knowlton Baker, engineer at the National Carbon Company, Inc., Cleveland, Ohio, died on May 7, 1933. He was born at Washington, Pa., on May 29, 1894. After being graduated from the Case School of Applied Science, Cleveland, with a B.S. degree in mechanical engineering, in 1915, he worked for three years for the Upson Nut Company, successively as assistant master mechanic, foreman, and assistant general foreman.

In 1918 and 1919 he was a lieutenant in the Coast Artillery Corps of the U.S. Army. He then spent about a year in each of the following connections: research engineer and assistant to the president of the National Safe Company, assistant mechanical engineer, National Screw and Tack Company, designer, E. W. Bliss Co.,

and sales engineer, York Safe & Lock Co. During these years he directed the design and construction of safes and automatic machines for making and finishing nuts and bolts, and also engaged in research work.

Mr. Baker had been with the National Carbon Company since 1924. After being at the Cleveland works for a time he was transferred as construction engineer to the Niagara Works of the company, and later was stationed at the Fostoria Works in Ohio. In 1928 he was transferred to the Edgewater Plant in Cleveland as works engineer, and in 1920 he was included in the staff of the General Engineering Department at the main office in Cleveland.

Mr. Baker became an associate-member of the A.S.M.E. in 1928. He had also been a member of the Cleveland Engineering Society. He is survived by his widow, Helen (Shackleton) Baker, and by two children.

JOHN SIDNEY BARELLI (1867–1933)

John Sidney Barelli, representative and manager of the New Orleans office for the Heine Safety Boiler Company, died on April 11, 1933. Mr. Barelli was born in New Orleans on June 2, 1867, and attended public school there. He then served an apprenticeship as a machinist with H. Dudley Coleman & Bros., New Orleans, from 1884 to 1888, and was with the Gullet Gin Company, Amite, La., during the next three years. Between 1891 and 1897 he worked at the Whitney Iron Works, Southern Electric Works and New Orleans Traction Company, all of New Orleans.

Mr. Barelli engaged in machine-shop work as a member of the firms of Barelli & Gruber and Barelli & Kittredge from 1897 to 1904. During the next two years he was chief engineer of the Schutton & Fallon Marble Works and the following year held the same position with the DeSoto Hotel. He had been connected with the Heine company since 1907.

Mr. Barelli was a member of the Louisiana Naval Militia from 1898 to 1916, rising to the rank of lieutenant-commander and chief engineer. He joined the A.S.M.E. in 1917. He was president of the New Orleans Chess, Checkers and Whist Club and of the Pine Island Fishing Club and was an Episcopalian. He is survived by his widow and by a daughter, Mrs. Leonard Scheuermann.

HENRY GREGORY BARNHURST (1872–1933)

Henry Gregory Barnhurst, middle-west representative of the Cement Sales Department of The Babcock & Wilcox Company, died of heart failure during the night of March 18, 1933, while asleep at the home of a co-worker in the company's Chicago office. His home was in Forest Hills, Long Island, N.Y.

Mr. Barnhurst was born in Philadelphia, Pa., on June 15, 1872. After being graduated from Haverford School, Haverford, Pa., he spent seven months in the drafting room of V. W. Payne & Sons Engine Co., Elmira, N.Y., and two years as an apprentice machinist with the Humboldt Iron Works, Erie, Pa. He worked in Erie for about six years, four as draftsman and general office assistant for the Union Iron Works, and two as draftsman in the Boiler Department of the Erie City Iron Works and with the Ball Engine Company, manufacturers of high-speed engines.

During the next nine years he worked in positions of increasing responsibility: draftsman for the Atlas Portland Cement Company, New York; mechanical engineer for the Lehigh Portland Cement Company, Allentown; construction engineer for the Mississippi Valley Portland Cement Company; and superintendent of the Diamond Portland Cement Company, Cleveland, Ohio.

From 1906 until recently Mr. Barnhurst had been associated with the same organization, the Fuller Engineering Company and its successor, the Fuller-Lehigh Company. He was chief engineer, with headquarters in Allentown, Pa., until 1924, when he was made advisory engineer, stationed in Fullerton, Pa. His work in the early development of pulverized fuel, as well as in the design and construction of cement plants and other activities in the cement industry, made him well fitted for his appointment as representative of The Babcock & Wilcox Company, when that company took over the Fuller-Lehigh Company in 1926.

Mr. Barnhurst became a member of the A.S.M.E. in 1916.

EDGAR GRANT BARRATT (1864–1933)

Edgar Grant Barratt, who died on February 16, 1933, was born in New York, N.Y., on February 8, 1864, the son of Oliver and Frances (Terry) Barratt. After securing a C.E. degree from the Columbia School of Mines in 1884 he went to Chicago to work for the Exhaust Ventilator Company. He was engineer in charge of erection and subsequently president of the company.

About 1900 Mr. Barratt became chief engineer for the Union Bag & Paper Co., Chicago. He returned to New York a few years later and opened his own office there. In 1905 he again became associated with the Union Bag & Paper Co., as first vice-president, with office in New York. Three years later he was made president of the company, with which he remained until 1925. Since then he had engaged in consulting work.

Mr. Barratt became a member of the A.S.M.E. in 1888. He also belonged to the University Club of Chicago, City Club and Columbia University Club in New York, and several clubs in New Jersey. He made his home in East Orange, N.J. He is survived by his widow, Katharine Bridge (Forman) Barratt, whom he married in 1889, and by a son, Roswell Forman Barratt.

ELMER D. BARRY (1870–1933)

Elmer D. Barry, whose death occurred at Mackenzie City, Demerara, British Guiana, on July 23, 1933, was born at Irasburg, Vt., on February 4, 1870. His first position after leaving high school was in the Turbine Department of the General Electric Company, working in the shops and on the road on the assembly, testing, installation, and maintenance of turbines. After four years in this position he became chief operating engineer, in 1900, of the Stone & Webster Engineering Corp. Of his six years with that company two were spent in charge of a power plant at Key West, Fla., two at Jacksonville, Fla., in charge of a traction company power plant, and two at Savannah as chief engineer of the Savannah Electric Company, in full charge of power plant and substation.

From 1916 to 1919 Mr. Barry was with the Westinghouse Electric & Manufacturing Co., engaged in the erection, testing, and maintenance of turbines and condensers in the Chicago district. During the next three years he handled similar work for the Kerr Turbine Company. In 1922 and 1923 he was chief operating engineer for the Crossett Lumber Company, Crossett, Ark., building a new power plant to change the drive of their mills from mechanical to electrical. The next few years were spent as chief operating engineer with the Arkansas Utilities Company, Helena, Ark., putting old equipment into usable condition, and subsequent power plant work took him to Texas and Marion, S.C. Since 1929 he had been superintendent of power for the Demerara Bauxite Company Limited, Mackenzie, Demerara, British Guiana, South America.

Mr. Barry became an associate member of the A.S.M.E. in 1924. He is survived by his widow, Frances C. Barry, whom he married in 1902, and by two daughters, Pauline Frances Barry and Helen J. Derry, and by one son, Robert Elmer Barry, all of Boston, Mass.

CARL BARTELS (1863–1933)

Carl Bartels, factory manager for the Mosler Safe Company, Hamilton, Ohio, died at his home in that city on February 21, 1933.

Mr. Bartels was born in Germany on April 14, 1863. He attended school there and for several years owned and operated a steam threshing outfit before coming to the United States in 1888.

During his first two years in this country Mr. Bartels was employed by the Chicago Safe & Lock Co. He became associated with the Mosler Safe Company, then located in Cincinnati, in 1890, and went with it to Hamilton the following year. He was superintendent of the Burglar Proof Department from 1900 to 1905, general superintendent of the company from then until 1917, and factory manager of the gun carriage shop during the next two years, and had been factory manager since then. He not only helped to build but also to design the safes, bank vaults, safe deposit boxes, locks, etc., manufactured by the company, and held many patents, either in his own name, or jointly with Mr. Mosler, the president of the company, on these devices and methods of building them.

Mr. Bartels became a naturalized citizen of the United States in 1894. He had been a member of the A.S.M.E. since 1921 and was active in the Masonic fraternity, Elks, and St. John's Evangelical Church. He is survived by four sons, Carl P., Leo F., and Edwin J. Bartels, all of Hamilton, and Dr. Elmer C. Bartels, of Duluth, Minn. His wife, Elizabeth (Reuther) Bartels, died in 1920.

HENRY CLAY BECKWITH (1882–1933)

Henry Clay Beckwith, president of The Byers Machine Company, Ravenna, Ohio, died on January 31, 1933. He was born on January 12, 1882, at Amenia, N.Y. He prepared for college at the Cazenovia Academy, Cazenovia, N.Y., and was graduated from the mechanical engineering course at Cornell University in 1903.

During the first eighteen months following his graduation Mr. Beckwith was employed as a draftsman by the Westinghouse, Church, Kerr Company, New York, N.Y., and for nearly two years longer

was assistant engineer for the company, in charge of the design of a service plant for the Pennsylvania Railroad terminal in New York.

From 1906 to 1908 he was in charge of design, construction, and equipment of a new plant for the Clyde Iron Works at Duluth, Minn. He was then made chief engineer and works manager and during the next four years was responsible for everything pertaining to the organization except finances, purchases, and sales. In April, 1912, his position was again changed, the company making him manager of the Pacific Coast sales office. He also became Portland manager for the Contractors Equipment Company of Seattle and chief engineer for all branches of this company. He opened offices and warehouses in Portland for both companies.

Mr. Beckwith next was engaged by The T. L. Smith Co. as Chicago district manager, but left there to become treasurer and general manager in 1915 of The Byers Machine Company. He was made president of the company in 1928.

Mr. Beckwith became a member of the A.S.M.E. in 1913.

GEORGE GORDON BELL (1884–1933)

George Gordon Bell, of Chesley, Ontario, Canada, who died suddenly of heart failure at Pittsburgh, Pa., on February 26, 1933, was born at Fort Wayne, Ind., on August 17, 1884, the son of William Douglas and Jeannie Stark Bell. He attended public and high school at Chesley and in 1905 was graduated with honors in electrical and mechanical engineering from the School of Practical Science of Toronto University. From then until 1907 he worked in the engineering office of the Canada Foundry Company in Toronto. He then returned to Toronto University, from which he secured a civil engineering degree in 1908.

During the years 1908–1910 Mr. Bell worked for the Canadian Bridge Company, Walkerville, Ont., on structural drafting and the design of mechanical equipment for drawbridges. He next spent two years in structural and hydraulic engineering for the Sawyer-Moulton Company, of Portland, Me.

In 1912 Mr. Bell went to Pittsburgh, Pa., where until 1930 he was connected with the West Penn Power Company. During the first year he worked on water power developments, then spent two years in charge of steam station design. In 1915 he took charge of power station operation and extensions, including the development of mines at the two largest power houses. From 1922 his duties related entirely to extensions to steam and proposed hydraulic plants and associated problems. Ill health forced him to retire in 1930.

Mr. Bell became a member of the A.S.M.E. in 1924. He also belonged to the Engineering Society of Western Pennsylvania, and was active on the Prime Movers Committee of the National Electric Light Association. He had made several contributions to the technical press and taken part in discussions of papers presented before the societies to which he belonged.

DANIEL HARVEY BRAYMER (1883–1933)

Daniel Harvey Braymer, whose death occurred on October 29, 1932, was born at Hebron, Washington County, N.Y., on November 29, 1883, the son of George N. and Jennie Cordelia (Smith) Braymer. He prepared for college at the Granville (N.Y.) High School and secured his A.B. degree from Cornell University in 1906, having specialized in chemical engineering. Two years later, upon the completion of courses in both mechanical and electrical engineering, he was given an M.E. degree.

During the summer of 1906 Mr. Braymer was draftsman for the Morse Chain Company, Ithaca, N.Y., and the next summer was electrical tester for the Electrical Testing Laboratories, New York, N.Y. He also held this latter position for a short time in 1908, later in that year becoming an engineer in the service and maintenance department of the New York plant of the Western Electric Company. In 1909 and 1910 he was electrical engineer handling publicity for the power plant and telephone equipment of the Western Electric Company.

Mr. Braymer entered the publishing field in 1910 and until 1915 was at Atlanta, Ga., on the staff of *Electrical Engineering* and its successor, the *Southern Electrician*, being editor the latter part of the time. He then returned to New York as associate editor of *Electrical World*. In 1917 he went over to the *Electrical Record* as editor-in-chief but in 1919 returned to the employ of the McGraw-Hill Company, becoming managing editor, and in 1921 coeditor of *Electrical World*. From 1922 to 1925 he was editorial director of *Industrial Engineer*, which succeeded the *Electrical Review* and the purpose and plan of which were conceived by Mr. Braymer.

Many of the articles for these magazines were prepared by Mr. Braymer from notes made during inspections of steam generating stations and hydroelectric plants in all parts of the United States. He was also the author of the following textbooks published by the McGraw-Hill Company: American Hydroelectric Practice (1917), Armature Winding and Motor Repair (1919), Rewinding Small Motors (1925), Repair Shop Diagrams and Connecting Tables (1927), and Rewinding and Connecting A.C. Motors (1931).

In 1925 Mr. Braymer formed the D. H. Braymer Equipment Company at Omaha, Neb., specializing in consulting and sales work in connection with ventilation, dehumidification, and air conveying and exhaust systems in industrial power plants.

Mr. Braymer became a member of the A.S.M.E. in 1928 and also belonged to the American Institute of Electrical Engineers. He is survived by his widow, Ruth (McGuire) Braymer, whom he married in 1925, and by his parents.

CHARLES EDWARD BROOKS (1886–1933)

Charles Edward Brooks, chief of motive power and car equipment for the Canadian National Railways, Montreal, Canada, died suddenly of heart disease at his home in that city on April 10, 1933. Prior to his connection with that road he had been with the Grand Trunk Pacific Railway.

Mr. Brooks was born in Constantinople, Turkey, on July 3, 1886, but was educated in Canada, attending primary schools in Montreal and vicinity and Orillia, Ontario, Trinity College School at Port Hope, Ontario, and McGill University, Montreal, from which he received a B.Sc. degree in 1908. During his early scholastic years his holidays were spent working as lumber mill hand, deck hand on a lake steamship, and boilermaker's helper. From May, 1905, to September of the following year he served as special apprentice on the Grand Trunk Railway at Point St. Charles, Quebec, and in the summer of 1907 was a special apprentice and fireman at Turcot, Quebec.

After graduation Mr. Brooks began work as a machinist with the Grand Trunk Pacific Railway and was promoted through positions of increasing responsibility to that of superintendent of motive power, with headquarters at Transcona, Manitoba, in 1915. When the Grand Trunk Pacific Railway was taken over by the Canadian National Railways in 1920 he was appointed mechanical assistant (Locomotive Department) to the vice-president in charge of operation and maintenance and was transferred to Toronto. In 1923 he returned to Montreal in the capacity of chief of motive power of the road and in July, 1932, also took charge of car equipment. He was keenly interested in the development of oil electric cars and the oil electric locomotive.

Mr. Brooks became an associate-member of the A.S.M.E. in 1917, and since 1928 had been a member of the general committee of the Railroad Division of the Society. He was also identified with committee work in the Mechanical Division of the American Railway Association, having been a member of its general committee and committee on locomotive design and construction. He served as president of the Canadian Railway Club in 1924-1925, and belonged to the University Club in Montreal and Kanawaki Golf Club, Quebec.

Mr. Brooks is survived by his widow, Florence (Rowe) Brooks, and by two children, Carol and Noel.

FRANK WILSON BUNN (1866–1933)

Frank Wilson Bunn, manager of plants for the John A. Roebling Sons Co., Trenton, N.J., died of pneumonia at Trenton on May 1, 1933. He had been with the Roebling company since 1905.

Mr. Bunn was born at Sterling, Ill., on April 8, 1866, the son of Martin A. and Sarah (McCune) Bunn. He attended the Sterling High School and worked for a year in the shop of the Eureka Manufacturing Company, Rock Falls, Ill., then spent three years, 1883–1886, at the University of Illinois, Urbana, taking the mechanical engineering course. Upon the completion of his college work he was employed for several months at Sterling in the shop of the Williams & Orton Maufacturing Co., and from November, 1886, to February, 1888, represented that company in New York and was in charge of gas engines for the Zell Engineering Company.

During the remainder of 1888 and first half of the following year Mr. Bunn was connected with the Southern Pacific Railroad Company, in the shops at Sacramento, Calif., and making fuel tests on the road. From then until the first of 1892 he spent part time with Robinson & Burr, Champaign, Ill., in shop work, and served as superintendent of the Sterling Gas & Electric Light Co.

In 1892 Mr. Bunn became Chicago representative of the Southwark Foundry & Machine Co. of Philadelphia, Pa. Three years later he was transferred to Philadelphia as sales engineer for the company, and served in that capacity and as assistant secretary until

he became associated with John A. Roebling Sons Co. as engineering assistant to the president in 1905. He was made chief mechanical engineer of the company in 1917, chief engineer two years later, and since 1929 had been manager of plants.

Mr. Bunn became a member of the A.S.M.E. in 1894. He was a Mason and Presbyterian. His wife, Caroline (Glenn) Bunn, whom he married in 1889, died in 1931.

FRANK GEORGE CARPENTER (1879–1933)

Frank George Carpenter, who died on April 11, 1933, from injuries sustained in a fall at Muncie, Ind., was born at Orion, Mich., on February 17, 1879, the son of Charles Ira and Eliza J. (Coryell) Carpenter. He was graduated from the Michigan State College of Agriculture and Applied Science, East Lansing, in 1902, and spent the next eight years with Swift & Co., Chicago, as draftsman, assistant to the master mechanic and civil engineer, and superintendent of construction of packing plants at St. Joseph, Mo., San Francisco, Calif., Hutchinson, Kan., Portland, Ore., and other cities.

In 1911 Mr. Carpenter entered upon similar work for P. Burns & Co., Calgary, Canada, for which he became chief engineer and master mechanic and later plant superintendent and manager of construction and of the engineering department. He designed and built packing plants in various parts of Western Canada. In 1920 he was general superintendent of the Midland Packing Company Stock Yards, Sioux City, Ia., and the following year superintendent of Roberts & Oakes, Chicago. He then established a packing business, the F. G. Carpenter Co., at Lansing, Mich., which he operated until 1929. He had engaged in consulting work since that time.

Mr. Carpenter became a member of the A.S.M.E. in 1918. He also belonged to the Masonic fraternity, in which he had attained the rank of a Shriner, and to the Sons of the American Revolution and the Presbyterian Church.

Surviving Mr. Carpenter are his widow, Chloe (Goodrich) Carpenter, whom he married in 1910, and two children, Charles David and Ruth Ann Carpenter.

GEORGE HENRY COBB (1856–1933)

George Henry Cobb, the son of George Washington and Mary M. (Hamm) Cobb, was born at Northampton, Mass., on July 10, 1856. He was graduated from the mechanical engineering course of Lehigh University, Bethlehem, Pa., in 1886, and during the next two years worked for Harrison Bros. & Co., Philadelphia, Pa., as assistant to the chief engineer. During the next year he was chief engineer of the Kalion Chemical Company, Philadelphia.

In 1889 Mr. Cobb went to Elmira, N.Y., to take the position of master mechanic of the New York Division of the National Transit Company. He remained there until 1900, when he transferred to Passaic, N.J., as chief engineer of the N.Y. Transit Co. Subsequently he served the company successively as master mechanic, general manager, superintendent, and vice-president. He was located at Binghamton, N.Y., from 1906 until he retired in 1920.

Mr. Cobb became a member of the A.S.M.E. in 1891, and also belonged to the Masonic fraternity, in which he was a Shriner and Knight Templar. He married Minnie A. Downing in 1887 and is survived by her and by a daughter, Beatrice E. Cobb. He died at his home in Santa Barbara, Calif., on January 21, 1933.

WILLIS EDWARD CORWIN (1900–1933)

Willis Edward Corwin, son of Willis W. and Marguerite E. (Day) Corwin, Bloomfield, N.J., died of tuberculosis at Banning, Calif., on May 31, 1933. Mr. Corwin was born in Newark, N.J., on February 20, 1900, attended the Irvington, N.J., High School, and was graduated from the mechanical engineering course at Stevens Institute of Technology in 1923. From then until ill health forced him to give up his work, he was field engineer and plant inspector for the Western Electric Company, Kearny, N.J., and New York, N.Y.

Mr. Corwin became a junior member of the A.S.M.E. in 1923. He belonged to the Beta Theta fraternity at Stevens and was a member of the Irvington Methodist Church.

HARRY O. CREAGER (1890–1930)

Harry O. Creager was born at Richmond, Ind., on December 1, 1890, the son of Johnothan W. and Hannah (Brown) Creager. He supplemented his high school education with night school courses in higher mathematics, mechanical drafting, and factory management.

From 1913 to 1925 Mr. Creager was employed by the Dayton Engineering Laboratories Company, except that during 1918 he was with the U.S. Army Air corps, stationed at Wilbur Wright Field, at Dayton, Ohio, as expert motor mechanic. Since 1925 he had been with the Delco Products Corporation. At the time of his death on March 10, 1930, Mr. Creager was in charge of the tool supply division of the company.

Mr. Creager became an associate-member of the A.S.M.E. in 1928. His widow, Marie (Himes) Creager, whom he married in 1917, survives him.

THOMAS CUNNINGHAM (1854–1932)

Thomas Cunningham, long identified with the iron industry, died suddenly of heart failure at Davis Island, Fla., on December 27, 1932. He was born on November 23, 1854, at Charlestown, Mass., and attended the public schools and a commercial college there. His parents were Thomas and Sarah (Miller) Cunningham.

In 1876 Mr. Cunningham became an apprentice at the iron and boiler works which his father had established in Charlestown in 1850. Upon his father's death about the year 1881 he succeeded to the control of the business, which he incorporated as The Cunningham Iron Works Company and removed from Charlestown to South Boston, where he built a new and extensive plant. In the capacity of treasurer and general manager of the company Mr. Cunningham prepared estimates and contracts and supervised the design and construction of boilers, standpipes, and general iron work. He retired in 1910, turning the conduct of the business over to his employees.

Mr. Cunningham was very fond of ocean travel. He had been around the world twice and made frequent crossings to Europe, and also spent considerable time on his own boats, owning a yacht, a speedboat, and a launch. He belonged to the New York Yacht Club and Bucks Harbor Yacht Club, Maine. When not traveling he spent the summers at South Brooksville, Me., and the winters in Boston, Mass. He had been in Florida for about a month before his death.

Mr. Cunningham became a member of the A.S.M.E. in 1899. He also belonged to the Algonquin and the Exchange Clubs in Charlestown, and the University Club, Boston, and was a 32d degree member of the Masonic fraternity and a member of the Episcopal Church. He was a director of the Fourth Atlantic Bank, Charlestown, for 15 years, a director of the Atlantic Works, East Boston, and for a number of years a trustee of the Rotch Infant Hospital, Brookline. He was also a member of the executive board of trustees of Tufts College, and received the degree of Master of Arts from that institution in 1905.

Surviving Mr. Cunningham is his widow, Florence (Clapp) Cunningham, whom he married in 1923. His first wife, Lilla (Sargent) Cunningham, died in 1920.

DALLAS WILLIAM DALE (1899–1932)

Dallas William Dale, whose death occurred on November 16, 1932, was born at Toledo, Ohio, on March 19, 1899, the son of Elmer E. and Emma (Strite) Dale. He attended the East High School, Minneapolis, Minn., and during the year after his graduation worked as draftsman on sawmill machinery and gas engines for the Diamond Iron Works, Minneapolis, designer and assistant master mechanic for the Waldorf Paper Products Company, St. Paul, Minn., on special paper box machinery, and designer of tools and fixtures for machining shells for the Munition Plant of the Twin City Forge & Foundry Co., Stillwater, Minn.

After two months in the army he entered the University of Minnesota, in December, 1918, and was graduated in 1924 with a B.S. degree in mechanical engineering. During his vacations he worked for the Diamond Iron Works, and in the Bridge and Building Department of the Milwaukee, St. Paul & S. Ste. Marie Ry.

For two years after he completed his college work he was employed successively as a designer for the National Supply Company and Merrell Manufacturing Company in Toledo and the Cadillac Motor Car Company, Detroit. Since 1927 he had been structural engineer for the City of Detroit.

In addition to the design work which he performed for the companies by which he was employed, Mr. Dale had assisted in the design of the Strite automatic toaster and had worked on a machine for converting flax straw into linen, one for creasing shipping containers, and another for applying paraffin to butter cartons.

Mr. Dale became a junior member of the A.S.M.E. in 1925 and also belonged to the Masonic fraternity and the Lutheran Church. He is survived by his widow, Esther (Hendrickson) Dale, whom he married in 1925.

WILLIAM POSTAN DALLETT (1860–1933)

William Postan Dallett, president and general manager of the W. P. Dallett Co., Philadelphia, Pa., dealers in pumps and other hydraulic machinery and contractors for waterworks, filtration, and sewage-disposal plants, died on March 31, 1933.

Mr. Dallett was born near West Chester, Pa., on December 3, 1860, the son of William H. and Anne Maria (Cooper) Dallett. After attending public schools near his home until he was thirteen he spent six months at the Friends Central Grammar School in Philadelphia and four years at the state normal school at West Chester. He then entered the Worcester Polytechnic Institute, from which he was graduated in 1881 with a B.S. degree in mechanical engineering. He was secretary of his class, in which he ranked third, and served in that capacity for many years. At the fiftieth reunion he represented the class as its president. He served two three-year terms as vice-president of the W.P.I. Alumni Association, and in 1920 was elected a trustee of the Institute. He was re-elected in 1922 and served until 1927. He was also one of the charter members and an early president of the Worcester Tech Club of Philadelphia.

Shortly after his graduation Mr. Dallett engaged in tool and experimental work in the drafting room and shops of Wm. Sellers & Co., Philadelphia. He was there until 1883, and again in 1889 as foreman of the erecting shop. From 1883 to 1889 he was a member of his uncle's firm, Thomas H. Dallett & Co., of Philadelphia, manufacturers of machine tools, dynamos, and motors, and from 1890 to 1893 was manager of the Philadelphia office of the Deane Steam Pump Company. In 1890 he also began to conduct business under his own name, and when the company was incorporated in 1918 he became its president and general manager. Mr. Dallett held a patent for an automatic relief valve for pumps.

Mr. Dallett became a member of the A.S.M.E. in 1888. He was an active member of the Engineers' Club of Philadelphia for more than forty years, serving as director, vice-president, and president. He was also a member of the Pennsylvania Water Works Operators Association, Philadelphia Academy of Fine Arts, the University Club, Army Ordnance Association, and the Masonic fraternity. He was active in the civic affairs of Media, Pa., where he made his home, and served as president of the Media Club.

Surviving Mr. Dallett are his widow, Rebecca R. (Thurber) Dallett, whom he married in 1886, and three daughters, Mildred, Dorothea, and Jean Dallett.

AUGUST DEMANGEON (1863–1932)

August Demangeon, whose death occurred at Portland, Oregon, on September 19, 1932, was born in San Francisco, Calif., on August 23, 1863. After leaving high school he served an apprenticeship as machinist, steam engineer, and mechanical draftsman and also studied drafting and mathematics in night school, in San Francisco. In 1886 he became machinist and steam engineer for the Tacoma (Wash.) Mill Company, where he remained for about a year.

From 1887 to 1903 Mr. Demangeon was identified with two of the largest lumber mills in the Pacific Northwest. He was mechanical superintendent during the first year for the Port Discovery (Wash.) Mill Company and then was employed in the same capacity by the Tacoma Mill Company. In 1908 and 1909 he was general superintendent for the C. A. Smith Lumber & Manufacturing Co., of Marshfield, Ore., the largest lumber manufacturing plant in that part of the country. In all three positions he had full charge of construction, operation, and repairs of buildings and machinery and designed and directed the installation and operation of many mechanical devices and machines for manufacturing lumber.

For four years beginning in 1903 and from 1911 to 1926 Mr. Demangeon was sales engineer for the Allis-Chalmers Manufacturing Company, of Milwaukee, Wis., during the latter period having his headquarters at Portland, Ore. About half of his time was spent in actual sales work and the remainder in designing lumber plants and also equipment and steam and electric power plants for them.

After leaving the Allis-Chalmers company he was connected for several years with the Chas. R. McCormick Lumber Co., being located at St. Helens, Ore., and at Port Ludlow and Port Gamble, Wash.

Mr. Demangeon became a member of the A.S.M.E. in 1925. He is survived by his widow, Ella (Wright) Demangeon, whom he married in 1904.

JOHN OVIATT DEWOLF (1870–1932)

John Oviatt DeWolf, who died of peritonitis on November 17, 1932, was born at Greenfield, Mass., on May 10, 1870, the son of Austin and Frances Orphelia (Oviatt) DeWolf. He prepared for college at the Greenfield High School and at the age of 20 was graduated with an S.B. degree from the Massachusetts Institute of Technology. During the next two years he was assistant instructor there to Professor Peabody in marine engineering.

From 1892 to 1899 Mr. DeWolf was mechanical engineer and assistant superintendent for the Boston Woven Hose & Rubber Co., Cambridgeport, Mass., and was associated with them as consulting engineer until his death.

In 1899 he took charge of the Boston office of W. B. Smith Whaley Company, later becoming a member of the firm. During that time he designed cotton mills in New Bedford and South Carolina. In 1906 the partnership was dissolved and from that time Mr. DeWolf conducted a general consulting engineering practice under the name of John O. DeWolf & Co., with offices in Boston.

During the World War, in addition to his regular practice, he was engineer and mill architect for the Simonds Saw & Steel Co., Fitchburg, Mass., which had plants in different parts of the country, and also for the Cape Ann Tool Company, Rockport, Mass. He continued to serve both these companies as consulting engineer until his death.

Mr. DeWolf became a member of the A.S.M.E. in 1901. He also belonged to the Boston Society of Civil Engineers, Engineering Societies of Boston, Inc., Massachusetts Society of Mayflower Descendants, Massachusetts Chapter, Sons of the American Revolution, Masonic fraternity, Boston Art Club, University Club of Boston, Boston Engineers Club, Technology Club of New York, Fay Club, Fitchburg, Mass., and Tuscarora Club, Lockport, N.Y. He was a member of the Episcopal Church.

Mr. DeWolf was always deeply interested in the Massachusetts Institute of Technology. He was a member of the Alumni Council, representing the Class of 1890 and of the Faculty Club, and frequently lectured before the classes in mechanical engineering.

Mr. DeWolf made several collections of antiques. He added to pieces of old pewter which he had inherited, built up a collection of firearms showing the evolution of mechanical devices, collected old colonial lamps and antique oriental lanterns and wired them for use in his home, and acquired antique brass and copper and ancient coins. He liked working in wood and metals, was an expert photographer, and held a patent for a method of making metallic printing plates.

Mrs. Anna Sprague (Frothingham) DeWolf, whom he married in 1901, survives him.

WILLIAM JOHN MARSHALL DOBSON (1847–1932)

William John Marshall Dobson, a member of the A.S.M.E. since 1881, died at the home of his sister-in-law, Mrs. J. Harding Price, in West Bridgewater, Mass., on April 28, 1932.

Mr. Dobson was born in England on April 23, 1847, and attended school there. His parents were William John Marshall Dobson and Frances Ann (Smallcorn) Dobson. After coming to the United States Mr. Dobson was for ten years (1876–1886) associated with McKesson & Robbins, wholesale druggists and manufacturing chemists, New York, N.Y., for whom he designed and erected an extensive chemical plant and served as superintendent of all chemical appliances.

During the remainder of his life he engaged in consulting work, chiefly in New York and Brooklyn, preparing plans and specifications for factory buildings and power plants and supervising construction and installation. He specialized in ice-making machinery, glue, paint, and enamel factories, chemical works, and wall paper mills. Among the many companies by whom he was employed were the American Druggists Syndicate, Inc., De La Vergne Machine Company, ice-making machinery, and G. W. Koch & Son, Inc., parquet flooring, all of New York, the Standard Wall Paper Company, Hudson Falls, N.Y., and J. H. White Manufacturing Co., brass founders, Brooklyn. He made a number of inventions, among them an auger guide, a belt tension indicator, and a drying system for wall paper and skins.

Mr. Dobson married Sarah Jane MacDonald in 1875 and is survived by her and by a son, William S. Dobson, of Red Lodge, Mont., with whom he spent considerable time during the latter years of his life. He was a member of the Episcopal Church.

HERMAN DOCK (1860–1933)

Herman Dock, whose death occurred on April 6, 1933, was born on March 29, 1860, in Philadelphia, Pa. He had four years' experience in mechanical drafting and seven years' in machine shop, and was associated for about five years with a leading British engineer. He then became a director in the Schlichter Jute Cordage Company of Philadelphia, with which he remained until 1892. He next established a Philadelphia office for mechanical and experimental engineer-

ing and continued in that work until 1907, the latter part of the time at Wyncote, Pa.

From 1907 to 1910 Mr. Dock was chief engineer for the Nichols & Langworthy Machine Co., New York, and the Safety Steam Power Company, Hope Valley, R.I. He then located at Westerly, R.I., where he was mechanical engineer for the U.S. Motor Co. until 1917. During the next two years he was connected with the American Rotary Power Company, in Boston, as chief engineer. He returned to Philadelphia in 1919 and the following year went to New York. Since 1925 he had resided at Guadalajara, Jalisco, Mexico.

Mr. Dock became a member of the A.S.M.E. in 1889. He also belonged to The Society of Naval Architects and Marine Engineers.

JOSEPH FABIUS DORFNER (1887–1933)

Joseph Fabius Dorfner was born at Cracow, Poland, on July 1, 1887, of Austrian parentage. After completing his high school work he entered the Polytechnic University at Vienna, from which he received his M.E. degree in 1912, after four years of practical experience at the Daimler Works, and for the Wiener Neu Stadt and Vienna Municipal Railway. He then came to the United States and was employed for two years in efficiency work and the design department of the Eiseman Magneto Company, Brooklyn, N.Y. From 1914 to 1919 he was engaged in similar work as shop foreman for the American Machine & Foundry Co., Brooklyn. During the next two years he was professor of machine design and mechanical drafting at the Newark (N.J.) Technical School. He then became associated with C. B. Comstock, engineer and architect, New York, in the design and supervision of power plants and mechanical bakery equipment for the Ward Baking Company at Ampere, N.J., and other plants in Cleveland and Youngstown, Ohio.

In 1923 Mr. Dorfner accepted the position of assistant engineer with the Electric Bond & Share Co., New York, with which he remained two years, designing steam electric stations in Houston, Texas, Memphis, Tenn., and Miami, Fla. For a short time after that he was appraisal engineer for the Murrie Company, New York, and then he established his own office in New York as a consulting engineer for steam and electric power plants. Among the companies which he served were the New York Edison Company and the Philadelphia Electric Company. Ill health made it necessary for him to give up active work several years prior to his death, which occurred at Nashville, Tenn., on January 8, 1933. He is survived by his widow, Mildred (Allen) Dorfner, whom he married in 1920.

Mr. Dorfner became a member of the A.S.M.E. in 1925. He also belonged to the Brooklyn Engineers' Club.

WYLLYS EDMUND DOWD, JR. (1878–1933)

Wyllys Edmund Dowd, Jr., vice-president and director of the Foster Wheeler Corporation, New York, N.Y., died on August 14, 1933, at his home in Greenwich, Conn.

Mr. Dowd was born in New York on October 13, 1878, the son of Wyllys E. and F. Isabel (Chesebrough) Dowd. He was graduated from the Sheffield Scientific School of Yale University in 1900 with the degree of Bachelor of Philosophy in the Department of Mechanical Engineering.

After his graduation Mr. Dowd joined the staff of the chief engineer of the Manhattan Elevated Railway Company, with which he was connected until the middle of 1902. He was then employed as mechanical engineer for the East Jersey Pipe Company, of Paterson, N.J., for whom he was in charge in 1903 of the erection of a complete plant where lock bar pipe was first fabricated in this country. In 1903–1905 he held various engineering positions with the Crane Company in Chicago and in Bridgeport, Conn., becoming assistant to the general superintendent.

In 1906 Mr. Dowd became associated with the Power Specialty Company of New York as manager of the Philadelphia office. He later became a director and secretary of the company. In 1927 the Power Specialty Company and other interests combined to form the Foster Wheeler Corporation, and Mr. Dowd became a director and a vice-president of the new corporation.

During the World War Mr. Dowd was captain of engineers.

Mr. Dowd became a member of the A.S.M.E. in 1911 and also belonged to the Society of Naval Architects and Marine Engineers, the Society for the Promotion of Engineering Education, and a number of clubs, including the Union Club, Down Town Association, and Racquet and Tennis Club. He was president of the Yale Engineering Association and the Round Hill Club Stables Company, secretary of the Woodstock Hotel Company of New York, and a director of the Greenwich Riding Association. He was a supporting member of the American Museum of Natural History, Metropolitan Museum of Art, New York Zoological Society, and New York Botanical Gardens.

In 1920 Mr. Dowd married Mrs. Anna Clement Knowles, daughter of a former governor of Vermont, Percival W. Clement. Mr. Dowd is survived by her and by two children, Clement and Nancy Chesebrough Dowd.

PAUL ANDREW DRATZ (1877–1932)

Paul Andrew Dratz, who died at Geneva, Ill., on October 26, 1932, following an abdominal operation, was born at Muskegon, Mich., on August 26, 1877, the son of John Adam and Johanna Christine (Haisch) Dratz. He prepared for college at the Muskegon High School. After receiving a B.S. degree in mechanical engineering from the University of Michigan in 1900 he was in charge of electrical construction work for the J. A. Erner Construction Co., Columbus, Ohio. The following year he began an association with the Whiting Foundry Equipment Company, Harvey, Ill., which continued until 1918. He was successively draftsman, inspection and erection engineer, estimator and salesman, and Chicago representative, in the latter position handling both consulting and sales work.

Since 1918 Mr. Dratz had been a partner in the firm of Clement A. Hardy & Co., Chicago, consulting and construction engineers and specialists in foundry engineering, and since 1925 he had also been connected with H. M. Byllesby & Co., Chicago, Ill. From 1921 to 1925 he was a director of the First National Bank of Harvey, Ill.

Mr. Dratz became a member of the A.S.M.E. in 1918 and also belonged to the Illinois Athletic Club, Glen Oak Country Club, Elks, and the Masonic fraternity. He is survived by his widow, Grace M. (Lyon) Dratz, whom he married in 1923.

CHARLES REGINALD ELAM (1881–1933)

Charles Reginald Elam was born at South Hill, Va., on January 31, 1881, the son of Thomas David and Linia (Ogburn) Elam. He attended the Chase City Academy for two years and the Virginia Polytechnic Institute for a year. From 1900 to 1905 he was chief draftsman and machinist in the engineer's office of the Norfolk Division of the Southern Railway Company. He then carried on machine shop work in his own name for five years. In 1910 he became vice-president of the Thomas Hardware Company, Suffolk, Va., and until 1915 was engaged in designing and supervising the construction of industrial and power plant equipment. He severed that connection to take a similar office with the Virginia Machinery & Well Co., in Richmond, directing the design and installation of water works and power plant equipment. In 1924 he became mechanical and sales engineer for the Virginia Engineering Company, Richmond. At the time of his death on February 25, 1933, he was in business for himself under the firm name of Chas. R. Elam, Engineer, specializing in power plant and water supply equipment. He was also Richmond representative of the Pardee Engineering Company, The Anthony Company, Maris Bros., Inc., Anderson Engine & Foundry Co., Schutte & Koerting Co., Goulds Pumps, Inc., Westco Pump Corporation, and Waterous Company.

Mr. Elam became an associate member of the A.S.M.E. in 1923. He is survived by his widow, Ella (Ogburn) Elam, whom he married in 1920, and by two children, Charles R. Elam, Jr., and Frances H. Elam.

ADOLPHE ST. ARMANT FAIRBANKS (1878–1932)

Adolphe St. Armant Fairbanks, whose death occurred on August 15, 1932, at Portland, Ore., where he had been located for several years, was born in Cleveland, Ohio, on March 18, 1878. His education was secured in the public schools of Brooklyn, N.Y., and at Pratt Institute, from which he was graduated in 1896 after three years of engineering studies.

For about a year after his graduation Mr. Fairbanks worked as an assistant in a chemical laboratory in New York. He then took a position with the Lawrentide Pulp Company as assistant superintendent of the construction of a paper mill at Grand Mère, Quebec, and a considerable part of his work from then on had to do with the design and construction of paper and pulp mills. Among the companies in this field for which he worked were the Central Paper Company, Muskegon, Mich., Union Bag & Paper Co. and Paper Products Company, Chicago, Ill., Sturgeon Falls Pulp Company, Ontario, Canada, West Virginia Pulp Products Company, Covington, Va., Paper Products Company, Baltimore, Md., Hawley Pulp & Paper Co., Oregon City, Ore., and Ranier Pulp & Paper Co., Shelton, Wash.

Mr. Fairbanks also specialized in the design and construction of steam and hydroelectric power plants, particularly during recent

years. In 1929 and 1930 he worked with the chief engineer of the Pacific Power & Light Co. on the design of a hydroelectric plant for Joseph, Ore., assisted in the design of a 35,000-kw addition to the steam generating plant of the Portland Electric Power Company, directed the design of a 6,000-kw stand-by plant for the City of Eugene, Ore., and served on the Eugene Water Board, supervising the construction and operation of a municipal steam plant. Earlier he had designed additional equipment for a municipal steam power plant for the village of Hinsdale, Ill., designed and built a central station for the Southern Illinois Light & Power Co. at Collinsville, Ill., and assisted in power plant design for Westinghouse, Church, Kerr & Co., New York, N.Y.

Among other public utility projects, Mr. Fairbanks was assistant engineer for a street lighting development for Oak Park, Ill., made appraisals for the Oregon-Washington Water Service Company, Portland, and designed and built a water pumping, softening, and filtration plant and an ice plant for Hinsdale, Ill.

Mr. Fairbanks was interested for a time in the Yaquina Fibre Company in Portland, made studies for a large insulating board mill there, and prepared designs for the Fir-Tex Insulating Board Company at St. Helens, Ore.

As a consulting engineer he served many other companies in the fields in which he specialized.

In 1915 and 1916 Mr. Fairbanks was engaged in the design and construction of two smokeless powder plants, one for the Union Powder Corporation at Parlin, N.J., and the other for the Western Cartridge Company at Springfield, Ill. He entered the Officer's Training Camp at Fort Sheridan in May, 1917, secured a commission as a captain in the Engineers Officers Reserve Corps, and served a year in France. Upon his return to the United States he took an examination for the regular army and was made a captain in the Corps of Engineers. He was sent to Ellington Field, Texas, to construct a storm drainage system, after which he was stationed for a year at New Orleans, working on coast defenses and other engineering assignments. He was then transferred to Camp Pike, Ark., as adjutant in the 6th Regiment of Engineers, and subsequently spent two years at Fort Lewis, Wash., and one year at the Army Engineers School, after which he was transferred to the Coast Artillery Corps. He resigned from the army in December, 1924.

Mr. Fairbanks was elected to junior membership in the A.S.M.E. in 1899. Five years later he was advanced to the grade of associate. He dropped his membership in 1911, but joined again, in 1930, as a member in full.

Mr. Fairbanks is survived by his widow, Edith M. Fairbanks, and by three children, John and Pauline Fairbanks, of Portland, and Charles M. Fairbanks, New York.

ARTHUR FALKENAU (1856–1933)

Arthur Falkenau, who died at Stamford, Conn., on June 10, 1933, was born in New York, N.Y., on April 13, 1856, the son of Moritz and Theresa (Bruckman) Falkenau. He attended the College of the City of New York from 1870 to 1872 and during the next three years served an apprenticeship as a machinist at the DeLamater Iron Works and attended Cooper Institute. He then went to Cornell University, from which he was graduated with a B.M.E. degree in 1878; he secured his M.E. degree there in 1898.

After his graduation in 1878 Mr. Falkenau spent two years in drafting work for the Brooklyn Elevated Railway, New York, and Wilson Bros. & Co., Wm. Sellers & Co., and I. P. Morris Co., Philadelphia, Pa. In 1880 he opened an office at Leadville, Colo., for consulting mining engineering. The following year he established a machine shop and foundry which he operated until 1884, when poor health forced him to lease the works and leave Leadville. In 1885 he took a position as assistant engineer with the Dickson Manufacturing Company, Scranton, Pa., soon being made chief engineer. He did not remain in Scranton long, however, but in 1887 went to Philadelphia, where he established an office and shop as mechanical engineer and manufacturer of machinery. He continued in this work until 1902, from 1896 to 1899 also being president of the Falkenau Engineering Company, electrical contractors.

In 1902 Mr. Falkenau helped to establish the Falkenau-Sinclair Machine Company, in Philadelphia, and served as its president until the company was dissolved five years later. After engaging in industrial consulting engineering for a short time, and serving as secretary and treasurer of the Reliance Steel Foundry Company at Delawanna, N.J., for several years, he became vice-president, in 1910, of the Hooper-Falkenau Engineering Company, industrial engineers, New York. He continued in this office until his retirement in 1920.

The first pneumatic postal system in the United States was built under the direction of Mr. Falkenau, and described by him in an article published in the Journal of the Engineers Club of Philadelphia in 1895. He designed and manufactured mine exploring apparatus, the forerunner of the modern gas mask, in 1880. Among other important works he designed and built an 800,000-lb chain testing machine for the Boston Navy Yard. He served in the Tank and Tractor Section of the U.S. Ordnance Department in 1918 and 1919.

Mr. Falkenau became a member of the A.S.M.E. in 1886. He was a member of the Committee on Science and Arts of The Franklin Institute; served as president of the Engineers Club of Philadelphia in 1895 and of the Metal Manufacturers Association in 1904; was a councilor of the National Metal Trades Association; and belonged to the American Society for Testing Materials, the American Geographic Society, and Tau Beta Pi fraternity. He was a former member of the Manufacturers, Aronamink Golf and City Clubs of Philadelphia, and the Machinery Club, New York.

Since his retirement from business Mr. Falkenau had resided in New York, Katonah, and Pelham, N.Y., and Stamford, Conn. He was a violinist and student of botany, particularly the wild flowers of New England and Middle Atlantic states. His wife, Emily T. (Eidlitz) Falkenau, died in 1927. He is survived by his son, Robert M. Falkenau, of New Rochelle, N.Y.

FRED WILLIAM FISCHER (1886–1932)

Fred William Fischer, general manager of the Fischer Machinery Company, Knoxville, Tenn., died on September 7, 1932, of carbon monoxide gas poisoning, being overcome while working on his automobile.

Mr. Fischer was born in Knoxville on April 7, 1886, the son of Barbara Ursula Fischer and William Victor Fischer. After completing his high-school education he served a five-year apprenticeship in the mechanical department of the United States Navy, at Washington, D.C., receiving honorable discharge in 1907. He married Miss Hazel Adell Levy in 1908, during which year he was sales and erecting engineer for the Keystone Lubricating Company, Philadelphia. In 1909 he was lubricating engineer for the Tennessee Oil Company, Knoxville. During the next two years he was in charge of maintenance work for the Evans Marble Company, Knoxville, in the capacity of assistant chief engineer and master mechanic. While in that position he took courses in steam-electrical engineering through the International Correspondence Schools and subsequently studied power plant economy at the University of Tennessee.

From 1911 to 1918 he was chief engineer and master mechanic for the Standard Knitting Mills, Knoxville, supervising the operation of power plants and mechanical equipment and the design and erection of all plant machinery. He also did considerable consulting work along combustion lines. In 1919 and 1920 he was in Jacksonville, Tenn., part of the time serving as boiler plant supervisor for the Du Pont Engineering Company and later as chief engineer of the Old Hickory Powder Plant. From there he went to Denver, Colo., on consulting work, becoming owner there of a metropolitan garage.

In 1924 Mr. Fischer became president and general manager of the Tennessee Tool Works, Knoxville, with which he remained for four years. He was next general superintendent for the W. J. Savage Co., Knoxville, and general superintendent of the Sterling Wood Products Company, Knoxville. After engaging in patent development work for some time, he became president and general manager of the Fischer Machinery Company, the position he held at the time of his death.

Mr. Fischer became a member of the A.S.M.E. in 1918. He was also a Shriner, 32d degree, a member of the St. John's Lutheran Church, and member of several other engineering societies.

He is survived by his children, Fred W. Fischer, Jr., Shirley Mae Fischer, and Alva Louis Fischer, and by his father, three brothers, and four sisters.

JOSEPH (JACK) EMERSON FOSTER (1898–1932)

Joseph (Jack) Emerson Foster was born on September 4, 1898, at Slater, Mo., the son of Jasper Peter and Harriet Foster. After completing his high school education he studied for a time at the University of Illinois. He enlisted in the Air Corps during the World War and afterward spent several years as a mechanical engineer in sales and design work for different companies, including the K. C. Oxygen Gas Co. and Hugh L. Thompson Engineering Co., Kansas City, Mo., Wharton Motors, Dallas, Tex., and National Steam Automotive Company, St. Louis, Mo. From 1928 to 1930 he was chief engineer for the American Eagle Aircraft Corporation, Kansas City, and subsequently held that position with the Cross-Foster Aircraft Company, Kansas City. He patented the wing and fuselage construction of the Cross-Foster all-metal airplane.

During the latter part of 1931 and early 1932 Mr. Foster was with

the Foster Aircraft Company, Alliance, Ohio, and from the first of March until his death on May 18, 1932, at Saginaw, Mich., as the result of an automobile accident, was engineer for the Dow Chemical Company, Midland, Mich., working on an engineering handbook on the use of Dow metal for aircraft.

Mr. Foster became an associate member of the A.S.M.E. in 1929. He also belonged to the Society of Automotive Engineers. He was affiliated with the Baptist Church. He is survived by his widow, Thelma (Shaw) Foster, whom he married in 1930, and by one child, Lee Mast Foster.

A. WARREN FRANCE (1868–1933)

A. Warren France, president of The France Packing Company, Philadelphia, Pa., died at his home in that city on March 8, 1933, after being in ill health for more than a year. Mr. France, who held a number of patents in the United States and abroad on piston rod packing, especially metallic packing, founded the company in 1898. From 1905 to 1912 he also owned and operated a 200-ton absorption ice plant and a 70-ton compression plant at Atlantic City, N.J.

Mr. France was born in Philadelphia on March 3, 1868. After leaving school he spent four years at sea as an oiler, water tender, and engineer, and from 1888 to 1891 was engaged in construction work with the Union Iron Works, San Francisco, and E. Pallis Co., Milwaukee. He next went to Fitchburg, Mass., where he was erecting engineer for the Fitchburg Steam Engine Company for three years. For an equal period, prior to the establishment of his own company, he was chief engineer of the Suburban Electric Company, Philadelphia.

Mr. France became a member of the A.S.M.E. in 1921.

J. PORTER FREEMAN (1865–1933)

J. Porter Freeman, who died at his home in Yonkers, N.Y., on May 26, 1933, was born on June 8, 1865, at Lancaster, Mass., the son of Joshua and Jane (Wellington) Freeman. He attended school at Lancaster and Worcester, Mass., and served an apprenticeship with the Bigelow Carpet Company, Clinton, Mass. He rose to the position of chief engineer of this company, with which he was connected until 1893. He then went to Yonkers as consulting and construction engineer for Alexander Smith & Sons Carpet Co., and had held that position continuously until his retirement at the beginning of 1933.

Mr. Freeman became a member of the A.S.M.E. in 1908 and was a very active member of the Masonic fraternity. He was fond of music and was organist for the Clinton Lodge of Odd Fellows for a number of years. He had served as a member of the Board of Education of the Saunders Trade School at Yonkers.

Surviving Mr. Freeman are his widow, Ethel (Hatfield) Freeman, whom he married in 1899, and a son, John Porter Freeman.

ROSS LAUDER FRYER (1881–1933)

Ross Lauder Fryer, consulting engineer, Washington, D.C., died on January 3, 1933. Mr. Fryer had been a member of the A.S.M.E. since 1918 and also belonged to the American Society of Marine Draftsman, American Society of Naval Engineers, and Washington Society of Engineers.

He was born in New York, N.Y., on April 24, 1881. He served an apprenticeship in the machine shop of the Arrow Steamship Company, Baltimore, Md., attended the Washington Business High School, and studied three years at George Washington University, Washington, D.C. At the age of twenty he secured a position as secretary to the Quartermaster General, U.S. War Department, Washington, and continued in that work until 1906. In 1905 he began the study of naval architecture and marine engineering under private tutorship and the following year became an ensign in the U.S. Naval Militia, District of Columbia, and subsequently worked up through the grades of lieutenant and assistant engineer to the rank of senior engineer officer. He remained in the Militia until 1913. From 1908 to 1915 he was also assistant marine engineer to the Quartermaster General, in responsible charge of the design, construction, and operation of a fleet of Army transports, harbor boats, and lighters. Since 1915 he had practised consulting engineering.

Mr. Fryer was one of the pioneers in applying the Diesel principle of propulsion, and in 1916 took over the representation of the Winton Engine Corporation before the United States Government, which position he held until the time of his death. Through his faith, enthusiasm, and efforts, Diesel engines have been installed and are operating most successfully in the U.S. Coast Guard, Lighthouse Bureau, Engineer Corps of the Army, and other departments of the Government.

CHARLES RALEIGH GABRIEL (1866–1933)

Charles Raleigh Gabriel, consulting and designing engineer for the E. W. Bliss Co., Brooklyn, N.Y., died on February 24, 1933. He had been a member of the A.S.M.E. since 1901.

Mr. Gabriel was born on July 18, 1866, at Seymour, Conn. He attended public school in Bridgeport, Conn., and learned the machinist's and toolmaker's trade at the Bridgeport Brass Company. He worked as a draftsman for W. F. Durfee, of Bridgeport, for about a year and then spent nine months in the employ of the Bridgeport Gun Implement Company, designing and constructing tools.

In January, 1887, Mr. Gabriel began to work for the Union Metallic Cartridge Company, at Bridgeport, constructing automatic machinery and tools. After three years there he spent part of a year in design work for the Baxter Brothers, electricians, Brooklyn, in connection with the manufacture of graphophone motors. From 1890 to 1895 he was connected with the H. L. Judd Co. of New York, designing and supervising the construction of special automatic machinery for brass work.

The Brown & Sharpe Manufacturing Co., Providence, R.I., engaged Mr. Gabriel in 1895 to design special machinery and tools. He remained with that company until the middle of 1901, when he became mechanical expert for the Gorham Manufacturing Company, silversmiths, Providence, for which he designed and supervised the construction of special machinery and tools for the silver business in all its branches and made a study for the improvement of manufacturing methods. He was connected with the Gorham company for two years, and he spent equal periods after that as chief engineer of the Dow Composing Machine Company, New York, and chief draftsman and designer of the Cincinnati Milling Machine Company, Cincinnati. He had been with the Bliss company since 1907.

HENRY DECATUR GORDON (1848–1932)

Henry Decatur Gordon, who died at his home in East Orange, N.J., on October 14, 1932, was a former consulting engineer to Jenkins Bros., manufacturers of Jenkins valves, New York, N.Y. He retired in 1923.

Mr. Gordon was born at Waltham, Mass., on August 20, 1848. His childhood was spent in Rochester, N.Y., and after completing his public school education there he served an apprenticeship as a machinist with the N.Y. Central Railroad, at the same time studying drafting. Subsequently he was employed by the Philadelphia, Washington & Baltimore R.R. and Pennsylvania Railroad, being in charge of the latter's shops at Altoona from 1889 to 1895. His association with the Jenkins firm dated from 1895.

Mr. Gordon became a member of the A.S.M.E. in 1896.

ROBERT STANISLAUS GRIFFIN (1857–1933)

Rear-Admiral Robert Stanislaus Griffin, U.S.N., who retired from service in 1921, died at the Naval Hospital in Washington, D.C., on February 21, 1933. Admiral Griffin's retirement followed a period of eight years as engineer-in-chief of the Navy and chief of the Bureau of Engineering, during which the scope of the Bureau's work was very wide and the amount enormous.

Admiral Griffin was born in Fredericksburg, Va., on September 27, 1857, and received his early education there. He was graduated from the United States Naval Academy, Annapolis, Md., in 1878, one of the five honor men of the class. His first cruises were on the *Alliance* and *Quinnebaug*, in European waters, and the *Tennessee*. He attained the rank of assistant engineer in 1880. From 1885 to 1890 he was on shore duty, with the Naval Advisory Board, Office of Naval Intelligence, and Bureau of Steam Engineering, where he served under George W. Melville, the famous engineer and Arctic explorer.

In 1890 he was returned to sea duty and for two years was on the *Philadelphia*. He next spent a few months as inspector of machinery on the *Bancroft*. From 1893 to 1897 he was again with the Bureau and subsequently on the *Vicksburg*. He was made chief engineer in 1898 and in that capacity served on the *Mayflower* during the Spanish-American War, on blockade duty north of Cuba. His promotion to the rank of lieutenant came in 1899, when the Line and the Engineers were combined. In 1901-1902 he was with the *Illinois*, then he spent a year each on the *Chicago* and *Iowa*. He terminated his service at sea as fleet engineer of the North Atlantic Fleet in 1904-1905. He was promoted to Commander in 1906, Captain in 1910, and Rear-Admiral in 1916.

Admiral Griffin was with the Bureau of Steam Engineering constantly from 1905 until his retirement. He was appointed assistant to Admiral Cone, the chief, in 1908. He was commissioned engineer-in-chief in 1913, and was reappointed in 1917. With other

Bureau chiefs he accompanied Secretary Daniels to Europe in the spring of 1919 to inspect naval materiel and personnel.

For several years after his retirement Admiral Griffin engaged in consulting work in New York with Commander W. L. Cathcart. He was also actively interested in the work of the Navy Relief Association.

In recognition of his achievements during the World War Admiral Griffin was made a Commander of the French Legion of Honor and received the Distinguished Service Medal of the United States. He was elected to honorary membership in the A.S.M.E. in 1920 and held the degrees of Doctor of Science from Columbia University and Doctor of Engineering from the Stevens Institute of Technology. He was a member of the Society of Naval Architects and Marine Engineers and an honorary member and past-president of the American Society of Naval Engineers, of whose Journal he was the first editor.

In the May, 1933, issue of that Journal, pages 207–224, will be found an appreciation of his life and work by Walter M. McFarland, a naval engineer from 1875 to 1899, who succeeded him as editor of the Journal, had been associated with him in the Navy, and was an intimate friend for more than fifty years.

Mr. McFarland has prepared for inclusion in this memorial notice the following paragraphs referring particularly to Admiral Griffin's connection with the Bureau of Engineering.

"Admiral Griffin's eight years as engineer-in-chief of the Navy and chief of the Bureau of Engineering, from 1913 to 1921, covered the period of the World War with the great increase in materiel and the responsibility of maintaining in a state of constant readiness and efficiency the machinery of the greatest Fleet ever possessed by the United States.

"The variety of the Bureau's work was great and the amount immense. A very brief summary is as follows: A great increase in the number of vessels and in the variety of the machinery equipment of the Fleet; the equipment and maintenance abroad of repair ships and repair bases; the construction of destroyers, submarines, subchasers, 'Eagles,' mine-layers, and tugs; the development of the devices for the detection of submarines; the creation of an organization for handling the power of aircraft; the production of helium in commercial quantities and the establishment of numerous stations for the production of hydrogen for lighter-than-air craft; the enlargement of the machinery equipment of the Navy Yards; the maintenance of the large fleet of Naval Overseas Transport Service; and the great extension of radio in shore stations and the Fleet.

"One of the most important features was the repair and rehabilitation of the machinery of the interned German merchant vessels, which had been wrecked by their crews with the idea that it would have to be rebuilt. Investigation led Admiral Griffin to decide to make the repairs by welding, which brought about a saving of a year's time in the work as well as many millions of dollars; and, of much greater importance, it enabled about 600,000 American soldiers to be transported to Europe a year earlier than had been believed possible.

"The repair ships and repair bases abroad were most important in the sustained efficiency of naval vessels and transports, especially of the overworked destroyers.

"During the War, all radio material work afloat and on shore was directed by the Bureau; this meant the maintenance of about 4000 ships and 210 shore stations. The Bureau designed the high-power station at Bordeaux, the most powerful station in the world, which upon completion was turned over to the French government. There was also constructed a station at Vladivostok for communicating with our troops in Siberia. At the Peace Conference after the war, his assistants were in charge of communications. In Central Europe, then in revolution, wherever a Peace Conference commission was sent, with it went his portable sets and men and officers to operate them.

"Under Admiral Griffin's administration, the horsepower of the Fleet increased from 2,000,000 to 10,600,000 for ships actually completed, and from about 400,000 to nearly 2,500,000 for ships under construction. During this time there were added to the Navy, 12 battleships, 295 destroyers, 95 submarines, 60 'Eagles,' 49 auxiliary vessels, and a large number of mine sweepers, tugs, yachts, and subchasers. The adoption of the electric drive for capital ships (battleships and battle cruisers) is an outstanding event in Griffin's régime. The machinery for six battle cruisers was designed under his direction, the most powerful marine installations in the world. Only two of them, the *Saratoga* and the *Lexington*, were completed and had their trials after his retirement. They developed over 200,000 shp each. Another momentous change was the transformation of the Fleet from coal-burning to oil-burning.

"The office of engineer-in-chief of the Navy requires for complete efficiency much more than professional ability: he must also be a great executive and administrator. In this respect, Griffin was ideal. All the officers who served under him testify to his remarkable ability in anticipating and preparing for necessary work, and the ease with which he bore responsibility. When the tremendous burden due to the World War came upon him, it found him ready and efficient. His name will ever be associated with those other great engineering executives also honorary members of our Society, Haswell, Isherwood, and Melville, who were his predecessors as engineer-in-chief of the Navy in troublous times, and like him made history."

HERBERT CARLTON HALE (1874–1933)

Herbert Carlton Hale died at his home in Washington, D.C., on April 16, 1933, after an illness of about five months. He was district sales manager for the Elliott Company, steam power specialties, Washington, D.C. He was located at the district office in Baltimore for four years before it moved to Washington in 1932.

Mr. Hale was born at Huntington, W.Va., on March 15, 1874. He prepared for college at public schools in Akron, Ohio, and the Oberlin, Ohio, Academy. He received a B.S. degree from the Case School of Applied Science in 1896 and won his M.E. three years later. During this period he secured practical experience in the shops of the Arctic Machine Manufacturing Company, Cleveland, and drafting experience with the Automatic Refrigerator Company, Cleveland, and Webster Camp & Lane Co., Akron.

In 1899 he became chief draftsman of the Webster Camp & Lane Co., and he held this position until the company consolidated with the Wellman-Seaver-Morgan Company of Cleveland in 1903. He transferred to Cleveland as a member of the Engine and Mining Department, where he remained for about a year. He then became chief engineer of the Crown Dryer Company, Cleveland, with which he was associated until 1906. During the next few years he was superintendent and general manager of the Mineral Ridge (Ohio) Manufacturing Company and engaged in contracting and designing in Cleveland.

In 1911 Mr. Hale became district manager for the Ridgway Dynamo & Engine Co., Cleveland. He was later made sales engineer and advertising manager for the company, with which he remained until it was taken over by the Elliott Company in 1926.

Mr. Hale became a member of the A.S.M.E. in 1904. He also belonged to the American Institute of Mining and Metallurgical Engineers and was on the executive board of the Alumni Association of the Case School of Applied Science, and a member of the Case Corporation. He is survived by his widow, Fannette L. Hale, two sons, Clarence H. and Gordon M. Hale, and one daughter, Elizabeth (Hale) Lally.

ROBERT CARL HANDLOSER (1875–1933)

Robert Carl Handloser, manager of the Detroit office of The Motch & Merryweather Machinery Co., died on January 3, 1933, at his home in Detroit after a short illness.

Mr. Handloser was born in Trenton, N.J., on October 26, 1875, the son of Thomas Valentine and Louisa (Herrmann) Handloser. After attending the Trenton grade schools and high school in New York, N.Y., he worked for two years as a machinist for R. H. Wolfe & Co., New York. He then entered Stevens Institute of Technology, Hoboken, N.J., from which he was graduated in 1898 with a degree in mechanical engineering.

For a few months following his graduation Mr. Handloser was engaged as a draftsman in the Switchboard Department of the Western Electric Company, New York, then was assistant to the inspector of machine tools for the Garvin Machine Company, New York, for about six months and draftsman and engineer with the Keuffel & Esser Co., Hoboken, for two months.

In May, 1899, Mr. Handloser entered upon a student course in machinery, spending some time with the Brown & Sharpe Manufacturing Co., The Pond Machine Tool Company, The Niles Tool Works Company, and others. Upon the completion of his course he was sent abroad to sell the products of these companies in Austria and Germany and until the middle of 1901 was manager of the Vienna office.

During the next year he represented the Vienna steel firm of the Bohler brothers in England and subsequently returned to the United States, where he worked for a time in his father's machine shop, designing and operating machines, and sold steel for Houghton & Richards, American agents for the Bohler firm.

From May, 1903, to June, 1905, he was in charge of the New York office of the Dilworth Porter & Co., Ltd., of Pittsburgh, Pa. He then spent some time in the plants of the Niles-Bement-Pond Company, after which he again represented those organizations in Germany and Austria for nearly two years.

Mr. Handloser joined the Motch & Merryweather organization in April, 1907, and from then until his death was in charge of the Detroit office. He was also a director of the company.

He became an associate-member of the A.S.M.E. in 1918 and also belonged to the Detroit Athletic Club and the Gowanie (Detroit) Golf Club. He is survived by his widow, Bessie Gertrude (Vorce) Handloser, whom he married in 1904, and by three sons, Robert, Jr., Thomas V., and Willard B. Handloser, all of Detroit.

HARRISON WASHBURN HAYWARD (1873–1932)

Harrison Washburn Hayward, professor of materials of engineering at the Massachusetts Institute of Technology, died at the Institute Infirmary on October 18, 1932, following a heart attack.

Professor Hayward was born at Dorchester, Mass., on January 1, 1873, the son of Edward S. and Emma (Washburn) Hayward. He attended public schools in Hyde Park, Mass., and the Berkeley School, Boston, and was graduated from the Institute in 1896 with an S.B. degree. He had been on the teaching staff of the Institute since his graduation with the exception of a year (1899-1900) as draftsman at the Universal Loom Works, Readville, Mass. He served as an assistant instructor in the chemical engineering department for two years. He then went into the mechanical engineering department, where he became assistant professor of applied mechanics in 1908. In 1912 he was made associate professor of theoretical and applied mechanics, and in 1920 he was advanced to professor of materials of engineering.

Since 1916 Professor Hayward had been in charge of the Testing Materials Laboratory at the Institute, and he had much to do with the development of this line of work. During the World War he rendered valuable service to the Government in connection with materials, and immediately following the war he accepted a commission as Major in the Reserves.

Professor Hayward was the author of a book entitled "Notes on Calculus," used by the students in the Lowell Institute School, in which he had been a teacher since it was founded in 1903, to provide evening instruction in engineering for those obliged to work during the day. He also completely revised "Materials of Construction, Their Manufacture, and Properties," written originally by A. P. Mills.

Professor Hayward was assistant director of the Institute's Division of Industrial Cooperation and Research and had served a number of industrial firms as a consultant on materials. He had been a member of the A.S.M.E. since 1915 and also belonged to the American Society of Civil Engineers, Boston Society of Civil Engineers, American Society for Testing Materials, the American Concrete Institute, the American Society for Steel Testing, and the Society for the Promotion of Engineering Education. He was a member of Theta Xi fraternity.

Professor Hayward is survived by his widow, Mabel E. (Holmes) Hayward, whom he married in 1902.

EDWIN MUSSER HERR (1860–1932)

Edwin Musser Herr, who for 18 years was president of the Westinghouse Electric and Manufacturing Company, died on December 24, 1932, at his home in New York, N.Y. Because of failing health Mr. Herr relinquished the presidency of the company in June, 1929. At the time of his death, he was vice-chairman of the board of directors of the company, and a director of the American Manufacturers' Export Association, Radio Corporation of America, and Westinghouse Air Brake Company. He had also held office as president of the Westinghouse Lamp Company and as vice-president of the Bryant Electric Company of Bridgeport, Conn., and the R. D. Nuttall Company of Pittsburgh, Pa.

Mr. Herr was born on May 3, 1860, in Lancaster, Pa., the son of Theodore Witmer and Annie (Musser) Herr. When he was twelve years old the family moved to Denver and he began working as a messenger for the Western Union Telegraph Company during summer vacations. Before completing his high school course he had learned to be an operator and after leaving school was operator and station agent for the Kansas Pacific Railway at Deer Trail, Colo. He continued his studies, while employed and after a course at the Boston Latin School he was able to enter Sheffield Scientific School of Yale University in 1881. He helped to pay his expenses by tutoring and was graduated with a Ph.B. degree in 1884.

During vacations, he worked as an apprentice in the Pennsylvania Railroad shops at Altoona, Pa., and after graduation in railroad shops of the Chicago, Milwaukee & St. Paul Ry. in Chicago until offered a job as a draftsman for the Chicago, Burlington & Quincy R.R. at Aurora, Ill. Subsequently he was made engineer of tests, superintendent of telegraphy, and at the age of twenty-nine division superintendent. In 1891 he became division master mechanic of the Chicago, Milwaukee & St. Paul Ry. and in 1892 and 1893 was general superintendent of the Grant Locomotive Works in Chicago. He then took a position as general manager of the Gibbs Electric Company, of Milwaukee, but this company failing soon afterward, he decided to visit Europe and study railroad practice there. He returned in 1895 as assistant superintendent of motive power for the Chicago & Northwestern Ry. A year later he became superintendent of motive power for the Northern Pacific Railway.

In 1898, George Westinghouse, whom Mr. Herr had met twelve years before while conducting a series of air-brake tests on the Burlington Railroad before the Master Car Builders' Association, offered him the position of assistant general manager of the Westinghouse Air Brake Company at Wilmerding, Pa. He became general manager a year later.

In 1905 Mr. Herr was elected first vice-president of the Westinghouse Electric and Manufacturing Company, to the development of which he devoted the remainder of his life. The company was forced into receivership in 1907, and he was one of the receivers and general manager in charge of reorganization. In 1911 he was elected president.

Mr. Herr was always deeply interested in educational matters and devoted much of his time to developing an educational system for the employees of his company. He was a member of the Yale Corporation for twelve years, retiring in 1932. A resolution adopted by the Corporation upon his retirement recorded his services to the University as follows:

"Before coming to the Corporation Mr. Herr had already served the University in many ways, chiefly as first president of the Yale Engineering Association and member of the Alumni Committee on Plan for University Development. He brought to these councils broad experience gained in engineering and in the management of large enterprises in transportation and industry. His advice has been sought constantly, not only in the development of the Sheffield Scientific School, but in all of the University's manifold work. He was a member of the Prudential Committee for seven years, the Committee on Educational Policy for five years, its chairman for 1922-1923. He has been a member of the Committee on Architectural Plan since 1929, of the Committee on Buildings and Grounds since 1925, and its chairman in 1928-1929 and 1931-1932. Above all he has kept a lively interest in young men and especially in those students who support themselves, for their problems were his own in his undergraduate days."

As chairman of the Building Committee of the Yale Corporation Mr. Herr laid the cornerstone of the Sterling Memorial Library. He had served on the advisory board of the *Yale Scientific Magazine*, and he was a contributor to the Fourteenth Edition of the Encyclopaedia Britannica.

Franklin and Marshall College conferred an honorary D.Sc. degree upon Mr. Herr in 1911, and four years later Yale University gave him an honorary M.A. degree. In 1920 he was decorated by the Emperor of Japan with the Order of the Rising Sun in recognition of his interest in training Japanese students at the Westinghouse works and of the company's effective aid in the electrical development of Japan. In 1924 he was chairman of an American Industrial Mission to Mexico.

He was also greatly interested in the graphic arts and had one of the finest collections of Cameron etchings in the United States.

Mr. Herr became a member of the A.S.M.E. in 1891 and served as vice-president for the term 1910–1912. He had also served as president of the American Manufacturers' Export Association and was a member of the American Institute of Electrical Engineers, The Franklin Institute, Pan-American Union, National Industrial Conference Board, American Committee of the International Chamber of Commerce, Historical Society of Pennsylvania, and the Board of the Carnegie Institute of Technology. His clubs included the Chicago Club, the Bankers', Engineers', and University clubs in New York, the Englewood (N.J.) Golf Club, the Congressional Country Club of Washington, and the Duquesne and University clubs at Pittsburgh.

He is survived by his widow, Mrs. Mary (Forsyth) Herr, whom he married in 1900, a sister, Mrs. J. W. Clise, of Altadena, Los Angeles, Calif., and two brothers, Arthur T., Denver, and Herbert T., Philadelphia, Pa.

LOUIS C. HIRSHHEIMER (1879–1933)

Louis C. Hirshheimer, president of L. C. Hirshheimer, Inc., manufacturers of gray iron castings, La Crosse, Wis., since its formation in 1926, died on June 29, 1933. Mr. Hirshheimer was born in La Crosse on March 27, 1879. He attended the University of Wisconsin for two years and Cornell University for a year.

Mr. Hirshheimer was put in charge of the foundry of the La Crosse

Plow Company in 1901, designed and built a new foundry in 1915, and for many years had charge of the power plant and also the purchase and installation of machinery for the company and served as its secretary. He also designed and erected an electric brass foundry for the General American Tank Car Corporation in 1918, and a gray iron foundry for the same company the following year.

Mr. Hirshheimer became a member of the A.S.M.E. in 1921 and was active in the Masonic fraternity.

IRA GOULD HOAGLAND (1877–1933)

Ira Gould Hoagland, secretary and treasurer of the National Automatic Sprinkler Association since he helped found it in 1914, died suddenly at his home in Brooklyn, N.Y. on August 5, 1933.

Mr. Hoagland was born in Brooklyn on January 14, 1877, and attended public schools and Pratt Institute in that city. He entered the insurance field in 1896 as a clerk and rose to the position of an inspector. He was the author of a number of articles on insurance in different industries and from 1912 to 1914 was editor of *Insurance Engineering* and its successor, *Safety Engineering*. Since that time he had devoted himself entirely to the work of the National Automatic Sprinkler Association, a liaison agency between the insurance companies and sprinkler manufacturers and between the insurance companies and the public, its purpose being the advancement of safety and the conservation of life and property. As a writer and speaker Mr. Hoagland helped to bring about wider use of sprinklers, thus lowering insurance rates.

Mr. Hoagland became an Associate of the A.S.M.E. in 1914 and also belonged to the American Water Works Association, New England Water Works Association, National Safety Council, National Fire Protection Association, International Association of Fire Engineers, New England Association of Fire Chiefs, Railway Fire Protection Association, Insurance Society of Philadelphia, Insurance Society of New York, American Trade Association Executives, the Holland Society, and the 12 St., Dutch Reformed Church, Brooklyn.

Surviving Mr. Hoagland are his widow, Louise (Evans) Hoagland, a daughter, Mrs. Dorothy Hammond Foster, and a son, Ira G. Hoagland, Jr.

JOHN M. JENCKES (1866–1933)

John M. Jenckes, who died on January 13, 1933, in Sherbrooke, Quebec, Canada, was born in that city, the son of Sylvester B. Jenckes, on February 17, 1866. He was graduated from the Academic course of the Sherbrooke High School in 1884, and during the next four years served an apprenticeship as a machinist under his father. He then went on the road selling machinery for two years. He became secretary, treasurer, and general manager of The Jenckes Machine Company, Limited, Sherbrooke, in July, 1890, and for nearly thirty years supervised the fabrication and erection of hydraulic plants and penstocks contracted for by that company. Among those served were The Ontario Power Company, Niagara Falls, Laurentide Pulp & Paper Co., Grand Mere, and the City of Sherbrooke. Mr. Jenckes was also general manager of the Engineering & Machine Works of Canada, Ltd., St. Catherines, Ontario, for a time, and during recent years had practised as a consulting engineer, with office in Sherbrooke.

Mr. Jenckes became a member of the A.S.M.E. in 1918. For ten years he was a member of the City Council of Sherbrooke, and he had served as chairman of the Protestant School Board and Protestant Hospital there. He was a member of the Congregational Church and St. George's Club in Sherbrooke.

Surviving Mr. Jenckes are his widow, Helen (Brooks) Jenckes, whom he married in 1892, a son, K. B. Jenckes, and two daughters, Mrs. J. K. Wilson and Mrs. W. L. Bones.

DAVID JOHN JENKINS (1888–1933)

David John Jenkins was born at Angus, Iowa, on November 20, 1888, the son of Samuel and Elizabeth (Woosnum) Jenkins. He secured his early education at the Cazenovia (N.Y.) Seminary and subsequently attended Syracuse University. He was graduated with an S.B. degree in mechanical engineering from the Massachusetts Institute of Technology in 1911.

Prior to the completion of his college work he had spent several years as a machinist for the Cottonwood Coal Company, Stockett, Mont., and erecting machinery for the Link Belt Company for a coal washer at Stockett. After leaving college he was engaged in similar work for the Jeffrey Company, for a washer at Midland, Ark., and then returned to the employ of the Cottonwood Coal Company, as a mining engineer at Windham, Mont. During the next few years he worked consecutively in fuel testing for the Harrisburgh Southern Coal Company, Chicago, Ill., transitman for the Oregon Short Line Railroad in Idaho and Oregon, and assistant manager of coal mines for the Great Northern Railroad, at Lehigh, Mont.

In 1916 Mr. Jenkins became fuel engineer at the United States Bureau of Mines, Pittsburgh. He enlisted as a private in the 27th Engineers in May, 1918, and served with the A.E.F. during the remainder of the World War, winning promotion and special recognition for his services. He returned to the Bureau of Mines for several years, then was connected with the Dallas Power & Light Co., Dallas, Tex. Since 1924 he had been general engineer for the Westinghouse Electric & Manufacturing Co.; he was transferred from the works at East Pittsburgh, Pa., to the Atlanta, Ga., District in January, 1925. His death occurred on June 23, 1932, at Dover, Ohio.

Mr. Jenkins became an associate-member of the A.S.M.E. in 1919. He also belonged to the National Electric Light Association and to the Atlanta Club and East Lake Country Club, both of Atlanta. He is survived by his widow, Margaret (Baker) Jenkins, of Dover, Ohio, whom he married in 1919.

EDWARD EUGENE JOHNSON (1874–1933)

Edward Eugene Johnson, superintendent of power production for The Tucson Gas Electric Light & Power Co., Tucson, Ariz., died on August 15, 1933.

Mr. Johnson was born on October 1, 1874, at Monticello, Ill., the son of Edwin and Alice Rhoda (Gifford) Johnson. After leaving high school he had about two years' experience as a shipwright apprentice, worked in a machine shop for three years, and from 1896 to 1899 fired locomotive and stationary boilers. From then until 1910 he was chief engineer for the United States Light & Traction Co., Denver, Colo., in charge of the operation of all steam equipment, working in Tucson, Ariz., and Albuquerque, New Mexico. He took a similar position with The Tucson Gas Electric Light & Power Co. in 1910 and became superintendent of power production in 1928. He was considered an authority on the operation and maintenance of Diesel oil engines.

Mr. Johnson became an associate-member of the A.S.M.E. in 1929 and also belonged to the National Association of Stationary Engineers. He is survived by his widow, Pauline Anne (Weber) Johnson, whom he married in 1904, and by three children, Pauline Eugenia, Jeanette Ada, and Alice Louise Johnson.

EDWARD CAMPBELL JONES (1861–1933)

Edward Campbell Jones, vice-president of the A.S.M.E. for the term of 1919–1921, died suddenly of heart failure at his home in Palo Alto, Calif., on July 22, 1933. Mr. Jones became a member of the Society in 1901 and was active in the work of the San Francisco Local Section for many years; he served as chairman of that Section in 1918–1919.

Mr. Jones was born in South Boston, Mass., on February 8, 1861, the son of Edward and Hannah F. (Campbell) Jones. He attended Lowell Institute and the Hawes School of Art. He served an apprenticeship under his father at the South Boston Gas Works and gained shop experience at the South Boston Gas Light Company, between the years 1876 and 1884. He was then made assistant superintendent and secretary of the latter company and put in charge of the reconstruction of the South Boston Works. Five years later he was advanced to the position of superintendent of the North End Station of the Boston Gas Light Company, and in 1890 was made assistant engineer of the company, in charge of manufacturing.

In 1891 the San Francisco Gas Light Company employed Mr. Jones as assistant engineer to construct the North Beach Gas Works. He took charge of the gas department of the San Francisco Gas & Electric Co. in 1899, and when the Edison Light & Power Co. merged with the San Francisco company in 1896, Mr. Jones became engineer of both the gas and electric departments of the San Francisco Gas & Electric Co. He was made chief engineer of the company in 1900.

In 1902 Mr. Jones accepted the position of chief engineer of the California Central Gas & Electric Co., and upon the absorption of that company by the California Gas & Electric Corp. two years later, he became chief engineer of all the plants of the Corporation. In 1906, when the San Francisco Gas & Electric Co. was purchased by the Pacific Gas & Electric Co., he was appointed chief engineer, a position which he held until 1920. Since then he had engaged in consulting gas engineering.

Mr. Jones was the inventor of many valuable improvements in gas manufacture and distribution, particularly in the field of purification and in the development of the oil-gas process. His research work for the betterment of the gas industry and his achievements in

this field won him two medals at the San Francisco Exposition in 1915 and also the gold medal of the Pacific Coast Gas Association. He had charge of the restoration of gas in San Francisco after the earthquake in 1906. He lectured in gas engineering at the University of California in 1913 and served the U.S. Bureau of Standards as advisory gas engineer for a time. He was the author of numerous articles relating to heating and gas.

Mr. Jones was a past-president of the Pacific Coast Gas Association and the American Gas Institute, an honorary member of the New England Association of Gas Engineers, and a member of the American Gas Light Association and the Masonic fraternity.

Surviving Mr. Jones are his widow, Florence C. (Harris) Jones, whom he married in 1926, and three children by a former marriage, Edward S., Leon B., and Dwight W. Jones. Their mother, Mary (Stratton) Jones, died in 1922.

FORREST SAMUEL JONES (1882–1933)

Forrest Samuel Jones, works engineer for many years for Chas. Pfizer & Co., Inc., manufacturing chemists, Brooklyn, N.Y., died at his home in that city on July 31, 1933.

Mr. Jones was born on July 24, 1882, at Alpena, Mich. He attended high school in Ann Arbor, Mich., and then spent four years in the machine shops of the Fletcher Paper Company, Alpena. After this practical experience he took a two-year special course in mechanical engineering at the University of Michigan.

From 1906 to 1911 he was employed as test engineer with the Westinghouse Machine Company, Pittsburgh, Pa., working on the development of the steam turbine and directing installations. He was next the vice-president and treasurer of the Pottle-Jones Engineering Co., Inc., New York, for a short time, then construction and operating engineer for the Federal Light & Traction Co., in connection with properties in Colorado, New Mexico, and Arkansas. In 1914 and 1915 he served as consulting engineer to Minneapolis firms and assistant engineer of power plant equipment in the appraisal of public utilities at Washington, D.C.

Mr. Jones became associated with Chas. Pfizer & Co., Inc., late in 1915, in charge of operation, construction, and maintenance, as well as design.

He became a junior member of the A.S.M.E. in 1911 and a member six years later. He belonged to the Michigan Club and the Chemists Club.

JAMES H. JOWETT (1872–1933)

James H. Jowett, executive vice-president and a director of the Ingersoll-Rand Company, New York, N.Y., died at the Flower Hospital in that city on February 16, 1933, after an extended illness. He was also vice-president and a director of the A. S. Cameron Steam Pump Works and a director of the Rathbun-Jones Engineering Corporation.

Mr. Jowett was born on September 15, 1872, in Cleveland, Ohio, and educated in the public schools and Manual Training School there. He then spent a year in marine boiler making at the Cleveland Ship Building Company and about a year and a half each as draftsman for the Variety Iron Works, Cleveland, detailing the Thaw steam shovel, Steel Motor Company, Johnston, Pa., designing street railway motors, and Anderson Dryer Company, working on dryer design.

His connection with the Ingersoll organization began in December, 1897, when he became draftsman for the Ingersoll-Sergeant Drill Company, at Easton, Pa., designing air compressors and compressed air machinery. In the fall of 1900 he engaged in general compressed air engineering and selling of air compressor and air operated machinery with the Ingersoll-Sergeant Drill Company of New York, and the following year became sales manager for the company. His duties included the design and superintendence of construction of compressed-air power plants, among which was one for use in connection with the Pennsylvania Railroad tunnels under the East River, New York. He was elected vice-president of the company in 1917 and executive vice-president in 1930.

Mr. Jowett became a member of the A.S.M.E. in 1907. He also belonged to the American Institute of Mining and Metallurgical Engineers, the Engineers' and Union League Clubs, New York, and several athletic and social clubs in the Metropolitan area. He is survived by his widow, Mrs. Genevieve (Elder) Jowett, whom he married in 1900, and by a daughter, Lucille.

AUGUST KEHM (1868–1932)

August Kehm, president of Kehm Bros. Company, steamfitting contractors of Chicago, Ill., died on December 11, 1932, in that city. His widow and a son survive him.

Mr. Kehm was born in Chicago on October 23, 1868. After leaving grammar school he served an apprenticeship with F. W. Lamb & Co., Chicago, in steam heating and fitting and machine shop operations, and continued with the company as chief estimator and designer until 1893. He then organized the firm of Kehm Bros. & Mertz, later reorganized as Kehm Bros. Company.

Mr. Kehm was a charter member and past-president of the Chicago Master Steamfitters' Association; a member of the board of governors of the American Society of Heating and Ventilating Engineers from 1908 to 1911 and treasurer of its Chicago Chapter for 24 years; and a member of the Chicago Engineers, Hamilton, Lake Shore, and South Shore Clubs. He became an associate of the A.S.M.E. in 1918.

CHESTER SCOTT KEMP (1886–1933)

Chester Scott Kemp was born on March 14, 1886, at Albany, N.Y., and was graduated from the high school there. He learned the machinists' trade and after several years' general shop experience became a co-partner and manager in 1912 of a garage and machine shop.

When the United States entered the World War Mr. Kemp went to the Watervliet Arsenal as an estimator in the Engineering Division. The following year he was made supervisor of tool requirements of the Seacoast Cannon Department and in 1919 foreman of the Planning Section of the Heavy Field Cannon Department.

After the War he worked for a time for the Amphion Piano Player Company, Syracuse, N.Y., in the capacity of production engineer. In 1924 he became vice-president and treasurer of the Jas. N. Kemp Machine Works, Inc., Albany, and in 1931 was made president of the company.

Mr. Kemp became an associate-member of the A.S.M.E. in 1920. His death occurred on June 30, 1933.

EDGAR ULF KETTLE (1868–1933)

Edgar Ulf Kettle, an expert in kiln drying of lumber, vice-president of the Grand Rapids Veneer Works, Grand Rapids, Mich., died on February 17, 1933.

Mr. Kettle was born in Birmingham, England, on March 22, 1868. After leaving school he spent four years in mercantile marine and three years in army service and worked for several years in woodworking plants in England. In 1908 he went to Kearney, Ontario, Canada, where he became manager of the Kearney Timber & Manufacturing Co., Ltd. He supervised the rebuilding of the plant, which had been destroyed by fire, and the installation of new machinery, and directed the operation of the plant and construction work in connection with getting out the timber. When this plant closed Mr. Kettle became manager of the plant of the Niagara Veneer Company, at Parry Sound, Ontario, which also burned, in 1912. Mr. Kettle then came to the United States, and had since been connected with the Grand Rapids Veneer Works. He also carried on consulting work on the design, installation, and operation of dry kilns. He became a naturalized citizen in 1921.

Mr. Kettle was the author of "Practical Kiln Drying," published in 1923. He became an associate-member of the A.S.M.E. in 1918 and a member in full in 1926. He also belonged to the National Association of Power (formerly Stationary) Engineers.

MORRIS KIND (1875–1933)

Morris Kind, president of the Hercules Cement Corporation, Philadelphia, Pa., died on March 17, 1933.

Mr. Kind was born on February 4, 1875, at Philadelphia. He was graduated from the University of Pennsylvania as a civil engineer in 1896 and during the next four years secured practical experience with the Milliken Brothers, New York. He then went to San Francisco where for many years he was general manager of the Pacific Portland Cement Company, Consolidated, directing the design, construction, and operation of cement plants for that company. He had been with the Hercules Cement Corporation since 1916.

Mr. Kind became a member of the A.S.M.E. in 1912.

HOMER LAUGHLIN (1876–1932)

Homer Laughlin, who died on December 27, 1932, after an illness of several weeks, was born at Wellsville, Ohio, on June 17, 1876. He attended the Pennsylvania Military College and Stanford University, receiving an A.B. degree in chemical engineering from the latter in 1896.

For several years following his graduation he was associated with his father in the Homer Laughlin China Company in East Liverpool, Ohio, holding the offices of vice-president and treasurer. The family

then went to Los Angeles, where father and son entered into various real estate projects, including the construction of office, store, and theater buildings. Upon the death of his father in 1913, Mr. Laughlin took over the management of these enterprises, becoming president of the Laughlin Fruit Refiners, Inc., and Homer Laughlin Engineers Corporation. These companies developed, respectively, machinery for separating and preserving lemon and orange juice and peel, and a front wheel drive automobile and the Laughlin tractor. From 1918 to 1920 Mr. Laughlin was also president of the Stability Building Corporation, during which time he erected the million-dollar theater in Los Angeles. He also laid out Laughlin Park, a Los Angeles subdivision, and organized the Grand Central Market.

Mr. Laughlin became an associate of the A.S.M.E. in 1921, was a 32nd degree Mason, and belonged to many clubs, including the California and University Clubs. He is survived by his widow, Mrs. Alta A. Laughlin, and a son, Homer Laughlin III.

AXEL GEORGE LINDBERG (1870–1933)

Axel George Lindberg, general superintendent of the U. S. Steel Foundries, Inc., Denver, Colo., died on June 29, 1933.

Mr. Lindberg was born at Lindsborg, Kan., on May 6, 1870. After leaving high school he attended Betney College and at the age of 21 began work as a foundry journeyman for the Stearns-Rogers Manufacturing Company, then located at Pueblo, Colo. Four years later he was appointed assistant foundry foreman of the plant, in 1899 general foundry and pattern shop overseer and foreman, and in 1911 general superintendent of the entire plant, consisting of machine shop, plate shop, forge shop, pattern shop, carpenter shop, gray iron foundry, and electric steel foundry.

In 1921 the Stearns-Rogers Manufacturing Company merged with four other companies of Colorado, the Denver Engineer Works, Colorado Iron Works, Vulcan Iron Works, and Queen City Foundry Company. The new organization, the General Iron Works, was established in Denver, and Mr. Lindberg was transferred there as general superintendent of the plant. The company joined with the U. S. Steel Foundries, Inc., in 1930.

Mr. Lindberg became a member of the A.S.M.E. in 1929.

VINCENT LINK (1878–1932)

Vincent Link, who died on March 19, 1932, was born at Bellevue, Ohio, on February 26, 1878. He attended high school in Bellevue and then secured a position as draftsman with the Automobile & Mfg. Co. in Geneva, Ohio. He went to Detroit four years later, in 1905, and entered the employ of the Packard Motor Car Company as chief draftsman and truck engineer. From 1910 to 1914 he was chief engineer and assistant general manager of the Universal Motor Truck Company in Detroit and from then until his retirement in 1930 did consulting work, chiefly for the Studebaker Corporation. Among other companies which he served were the Indiana Truck Corporation, Standard Motor Truck Company, Miller Transmission Company, J. C. Wilson Company, and Sewell Cushion Wheel Company.

Mr. Link became a member of the A.S.M.E. in 1918.

FRANK NORMAN MacLEOD (1866–1933)

Frank Norman MacLeod, president and owner of the Abrasive Machine Tool Company, East Providence, R.I., died at his summer home, Harwichport, Mass., on June 25, 1933. Mr. MacLeod was born at East Providence on June 4, 1866, and after attending the public schools of East Providence and Providence, served an apprenticeship at the George H. Corliss Engine Works in Providence. He then worked for about two years in the cotton mill supply business.

In 1890 Mr. MacLeod became connected with the Brown & Sharpe Manufacturing Co., Providence, as junior inspector of machine tools. Four years later he became first assistant to the chief inspector and in 1896 was promoted to the position of chief inspector. He was sent to Nashville, Tenn., in 1897, in connection with the company's exhibit at the Nashville Centennial. From 1898 to 1900 he was general representative of the company in Great Britain, with headquarters in Glasgow, and for the next fifteen years general representative and sales engineer in the United States. He resigned to form his own company in 1916 and was its president until his death.

Mr. MacLeod became a member of the A.S.M.E. in 1912 and was formerly a vice-president of the National Machine Tool Builders' Association. He was a member of the Providence Chamber of Commerce, Rhode Island Country Club, and British Empire Club.

Mr. MacLeod is survived by his widow, Helen B. (Wood) MacLeod, whom he married in 1906, and their daughter, Helen B. W. MacLeod, and by three children by a former marriage, Norman D., Colin G., and Kenneth B. MacLeod. Their mother, Grace L. (Martin) MacLeod, whom Mr. MacLeod married in 1890, died in 1905.

ALFRED FELLOWS MASURY (1882–1933)

Alfred Fellows Masury, vice-president, chief engineer, and director of Mack Trucks, Inc., New York, N.Y., died on April 4, 1933, when the U.S.S. *Akron*, on which he was a guest passenger, crashed at sea. Colonel Masury was very much interested in aerodynamics and aeronautics, particularly in the development of lighter-than-air craft. He was a passenger on the *Graf Zeppelin* on its attempted westward transatlantic flight in May, 1929, and had flown thousands of miles in various types of dirigibles.

Colonel Masury was born in Danvers, Mass., on September 2, 1882, the son of Charles Henry and Evelyn (Fellows) Masury. He prepared for college at the Danvers High School and was graduated from the mechanical engineering course of Brown University, Providence, R.I., in 1904. After going to New York to work, he took further courses at Columbia University.

He spent several summer vacations during college years in drafting and machine shop work and after graduation entered the employ of the General Electric Company, West Lynn, Mass., as a draftsman. For a time he was associated with the Corwin Manufacturing Company, Peabody, Mass., in the development of the "Gasaulec," a self-starting automobile, and subsequently was chief draftsman and assistant engineer for the Vaughn Machine Company, Peabody, manufacturers of leather working machinery, printing presses, engines, trucks, machine tools, giving him a varied experience.

In 1907 Colonel Masury went to New York, where he took the position of engineer for the Hewitt Motor Company, which was later absorbed by the International Motor Company and Mack Trucks, Inc., manufacturers of Mack trucks and buses. He became vice-president, chief engineer, and director of the company, and retained these positions until his death.

From the time that Colonel Masury joined the Hewitt organization he was concerned principally with the design of internal-combustion engines and the electrical problems involved in the manufacture of heavy-duty trucks, such as ignition, lighting, and starting equipment, magnetos, generators, welding and heat-treating by electricity.

During and after the World War he served the Army Ordnance Department in an advisory capacity, chiefly in connection with automotive equipment and transportation. This work led to his promotion to the rank of lieutenant-colonel in the Army Reserve Corps.

Colonel Masury became a junior member of the A.S.M.E. in 1905 and a member in 1913. He had been a vice-president of the Society of Automotive Engineers, chairman of its Ordnance Advisory Committee, and a member of its Military Motor Transport Advisory Committee. He also belonged to the American Society of Civil Engineers, Institute of Automobile Engineers (England), American Society of Municipal Engineers, American Institute of Electrical Engineers, American Association for the Advancement of Science, American Petroleum Institute, Institute of Metals, American Road Builders Association, Permanent International Association of Road Congresses, Society of American Military Engineers, New York State Society of Professional Engineers and Land Surveyors, New York State Board of Licensing for Professional Engineers, United States Naval Institute, and other professional organizations in this country and England.

Boating was Colonel Masury's chief relaxation. He was a commodore of the Lloyds Harbor Club and belonged to the North American Yacht Racing Association, the Cruising Club of America, and the Port Washington and Montauk Yacht Clubs. Other sports, such as golf, boxing, and racing, also interested him. He was a member of the New York Athletic Club and Psi Upsilon fraternity.

Colonel Masury is survived by his mother and by his widow, Edna (Lanphear) Masury.

EDWARD DOLIVER MAYO (1848–1933)

Edward Doliver Mayo, who died in Minneapolis, Minn., on March 30, 1933, was born on December 19, 1848, in Tremont (now Southwest Harbor), Me. His parents were Sarah Newman Doliver and Jacob Shoppy Mayo. After completing his early education he taught school for a year or so in Clearwater, Minn. He later entered Maine State College (now the University of Maine), from which he was graduated in mechanical engineering in 1875.

From 1876 to 1887 Mr. Mayo worked as draftsman and engineer at flour mills and grain elevators and on the construction of ore docks. He was secretary of the Great Western Manufacturing Company during the next year and of the Willford & Northway Manufacturing Co. in 1888–1889. From then until his retirement in 1921 he was located in Minneapolis as chief engineer at first, and

later consulting engineer for the Barnett & Record Co. He also served for a time as consulting engineer to the Barnett McQueen Company, of Ft. William, Ont. He was the inventor of the Mayo grain spout and of other equipment for grain mills and elevators.

Mr. Mayo became a member of the A.S.M.E. in 1914. He also belonged to the Minneapolis Engineer's Club, Professional Men's Club of Minneapolis, Minneapolis Institute of Arts, and the Minnesota State Horticultural Society. He was much interested in gardening and photography. He was a member of the National Society of Puritan Descendants and of the Wesley Methodist Church, in Minneapolis.

Mr. Mayo was twice married. His first wife, Sarah Elizabeth Mayo, whom he married in 1879, died in 1887. The following year he married Minnie Elizabeth Hunt, who died in 1897. He is survived by a son, William D. Mayo, of Des Moines, Iowa, and by two daughters, Mrs. John A. Casey, Bangor, Me., and Mrs. Paul W. Thayer, Minneapolis.

FRANK GOODMAN McCANN (1871–1933)

Frank Goodman McCann, chief of the Heating and Ventilating Division of the Board of Education of the City of New York, died of heart trouble on May 17, 1933, after an illness of several weeks.

Mr. McCann was born in Chicago, Ill., on September 25, 1871, the son of Henry Mackenzie and Fannie (Carkner) McCann. He was graduated from the Chicago Manual Training School (now part of the University of Chicago) in 1890 and spent the next few years in lock and hardware manufacturing, carpentering, and work in a sash and door mill. He then entered the Massachusetts Institute of Technology, from which he was graduated in 1896 with a B.S. degree in mechanical engineering. He worked on heat and ventilation design for the Boston Blower Company during the summer of 1895.

From 1896 to 1899 Mr. McCann was draftsman and construction superintendent for Evans, Almirall & Co., New York, power and heating engineers and contractors. Since then he had been with the Board of Education, for the first three years as mechanical draftsman. He took charge of heating and ventilating in 1902 as assistant to the superintendent of school buildings and prior to the formation of the Heating and Ventilating Division also handled power and light requirements. He originated the use of standard details and of standard specifications for the work of school building and equipment, wrote several articles for *Metal Worker* and other trade journals, and gave lectures on heating and ventilation to evening Building Trades classes in the College of the City of New York.

Mr. McCann became a member of the A.S.M.E. in 1915. He also belonged to the American Society of Heating and Ventilating Engineers, served on its council in 1914 and 1915, and was president of its New York State Chapter in 1912.

Surviving Mr. McCann are his widow, Louise C. (Dralle) McCann, whom he married in 1903, and a son, Forbes Ellard McCann.

JAMES ROBINSON McCLINTOCK (1883–1933)

James Robinson McClintock, of the firm of Fuller & McClintock, New York, N.Y., died on April 11, 1933, of a heart attack following an illness of several weeks with influenza and bronchitis.

Mr. Clintock was born in Malden, Mass., on February 5, 1883, the son of J. Y. and Mary (Robinson) McClintock. He was educated at the University of Rochester and the Massachusetts Institute of Technology, from which he was graduated with a B.S. degree in 1906. His entire professional career was spent with Hering & Fuller, the firm of George W. Fuller, and the firm of Fuller & McClintock, which was organized in 1916. In his earlier practice he was resident engineer on several pumping station and filtration projects at Burlington, Vt., Clarksburg, W.Va., and elsewhere. The major portion of his professional career was devoted to design work for the firm in the fields of water supply, water purification, sewerage and sewage disposal. His recent and best known work was his immediate charge of the design of the Wards Island (N.Y.) sewage treatment project. Prior to that he was in charge of the Toledo office of the firm, directing design work for Toledo, Lima, and several Florida projects. The most of his time from 1921 to 1925 was spent at Kansas City in charge of the design of the new water supply works of that city.

Mr. McClintock became a member of the A.S.M.E. in 1923 and also belonged to the American Society of Civil Engineers, American Institute of Consulting Engineers, American Water Works Association, and the American Public Health Association.

A talent for drawing and design won Mr. McClintock a first prize for the design of a school building when he was still a high school student in Rochester and gave him pleasure in sketching. He was always, as he put it, a student of the "aesthetics of life and living."

EDWARD FURBER MILLER (1866–1933)

Edward Furber Miller, head of the Department of Mechanical Engineering of the Massachusetts Institute of Technology since 1911 and a member of the faculty for 47 years, died on June 12, 1933, at his home in Newton Center, Mass.

Dr. Miller was born in Somerville, Mass., on January 18, 1866, the son of William Gibbs and Sarah (Furber) Miller. He was graduated from M.I.T. in 1886 with an S.B. degree and immediately joined the faculty as an assistant in mechanical engineering. He became an instructor in 1888, assistant professor of steam engineering in 1892, associate professor in 1899, and professor in 1905. On the retirement of Professor Gaetano Lanza in 1911, he became head of the mechanical engineering department.

Dr. Miller was very active and exercised a wise influence in the general affairs of the Institute. He was sent to Europe in 1904, by President Pritchett, to study the methods of engineering education in foreign technical schools. He visited many institutions in England, France, and Germany, and upon his return made a report to the Corporation which materially influenced later work at the Institute. He took an active part in the planning and work incident to the removal of M.I.T. from Boston to Cambridge. The plans for the laboratories, drawing rooms, and lecture rooms for the mechanical engineering department were drawn up under his supervision. The final layout of the mechanical engineering laboratories, machine tool laboratories, foundry, carpenter shop, forge shop, and mechanical engineering drawing rooms resulted from two years of intensive study under his direction.

Following the death of Richard C. MacLaurin, president of M.I.T., in 1920, Dr. Miller served as a member of the administrative committee which governed the institute prior to the inauguration of President Stratton in 1923. In 1921 he was elected chairman of the faculty.

Dr. Miller was an authority on smoke abatement, the operation and design of steam power plants, and boiler design, and his wide knowledge on these subjects brought about his service as an expert witness in many legal cases. He also served on many state boards and commissions investigating and regulating engineering matters.

He had written several books, including "Steam Boilers," jointly with Cecil H. Peabody, published in 1897, "Problems in Thermodynamics and Heat Engineering," with C. W. Berry and J. C. Riley, 1911, three editions of "Notes on Power Plant Design," the last two with James Holt, and "Notes on Heat Engineering," 1931. He also wrote articles on power plant design and heating and ventilation for engineering publications, and a pamphlet, "Training of Engineer Officers," published by the United States Shipping Board during the World War. He was the inventor of a patent on safety valves and an improvement in the Lyle gun. He was awarded the honorary degree of Doctor of Science by Rhode Island State College in 1921.

In 1917 Dr. Miller had charge of the establishment and control of a number of schools established at various places in the United States to give fundamental training to engineer officers in the operation of engine rooms of ships being constructed by the U.S. Shipping Board. Thirteen of these schools were established, one at M.I.T., and trained about 2000 men, a large number of whom were commissioned as engineer officers in the U.S. Merchant Marine. During the War Dr. Miller was engaged in confidential work for the Army under the Commanding General of the Northeastern Department.

In 1921 Dr. Miller was appointed Dean of Army Students at M.I.T. and took great pride and pleasure in facilitating the work of the numerous members of the military and naval services who were from time to time in attendance at the Institute. He was commissioned a Colonel in the Ordnance Reserve in 1922 and had been assistant district chief of ordnance in the Boston district since 1930. He was a former president of the Boston Post of the Army Ordnance Association and a charter member of the national organization. He was an active sponsor of the Reserve Officers Training Corps and helped to establish and served as first president of the unit at M.I.T.

Dr. Miller became a junior member of the A.S.M.E. in 1888 and a member three years later. He also belonged to the American Society of Civil Engineers, Boston Society of Civil Engineers, American Society of Refrigerating Engineers, and Massachusetts Charitable Mechanics' Association, and was an honorary member of the National Association of Stationary Engineers. His clubs included the Technology and University, in Boston. He is survived by his widow, Mary Willard (Reed) Miller, whom he married in 1900.

BENJAMIN MERWIN MITCHELL (1870–1932)

Benjamin Merwin Mitchell, for many years president of The Conveying Weigher Company, New York, N.Y., died suddenly of heart disease on October 8, 1932. Mr. Mitchell was also engineer of tests

for the N.Y. Lubricating Oil Co. and mechanical engineer for the Manhattan Rubber Manufacturing Company, Passaic, N.J.

Mr. Mitchell was born at South Britain, Conn., on October 24, 1870. He prepared for college at the Wesleyan Academy and received a B.S. degree from the Massachusetts Institute of Technology in 1893. During his summer vacations he worked in the shops and as locomotive fireman of the Old Colony Railroad Company. Following his graduation he entered the employ of the Manhattan Rubber Manufacturing Company. He also was connected with the Robins Conveying Belt Company, of which he was made second vice-president in 1898. In the same year he became a member of the board of directors of the N.Y. Lubricating Oil Co. and engineer for Fraser & Chalmers, Ltd., London. Five years later he was promoted to the position of assistant general manager of the latter company, designing and constructing mining plants on the Rand.

Mr. Mitchell served as captain in the Railway Pioneer Regiment of the British Army in the Boer War from 1900 to 1902. He became a junior member of the A.S.M.E. in 1894 and a member in 1905.

HENRY B. NEWHALL, JR. (1876–1933)

Henry B. Newhall, Jr., president of the Henry B. Newhall Corporation, hardware manufacturers, of Garwood, N.J., died at his home in Plainfield, N.J., on April 18, 1933. He is survived by his widow, Nellie (Elliott) Newhall, whom he married in 1903, and by a son, Richard Newhall.

Mr. Newhall was born in Plainfield, N.J., on December 13, 1876, the son of Henry B. and Ruth Frances (Evans) Newhall. He studied electrical and mechanical engineering at the Massachusetts Institute of Technology, receiving a B.S. degree in 1898. Since then he had been engaged continuously in electrical, mechanical, and civil engineering work. For many years he was vice-president of the New Jersey Foundry & Machine Co., Newhall Chain Forge & Iron Co., and Diamond Expansion Bolt Company, and secretary of the Garwood Company, with offices in New York. In 1922 he became president of the first three of these companies, and in 1928 president of the Henry B. Newhall Corporation. His work included numerous Government contracts in connection with the construction of lighthouses, lock operating machinery for dams on the Ohio River, high-pressure outlet gates for the Pathfinder and Shoshane Dams, in Wyoming, a coal-handling plant at the Newport Naval Station, and other projects. He directed the design, manufacture, and sales of the conveying apparatus, overhead track systems, etc., of the New Jersey Foundry & Machine Co., and such apparatus as expansion bolts, hand power and electric drills, of the Diamond Expansion Bolt Company.

Mr. Newhall became a member of the A.S.M.E. in 1916. He also belonged to the Union League, Engineers', Hardware, and Machinery Clubs, New York.

CLIFFORD H. OAKLEY (1869–1932)

Clifford H. Oakley, president and general manager of the Essex Rubber Company, Inc., manufacturers of mechanical specialties, rubber soles and heels, Trenton, N.J., died in Philadelphia, Pa., on August 9, 1932.

Mr. Oakley was born on October 28, 1869, at Cleveland, Ohio, the son of John Henry and Mary Ellsworth (Thompson) Oakley. He attended the Cleveland public schools and took technical courses in night school. From 1887 to 1892 he was an assistant engineer in the Maintenance of Way Department of the Erie Railroad at Cleveland. He then entered the employ of the Cleveland Rubber Company, working on the design and construction of special machinery at first and later being promoted to the position of assistant superintendent of the plant. In 1893 he was transferred to a subsidiary plant, the N.Y. Belting & Packing Co., Passaic, N.J., of which he was superintendent for two years. He returned to Cleveland in 1895 and served in the same capacity in the plant there for five years.

In 1900 Mr. Oakley took the position of factory manager of the Grieb Rubber Company, Trenton, N.J. Six years later he reorganized the company into the Ajax-Grieb Rubber Company, of which he was secretary and factory manager. In 1907 he organized the Essex Rubber Company and as its principal owner, president, and factory manager, had operated it continuously since then. For the Cleveland Rubber Company, as well as for his own, he planned and built new buildings and purchased or designed and erected the necessary machinery and other equipment.

Mr. Oakley became a member of the A.S.M.E. in 1915. He was past-president of the Trenton Chamber of Commerce, director of the New Jersey Manufacturer's Association, and commodore of the Trenton Sea Scouts. He belonged to the Trenton and Philadelphia Yacht Clubs, the Trenton and Carteret Clubs, and the Masonic fraternity. He was affiliated with the Methodist Episcopal Church.

Surviving Mr. Oakley are his second wife, Elizabeth (Moon) Oakley, whom he married in 1907, and two children, George T. Oakley, of Pennington, N.J., and Mrs. Joseph B. Hewitt, of Trenton. His first wife, Minnie (Cook) Oakley, died in 1902.

OLIVER M. OLSON (1883–1933)

Oliver M. Olson, vice-president of Samuel Olson & Co., New York, who died on April 26, 1933, was born at Sheboygan, Wis., on December 12, 1883, the son of Louis Sanders Olson. For a number of years he was employed by the Consolidated Indiana Coal Company, a subsidiary of the Chicago, Rock Island & Pacific Railway Co., advancing from clerk to assistant auditor, and by the C.R.I. & P. as accountant in the comptrollers office.

From 1912 to 1915 Mr. Olson engaged in track elevation and valuation work for the same road, then for nine years helped to supervise the machine shop and foundry of the Covel Manufacturing Company. In 1924 he went to St. Joseph, Mich., to become secretary and treasurer of Engberg's Electric and Mechanical Works, and remained there until he was made vice-president of Samuel Olson & Co.

Mr. Olson became a member of the A.S.M.E. in 1929 and also belonged to the Masonic fraternity. He is survived by his widow, Lenore (Andersen) Olson, whom he married in 1910.

FRANK EMERSON PALMER (1874–1933)

Frank Emerson Palmer, mechanical engineer for the Palmer Bros. Co., at its mills in Montville, New London, and Fitchville, Conn., died of heart failure at his home in Fitchville on April 30, 1933.

Mr. Palmer was born in Middletown, Conn., on December 23, 1874, the son of William Henry and Adelaide Randall (Wood) Palmer. In 1884 his parents moved to Norwich, Conn., where he attended the public schools and the Norwich Free Academy. He then spent two years at the Worcester Institute of Technology, Worcester, Mass., leaving that institution in 1897. The same year he entered the employ of the Palmer Bros. Co. at their Fitchville mill as carpenter's apprentice. After finishing his training he was advanced to the drafting room of the machine shop department and later made foreman of the machine shop. He had held the position of mechanical engineer since 1914. Two years later he also became general manager of the Fitchville plant and of the Bozrah Sterilizing Company, connected with the plant, and held this position until a reorganization of the Palmer Bros. Co. took place in 1929.

Mr. Palmer became an associate-member of the A.S.M.E. in 1931. In 1914 he became a trustee and shortly afterward a director of the Norwich Savings Society and also a director of the Uncas Merchants National Bank of Norwich, and continued to serve both banks until his death. He was a former member of the board of education of the town of Bozrah, Conn., and of the Connecticut National Guard. He belonged to the Phi Gamma Delta fraternity and the Episcopal Church.

Surviving Mr. Palmer is his widow, Helen Gay (Dawley) Palmer, whom he married in 1898.

FREDERICK WILLIAM PARSONS (1866–1933)

Frederick William Parsons, vice-president of the Ingersoll-Rand Company and general manager of the Painted Post, N.Y., and Athens, Pa., plants of the company, died at his home in Corning, N.Y., on April 1, 1933, following an illness of several weeks from heart trouble and complications.

Mr. Parsons was born in Corning on July 8, 1866, the second son of James A. and Emma (Land) Parsons. He attended the Corning Free Academy, graduating in the class of 1884. He served a three-year apprenticeship as a draftsman at the B. W. Payne & Sons Engine Works, Corning, was in charge of the drafting room there for two years, and then moved with the company to Elmira, N.Y., becoming superintendent of the plant.

Mr. Parsons left the employ of the Payne company in 1894 to become superintendent of the foundry of the Rand Drill Company at Ossining, N.Y. In 1898 the Rand company, upon Mr. Parsons' recommendation, took over the Weston Engine Company, at Painted Post, and established the Imperial Engine Company in its place, with Mr. Parsons as its treasurer. The first air compressors manufactured by the company were shipped in November, 1899. The next year Mr. Parsons developed an air compressor capable of obtaining pressure sufficient to produce liquid air. This machine was exhibited at the Paris Exposition that year and attracted a great deal of attention.

Records show that in 1898 the Painted Post plant employed 125

men and that the floor space was approximately 3375 sq ft. The story of expansion to the point where 1600 men were employed in a large modern factory is the story of the industrial side of the life of Mr. Parsons. He and his associates introduced many revolutionary modifications in the air compressor of those early days, permitting its application to enormous construction jobs and public works.

Products of the Painted Post plant have been used on many of the world's greatest construction undertakings during the last thirty years and more, including the Panama Canal, Boulder Dam, Ashokan Aqueduct, Italian government fortifications in the Alps, the Holland Tunnels, subway and harbor work for the City of New York, and many large buildings there, including the Empire State and Radio City. In oil fields all over the world and in gold and diamond mines in South Africa and Australia, Ingersoll Rand compressors are also used.

Mr. Parsons was responsible for a great deal of this expansion. About ten years before his death he built a large foundry at Painted Post, so that the company might cast its own parts. On his advice also, the company built many homes for its employees and aided them in purchasing them on easy terms. He worked untiringly to develop new machines and to carry the company and its employees through the depression.

In September, 1901, Mr. Parsons became superintendent of the plants at Tarrytown and Ossining, and of the Imperial Pneumatic Tool Company at Athens, making his headquarters at Tarrytown but continuing as superintendent of the Painted Post plant, which he visited weekly. He returned to Elmira to live in 1908, and since that time had been general manager of the Painted Post and Athens plants.

Four years later, in 1928, he purchased a residence in Corning and became a part of the business, social, and institutional life of his native city. He was elected a director of the First National Bank and Trust Company and was one of a small group of men who made possible the Baron Steuben Hotel in Corning. He was greatly interested in the Corning and Painted Post Community Chests and helped to plan improvements for the community. He was a director and active member of the Corning Country Club and helped to enlarge its golf course. He also belonged to the Corning Club, Elmira Country Club, and the Elmira Club. He became a member of the A.S.M.E. in 1889.

Mr. Parsons is survived by his widow, Lyda G. (Knapp) Parsons, and by three sons by a former marriage, Henry Parsons, of Great Neck, L.I., N.Y., and Frederick W., Jr., and Charles L. Parsons, both of whom are connected with the Painted Post plant of the Ingersoll-Rand Company. Their mother was Katherine (Spaulding) Parsons, who died in 1914.

JOHN BAILEY PEDDLE (1868–1933)

John Bailey Peddle died in his native city of Terre Haute, Ind., on April 6, 1933. He is survived by his widow, Alice Elliott (Oney) Peddle, whom he married in 1897, and by two daughters, Juliet Alice and Elinor Mary Peddle.

Professor Peddle was born on February 27, 1868, the son of Charles Rugan and Mary Elizabeth (Ball) Peddle. He received a B.S. degree in mechanical engineering from Rose Polytechnic Institute in 1888, and was given an M.S. in 1895 and an M.E. degree in 1900 by that institution. Following his graduation he was employed by the Thomson-Houston Electric Company, Lynn, Mass., testing dynamos and calibrating instruments for nearly a year. He then did drafting for the Dodge Coal Storage Company, Nicetown, Pa., for a few months and later assisted in the erection of storage plants for the company in New Jersey and Massachusetts. From early in 1891 until 1894 he was associated with Henry R. Worthington, Brooklyn, N.Y., in drafting work, and the Testing Department of the Worthington Hydraulic Works.

In 1894 Professor Peddle secured a position as instructor in drawing at Rose Polytechnic Institute. During the next ten years he advanced to the position of full professor and head of the machine design department. He served as acting president from 1928 to 1930, when a stroke of paralysis necessitated his giving up all work for a time. He was made professor emeritus on March 1, 1933.

Professor Peddle's work on the construction of graphical charts was published in 1910, and he wrote numerous articles in his field for publication in engineering journals. He became a member of the A.S.M.E. in 1909 and also belonged to the Society for the Promotion of Engineering Education, the American Association of University Professors, and the Theta Xi and Tau Beta Pi fraternities. He was active in the work of boys clubs and a member of the Congregational Church and much interested in pictorial photography, especially autochrome color photography.

CLIFTON DANCY PETTIS (1870–1933)

Clifton Dancy Pettis, who died in New York, N.Y., on July 9, 1933, was born in Paducah, Ky., on June 22, 1870, the son of the Rev. William Montrose Pettis and Katherine (Forrest) Pettis. At the age of 17 he entered the drafting room of the LaFayette Car Company, LaFayette, Ind., and after a year's experience there, worked as draftsman for the Terre Haute Car Company, Terre Haute, Ind., and as draftsman and superintendent for the Elliott Car Company, Gadsden, Ala., until 1892. From then until 1895 he was general manager of the American Car Company, Basic City, Va., during the next two years in charge of car drafting and specifications for the Southern Railway, Washington, D.C., and from 1897 to 1899 assistant to the master mechanic of Swift & Co., and the Swift Refrigerator Transportation Company, Chicago. He returned to railroad work as general foreman of the Car Department of the Illinois Central Railroad, at its Burnside Shops, Chicago, in 1899 and remained in that position for five years. From 1904 to 1908 he was supervisor of the Car Department of the St. Louis and San Francisco and the Chicago and Eastern Illinois Railroads, Frisco System, located at St. Louis, Mo.

In 1908 Mr. Pettis became connected with the Hewitt Manufacturing Company, with which he remained for three years. He then began an association of more then ten years with the American Brake Shoe & Foundry Co., first at Chicago, and later as works manager at Mahwah, N.J., and vice-president, with headquarters in New York.

After leaving this company in 1922 he engaged in research and development work in his field in New York for several years, leading to the establishment, in 1928, with his son, of the Continental Brake Shoe & Equipment Co., New York. Mr. Pettis was president of the company. He held many patents on repetition molds and brake shoes.

Mr. Pettis became a member of the A.S.M.E. in 1905 and was an Episcopalian. He is survived by his widow, Charlotte B. (Lyon) Pettis, whom he married in 1895, and by two children, Mrs. Elizabeth P. Croft, Washington, D.C., and William M. Pettis, Ardsley-on-Hudson, N.Y.

WILLIAM DESSAUER PHILIPS (1880–1933)

William Dessauer Philips, who died on February 4, 1933, was born in Brooklyn, N.Y., on December 17, 1880. Although his formal education did not go beyond high school, he studied steam engineering and heating and ventilating through correspondence courses of the International and American Correspondence Schools.

At the age of twenty Mr. Philips began work as New England sales representative of the Parson Manufacturing Company, New York, N.Y. Four years later, in 1904, he became head of the steam department of the Rossiter McGovern Company, in New York, with which he remained for three years. He next spent an equal period as head of the New York office and sales manager for the United States for the Bradley Pulverizer Company. For six months in 1910 he was salesman of general power equipment for the A. D. Granger Co., New York, then became sales manager for the Greeff Engineering & Manufacturing Co., Newark, N.J. His work there included air conditioning, heating, and ventilating, and during this period he originated a varnish dryer.

For about ten years, beginning in 1915, Mr. Philips was manager of engineering and sales for the A. S. Nichols Co., New York. He designed and directed the manufacture and sales of dryers for lumber, veneer, varnish, paints, as well as air conditioning equipment. He was sales engineer for Drying Systems, Inc., New York, from then until 1928, since when he had been vice-president of the Nichols Products Corporation, New York.

Mr. Philips became an associate-member of the A.S.M.E. in 1918.

CHARLES PIEZ (1866–1933)

Charles Piez, chairman of the board of the Link-Belt Company, Chicago, Ill., and Past-President of The American Society of Mechanical Engineers, died of pneumonia on October 2, 1933, at the Garfield Hospital, Washington, D.C. Mr. Piez's health had been failing for the past five years, and since February, 1932, he had been inactive in business. He had been living in Washington since May, 1933.

Mr. Piez had served the Link-Belt Company and its predecessor, the Link-Belt Engineering Company, ever since his graduation from Columbia University in 1889. His career was thus coincident with the great developments in material-handling and conveying machinery that have become such characteristic features of production and labor-saving methods for which this country is now noted. It

was another A.S.M.E. past-president, James Mapes Dodge, who saw the possibilities of developing the link belting invented by William D. Ewart, of Chicago, and joined with him, in 1888, in the establishment of the Link-Belt Engineering Company, in which Mr. Dodge carried out his ideas along strictly engineering lines and with a highly specialized engineering staff. Mr. Piez came under the influence of this environment within a month of his graduation from Columbia. Starting as a draftsman, he served successively as chief draftsman, chief engineer, general superintendent, general manager, president, and, from 1924 to February, 1932, chairman of the board. His career illustrates in a spectacular fashion how the technical graduate with capacity for executive responsibilities and a flair for the financial and non-engineering aspects of industrial life passes into a position of leadership in business following a helpful and necessary experience in the rigid discipline of engineering design and production. His estimate of the value of an education in engineering is contained in an address delivered at Akron, Ohio, in the fall of 1929, in which he said:

"If I had my life to live over again, I am certain that I would start it with a course in mechanical engineering, because that represents the best means of acquiring a broad foundation for a useful, practical life, one that not only provides opportunities for a professional career, but also affords abundant opportunity for success in a business career.

"This is true because engineering training develops the ability to dig up and properly weigh the facts before reaching a conclusion, and this ability is the basis of sound judgment in every walk of life."

As the chief executive of a large industrial enterprise, Mr. Piez had an opportunity to appraise the value of sound management principles. In a message to the members of The American Society of Mechanical Engineers, assembled in Washington in April, 1930, to celebrate the founding of the Society, Mr. Piez wrote: "It has been in large measure due to the engineer that management has been raised to the dignity of an art, and that it is now generally recognized as the most important factor in the conduct of industry."

He sensed keenly the progress that engineering has made in recent years toward a broader understanding of its economic possibilities and responsibilities. Unable, because of illness, to deliver the customary presidential address to the A.S.M.E. in December, 1930, he telegraphed his greetings and concluded with these words of high hope and far-sighted vision. "The A.S.M.E. ought to make itself a commanding factor in every field of mechanical engineering, for the profession has for its domain not only the strictly technical problems of industry, but the economic problems as well. There are glorious opportunities ahead. It is for our successors to embrace them."

Largely as a result of his ability as an organizer and manager, Mr. Piez was selected by Edward N. Hurley, then chairman of the U.S. Shipping Board, in November, 1917, to be vice-president and general manager of the Emergency Fleet Corporation. As the chief executive of this enterprise, and later succeeding Mr. Schwab as director general, Mr. Piez advised upon and directed the expenditure of three billion dollars. He had control over 600,000 persons employed in the shipyards and fabricating plants, and in industries furnishing supplies to the yards.

Mr. Piez joined the Emergency Fleet Corporation in its earlier days, and the character of the organization, its personnel, and its methods in accomplishing the great task assigned to it in the War, were largely his. Mr. Schwab, when leaving the Emergency Fleet Corporation, said of Mr. Piez: "I regard you, above all other men, as having contributed more to the work done in the Fleet Corporation than any one else."

Mr. Piez resigned on May 1, 1919, as director general, to return to his former business. He continued as president of the Link-Belt Company until 1924, when he became chairman of the board, and was active in this position until February, 1932.

Mr. Piez served as president of the Commercial Club of Chicago. His periods of service as president of the Illinois Manufacturers' Association were from 1911 to 1913 and again from 1924 to 1925. He was a director of the Drexel State Bank of Chicago; director, Illinois Bell Telephone Co.; a member of the Executive Committee of the Museum of Science and Industry founded by Julius Rosenwald. He received the honorary degree of doctor of commercial science from New York University. He was a member of the following engineering societies: American Institute of Mining and Metallurgical Engineers, Society of Naval Architects and Marine Engineers, Western Society of Engineers, and Engineers' Society of Northeastern Pennsylvania. He became a member of the A.S.M.E. in 1894, and was elected to the presidency in the fall of 1929. His term was coincident with the Fiftieth Anniversary of the Society, but failing health made it impossible for him to attend the celebrations in New York and Washington, and the Annual Meeting in 1930.

Mr. Piez was instrumental in framing much of the labor legislation of the State of Illinois, having been a member of the commission that drew the State Factory Act. He was chairman of the Workmen's Compensation Commission, and a member of the State Arbitration Board, State of Illinois.

Mr. Piez was born on September 24, 1866, at Mayence, Germany, the son of Jacob and Catherine Liebig Piez, naturalized American citizens who were traveling in Europe at the time. He was graduated from the School of Mines, Columbia University, in 1889, with the degree of engineer of mines. In 1896 he married Laura Oliva Flora, from whom he was divorced in 1919. His second wife was Mrs. Laura Sadler Cocke Piez, of Laurel, Md., whom he married in 1922. He is also survived by his sister, Miss Ernestine Piez, of New York, N.Y.

Mr. Piez was a member of the Chicago, University, Commercial, and Flossmoor Country clubs of Chicago, the Union League Club of Philadelphia, and the Chevy Chase Club of Washington. He was a Republican and a Mason.

EDWIN DANIEL PINGREE (1862–1933)

Edwin Daniel Pingree, for many years vice-president and engineer of the Manufacturers Mutual Fire Insurance Company, Providence, R.I. (one of the Associated Factory Mutual Fire Insurance Companies), died on February 1, 1933. He had been in ill health for some years.

Mr. Pingree, the son of Daniel Wentworth and Sarah Jane (Durham) Pingree, was born on December 28, 1862, at Lawrence, Mass., and was graduated from the high school there in 1878. He then worked for a time as a draftsman in the shop of J. H. Horne & Sons, paper mill machinery manufacturers, Lawrence, and later spent several years at the Ryegate (Vermont) Granite Works, becoming an expert in designing and erecting monumental granite work. He returned to Lawrence as an inspector of construction work for George G. Adams, architect.

In 1892 Mr. Pingree became an assistant to John R. Freeman, Providence, R.I., consulting hydraulic engineer and chief of the Inspection Department of the Associated Factory Mutual Fire Insurance Companies. His expertness as a draftsman quickly brought him opportunities to help Mr. Freeman in his work as a member of the Massachusetts Metropolitan Water Board, appointed to construct large additional water works for Boston, as well as in his work for the insurance companies.

Mr. Pingree entered the Massachusetts Institute of Technology in 1893 and was graduated with an S.B. degree in 1896. He was employed by Mr. Freeman during vacation periods, and returned to his office following graduation to assist him on water supply problems for Boston and New York, studies in connection with the Charles River Dam, and other investigations. He later joined the staff of the Manufacturers Mutual Fire Insurance Company, became a student of taxation, and was very helpful to the companies in litigation regarding Federal taxes in 1912 and 1913. He was elected vice-president and engineer of the Manufacturers Mutual Fire Insurance Company in 1907 and held that position until his retirement on July 1, 1932.

Mr. Pingree became a member of the A.S.M.E. in 1905. He also belonged to the Boston Society of Civil Engineers, New England Cotton Manufacturers Association, University and Turks Head Clubs, Providence, and the Congregational Church there. His wife, Louise C. (Sawyer) Pingree, whom he married in 1898, died in 1904. He is survived by a son, Daniel Pingree, of Providence.

STEPHEN HENDERSON PITKIN (1860–1933)

Stephen Henderson Pitkin, who died at his home in Akron, Ohio, on April 23, 1933, after a long illness, was first vice-president of the Wellman-Seaver-Morgan Company prior to his retirement in 1921.

Mr. Pitkin was born at Troy, Ill., on October 26, 1860, the son of Caleb J. Pitkin, a Presbyterian minister, and Elizabeth (Bancroft) Pitkin. He went to Akron in 1875 and after completing his high school education there served a three-year apprenticeship as a machinist in the works of the Webster Camp & Lane Machine Co. He then worked for the company as a draftsman for five years, as mechanical engineer for two years, and from 1887 until the company was consolidated with the Wellman-Seaver-Morgan Company in 1903 as secretary and general manager.

Mr. Pitkin has been a member of the A.S.M.E. since 1891 and of the American Institute of Mining and Metallurgical Engineers since 1887. He had served as a trustee and deacon of the First Congregational Church in Akron for many years and also belonged to the Masonic fraternity.

Surviving Mr. Pitkin are his widow, Bessie (Alexander) Pitkin, a son, Francis A. Pitkin, of Philadelphia, Pa., and three daughters,

Mrs. Elizabeth Rowell, Akron, Mrs. Grace Larkins, East Liverpool, Ohio, and Mrs. Marion St. John, by a former marriage, Canandaigua, N.Y. His first wife, Ada (Maltby) Pitkin, died in 1893.

HOLBROOK FITZ JOHN PORTER (1858–1933)

Holbrook Fitz John Porter, who after long experience as a consulting industrial engineer devoted his later years largely to the furtherance of prison reform and the establishment of a National Museum of Engineering and Industry, died of pneumonia at his home in New York, N.Y., on January 25, 1933.

Mr. Porter was a member of the Board of Directors, secretary, and one of the few honorary members of the Association of Grand Jurors of New York County and in 1926 and 1927 was editor of *The Panel*, official magazine of the Association. He is credited with being among the first to put the Association before the public as a militant civic group. He conceived the idea of removing the prisons of the City of New York from Welfare to Riker's Island and in 1924, upon designation of the August Regular Grand Jury for New York County, he prepared a comprehensive study of the conditions existing in the prisons on Welfare Island, and a plan for their removal to Riker's Island. This plan was endorsed and published by the Prison Association of New York and the Association of Grand Jurors of New York County. He was very active in obtaining the official action necessary to effect the plan, and the model penitentiary on Riker's Island, the cornerstone of which was laid in 1931, is the result of his work.

In 1920 Mr. Porter organized and became secretary of the movement to establish a National Museum of Engineering and Industry to trace and perpetuate the progress of practical scientific development. The scope of this institution, as he had envisioned it, was to be somewhat similar to that of the Deutsches Museum at Munich, Germany, and the South Kensington Museum in London, England. It was planned to have the main museum in Washington, D.C., with branches throughout the country. He had prepared a comprehensive plan for the establishment and maintenance of the museum, and this plan was shortly to have been brought before a group of educators, engineers, and museum experts for study.

Mr. Porter was born in New York on February 28, 1858, the son of General Fitz John, who fought in the Mexican and Civil Wars, and Harriet Pierson (Cook) Porter. He was educated at St. Paul's School, in Concord, N.H., and was graduated in 1878 from Lehigh University, Bethlehem, Pa., with a mechanical engineering degree. His first position was with the Delamater Iron Works, in New York, as apprentice and draftsman, from 1878 to 1882. He was then, for two years, assistant engineer of the New Jersey Steel and Iron Company, at Trenton, N.J. From 1884 to 1886 he was college engineer at Columbia University, installing heating, ventilating, and electric lighting systems in new buildings, and from 1886 to 1890 was superintendent of buildings and grounds there, being the first to hold that position. He made a thorough study of cost accounting while at the University.

During the next two years Mr. Porter worked as superintendent of the Cary & Moen Steel Wire & Springs Works, New York, and the Braddock Wire Company, Pittsburgh, Pa. He introduced the first cost system in these two companies. He then went to Chicago where he helped in the engineering work incidental to laying out the Columbian Exposition of 1893, being assistant mechanical engineer during the construction period and assistant chief in charge of Machinery Hall while the Exposition was in progress.

At the close of the Exposition Mr. Porter became associated with the Bethlehem Steel Company and was successively their western representative, with headquarters in Chicago, assistant sales manager, at Bethlehem, and eastern representative, in New York. A comprehensive paper on "Hollow Steel Forgings," presented with lantern slides before the A.S.M.E. St. Louis Meeting in 1896, was received with great interest and afterward given before engineering classes in several western universities. During the next few years Mr. Porter lectured on the subject of advanced methods in the making of steel forgings more than one hundred times, at various technical society meetings and before classes in western universities, in addition to writing articles on the subject for the technical journals. These addresses and articles were instrumental in arousing interest in nickel steels, and stimulated their increased use in industry.

As vice-president and general manager of the Westinghouse, Nernst Lamp Company from 1902 to 1906 Mr. Porter established in that firm the first shop committee with employee representation and the first factory fire drill in this country. In 1906 he opened his own office in New York for the practice of consulting engineering, specializing in introducing scientific management in industrial plants. He advanced employee representation and hygienic and safety measures, especially safeguards against loss of life by fire, and his papers and discussions before meetings of the A.S.M.E. in succeeding years reflected his strong interest in the humanitarian and educational aspects of his work.

In 1909 Mr. Porter was retained by the Russell Sage Foundation to study hygienic conditions in industrial plants in Pittsburgh in connection with the Foundation's survey of that city. His report on the condition of public swimming pools led to his appointment by the Board of Health of the City of New York to investigate pools there. He wrote the first article on this subject for *The Survey*.

Mr. Porter initiated a movement in New York which resulted in the creation by the State legislature of the New York State Factory Investigating Commission, to which he became adviser on fire hazard to life. His interest in this phase of safety work led to his invention of the vertical fire wall, a device which permitted the escape of persons through fireproof doors in a fireproof wall to an adjoining building or another part of the burning building, completely shut off from the flames. This was the first practical method of saving helpless inmates of hospitals and asylums from fires and the adoption of the device in the State of New York was required by law. His work also resulted in the revision of the New York State Labor Law and the enactment of the first fire prevention code in this country. Mr. Porter was engaged by the City of New York to install fire preventive measures in the hospital buildings of the Department of Public Charities, more than two hundred in number.

From 1915 to 1918 Mr. Porter was consultant to the Hercules Powder Company, Wilmington, Del., on employment management for increased efficiency. After the close of the World War he served as consultant on employment representation in industry to more than two hundred business concerns for the New Jersey State Chamber of Commerce.

Mr. Porter was a leading authority on the life of Captain John Ericsson. He had collected a large amount of Ericssonia and was instrumental in having appropriate tablets placed at historic sites to commemorate particularly eventful occurrences in his life. In 1918 he instituted a movement to nominate Captain Ericsson for the Hall of Fame.

In addition to his early lectures and writings on steel, Mr. Porter was the first lecturer in the course of industrial organization and management in the Alexander Hamilton Institute and was on its staff of lecturers at the time of his death. He also lectured at the Harvard University Graduate School of Business Administration, Columbia and New York Universities, Massachusetts Institute of Technology, Tufts College, the Universities of Illinois and Michigan, Lehigh University, and many other institutions of learning and engineering and business associations throughout the country. His writings included many on industrial management, as well as articles on safety and other subjects in which his interest has already been evidenced.

Mr. Porter became an associate of the A.S.M.E. in 1880 and a member four years later. In 1911 he organized and became the first secretary of the Efficiency Society, the first society devoting itself to the study of organization and management. In 1912 he was secretary of the organizing committee for the Congress of the International Association for Testing Materials. He was a member of the British Iron and Steel Institute, a member of the Board of Directors and of the executive committee of the American Society for the Prevention of Blindness, and a former president of the Lehigh University Alumni Association. He was for many years vestryman of the Church of the Ascension (Episcopalian), New York. His clubs included the Engineers', New York, and the Aztec Club of 1847 (Society of the Mexican War), Washington, D.C.

Surviving Mr. Porter are his widow, Rose (Smith) Porter, whom he married in 1888, a son, Fitz John Porter, and a granddaughter, Peggy Porter.

FRANCIS HENRY RICHARDS (1850–1933)

Francis Henry Richards, a Founder Member of the A.S.M.E., died on April 29, 1933, at a hospital in New Britain, Conn., where he had lived during the last ten years of his life. Mr. Richards, who in recent years was consulting engineer and designer for the Pratt & Whitney Co., Hartford, Conn., had more than 1,000 patents to his credit.

Mr. Richards was born at New Hartford, Conn., on October 20, 1850, the son of Henry and Maria (Whiting) Richards. He attended public and private schools at New Hartford, and for several years was employed as a mechanical engineer at the Stanley Rule and Level Works, New Britain, Conn., and by the Pratt & Whitney Co. He opened an office in 1886 at Hartford and made a study of patent laws. He removed his office to New York in 1898 and until his retirement in 1924 was consulting engineer and patent adviser to a number of large manufacturing companies.

Among the inventions of Mr. Richards was a machine for manufacturing golf balls; a machine to fold, gum, count, and bind envelopes in one process, which he invented for the United States Envelope Company; more than 250 patents for weighing machines; more than 200 for machine-shop tools and appliances; more than 100 for typographic machines; and many for coke furnaces and door springs.

Mr. Richards married Mrs. Clara (Blasdale) Dole, of Springfield, Mass., who died in 1908. His stepson, Frederick J. Dole, in charge of the New York office, survives him.

Mr. Richards was also a member of the American Association of Inventors and Manufacturers, Civil Engineers Club, Cleveland, Ohio, Odd Fellows, and Masonic fraternity.

FRANK RICHARDS (1839–1933)

Frank Richards, retired mechanical engineer and editor of engineering publications, died at his home in North Plainfield, N.J., on May 21, 1933.

Mr. Richards was born in Taunton, Somersetshire, England, on February 10, 1839, and came to the United States with his parents when he was ten years old. They resided in Whitehall, Plattsburg, and Troy, N.Y., at the latter place for 30 years. He was associated with a number of machinery firms during these years, among them the Starbuck Brothers and Tolherst Company, of Troy, and for several years after going to New York was superintendent of the Ingersoll-Sargent Company.

In later years Mr. Richards devoted himself to writing technical articles on engineering. He was assistant editor of the *American Machinist* for ten years and managing editor of the *Compressed Air Magazine* for twelve. During the past ten years he had lived with his son, Frederick H. Richards, and spent his time largely in reading, writing, and the keeping of scrapbooks containing poetry and records of all important happenings. He wrote for the *American Machinist* for several years under the pen name of Tecumseh Swift. Although in poor health during recent months, he had only two weeks before his death submitted an article to the *Compressed Air Magazine*.

Mr. Richards became a member of the A.S.M.E. in 1891.

HARRY ALLEN RISING (1880–1933)

Harry Allen Rising, mechanical engineer for the United Shoe Machinery Corporation, Beverly, Mass., died on April 19, 1933. He became a member of the A.S.M.E. in 1929.

Mr. Rising was born at Hoosick Falls, N.Y., on February 22, 1880, the son of William Henry and Isabel (Allen) Rising. His high school education was supplemented by private study in mechanical drawing, machine design, and advanced mathematics.

From 1900 to 1905 Mr. Rising was draftsman and designer for the Draper Corporation, Hopedale, Mass., working on textile machinery. The next year was spent as designer for the Chapman Valve Company, Indian Orchard, Mass., working mostly on jigs, fixtures, and small tools. At the H. B. Smith Co., Westfield, Mass., he was in charge of the design of steam radiator and boiler testing fixtures, conveyors, etc., for their factory use from 1906 to 1908. For part of the following year he designed wire forming machinery for the Scoville Manufacturing Company, Waterbury, Conn. His next position was that of designer for the Crompton and Knowles Loom Works, Philadelphia, Pa., where he remained from 1909 to 1912. After that he was again connected for four years with the Draper Corporation. He had been with the United Shoe Machinery Corporation since 1916. His work dealt only with shoe machinery until 1919. During the next three years he supervised the adoption of all machines, and since then he had been in charge of all design, standardization, experimental, and testing work for the company and served as a consultant with other companies. He had taken out a number of patents which were assigned to the United Shoe Machinery Corporation. He collaborated with Prof. Eliot F. Tozer, of Northeastern University, in the writing of a textbook on machine drawing, which was finished shortly before his death.

Mr. Rising became a member of the A.S.M.E. in 1929. He also belonged to the American Institute of Electrical Engineers, the Masonic fraternity, and the Unitarian Church. He was a private in the Massachusetts Volunteer Militia, Sixth Regiment Infantry, from 1901 to 1904.

Mr. Rising is survived by his widow, Marian (Harris) Rising, whom he married in 1906, and by a daughter, Priscilla E. Rising.

ALLAN DOUGLAS RISTEEN (1866–1932)

Dr. Allan Douglas Risteen, director of technical research and editor of safety publications for the Travelers Insurance Company of Hartford, Conn., died on December 30, 1932, at his home in that city.

Dr. Risteen, who was an author of internationally known texts upon technical subjects, with particular reference to safety engineering, was born on August 15, 1866, in Amesbury, Mass., the son of John C. and Hannah (Morrill) Risteen. He was graduated from Worcester Polytechnic Institute in 1885 with a B.S. degree in civil engineering and took advanced courses in foreign languages and physical science at Dartmouth College. Following three years of research in mathematics and physics, Dr. Risteen received a Ph.D. degree from Yale University in 1903. His thesis on "The Numerical Evaluation of the Absolute Thermodynamic Scale of Temperature" has been given to the Yale University library by Mrs. Risteen since his death. In 1929 he was awarded the honorary degree of doctor of engineering by Worcester Polytechnic Institute.

After his graduation from Worcester Polytechnic Institute he was associated with the United States Coast and Geodetic Survey. Together with Prof. Chas. S. Pierce he conducted a series of extensive pendulum observations at the Stevens Institute of Technology, Hoboken, N.J., for the Government, and later he worked for a time for the Survey in Washington, D.C. For a year beginning in August, 1887, he was mechanical editor for *Power*, and subsequently a regular contributor to that publication in the field of electricity.

In 1889 Dr. Risteen became connected with the Hartford Steam Boiler Inspection and Insurance Company as assistant editor of its house organ, *The Locomotive*, and in a short time was made its editor, a position which he retained until he joined the Travelers Insurance Company as director of technical research in 1911. During this period he also was in charge of computations for the Massachusetts State Typographical Survey at Boston; served in an editorial capacity for the Century Dictionary, of which he was an associate editor in 1892–1893, and for the Encyclopedia Americana; and wrote or directed the preparation of other scientific articles, so far as his time permitted.

Dr. Risteen wrote on astronomy, mathematics, civil engineering, and methods of promoting safety in industrial plants. His astronomical calculations have been widely used, particularly those for the orbit of 70 Orphiuca, one of the double stars, which were more minute than any previous calculations. An address delivered by him at the Worcester Polytechnic Institute in 1895 on "Molecules and the Molecular Theory of Matter," as well as special lectures in steam engineering which he gave later at Yale University, were subsequently published and are still used as textbooks. He was also a visiting lecturer in mechanical engineering at Yale. Among his other publications is a book of conversion tables for comparing metric units with other standards of measurement and a 200-page book on "Scaffolds" which he issued in the interest of safety. During the World War he worked untiringly to promote safety for workers in munitions plants.

The Yale University Library is also the recipient of three large typewritten, morocco-covered volumes, containing hitherto unknown facts about the life of Shakespeare collected by Dr. and Mrs. Risteen during the last twenty years or more of his life.

Dr. Risteen became a member of the A.S.M.E. in 1912. He was a past-president of the American Society of Safety Engineers (now the Engineering Section of the National Safety Council) and represented that society on the Sectional Committee on a Safety Code for Machinery for Compressing Air for which the A.S.S.E. and A.S.M.E. are joint sponsors. He had also served on the Joint Research Committee on Welding of Pressure Vessels, and on its Subcommittee No. 1 on Methods of Test, which were discharged in November, 1931, upon the completion of their work. He also belonged to the American Association for the Advancement of Science, Yale Engineering Society, Verein deutscher Ingenieure, the Chemist's Club of New York, and the Association des Industriels de France contre les Accidents du Travail.

In 1928 the American Welding Society, of which he was once an officer, chose Dr. Risteen to represent the organization at the world congress of engineers in Tokio, Japan, but illness prevented his acceptance. He was a vice-director of the American Bureau of Welding and a member of Sigma Xi, honorary scientific fraternity, Camp Fire Club of America, and the Twentieth Century Club of Hartford. For many years, he was a trustee of the Hartford Public Library.

In 1887 Dr. Risteen married Ella M. Whitney, of Upton, Mass., who survives him.

ROBERT RIPLEY RUST (1879–1933)

Robert Ripley Rust, for many years personal assistant to August Heckscher in both his business and charitable activities, died on July 23, 1933, at the New York Hospital-Cornell Medical Center,

New York. Mr. Rust, who had heart disease, had been taken to the hospital from his home, Five Acres, Millstone, N.J., a few days before his death.

Mr. Rust was born on February 28, 1879, at Lorraine, Minn., the son of John and Sarah (Ripley) Rust. He studied chemical engineering at the Armour Institute from 1893 to 1896 and spent the next four years working on chemical problems for Armour & Co. In 1900–1902 he was superintendent of the Somerset Chemical Company, Bound Brook, N.J., and during the next three years was connected with the New Jersey Zinc Company, at Beaumont, Tex., and as superintendent of its Waukegon, Ill., plant.

While with the New Jersey Zinc Company Mr. Rust first met Mr. Heckscher, who in 1907 gave him a position in The Central Foundry Company, one of his interests. Mr. Rust remained with the company until after the close of the World War, rising to the position of president.

Mr. Heckscher sent Mr. Rust to Germany in 1929 to study the housing situation there, particularly the German examples of slum clearance. On his return he became a member of the National Housing Committee for Congested Areas through which he and Mr. Heckscher advocated slum housing built on a large scale under a new state law with the aid of the city. Mr. Rust was also president of the Heckscher Foundation and of the Dry Ice Corporation from 1926 to 1931. He retired from the vice-presidency of the Somerville Iron Works, Somerville, N.J., in February, 1933.

Mr. Rust became a member of the A.S.M.E. in 1912 and also belonged to the Engineers' and Chemists Clubs in New York and the Raritan Valley Country Club. He is survived by his widow, Imogene (Bradford) Rust.

EDWIN RUUD (1854–1932)

Edwin Ruud, inventor of the Ruud automatic gas water heater and president of the Ruud Manufacturing Company, Pittsburgh, Pa., died on December 9, 1932, at his home in that city.

Mr. Ruud was born in Askim County, Norway, on June 9, 1854, and was educated there. After being graduated in 1876 as a mechanical engineer from the government's technical college at Horten, he worked as a draftsman and in the shops of the Katerineholms Jernvork, Frederickshold, Norway, for two years. Subsequently, for an equal period of time, he was employed as a machinist by the Bergunds Michine Werkstad, Stockholm, Sweden, principally engaged in the fitting up and erection of marine engines. He became interested in American-made machines and tools and American manufacturing methods and in 1880 came to the United States to learn more about them. During the next seven years he was employed by William Sellers, Philadelphia, Pa., the Pennsylvania Railroad Company, in its engineering office at Altoona, Pa., the Strong Locomotive Engine Company, Philadelphia, and the Scott Foundry, Reading, Pa., where he engaged in design work.

Mr. Ruud received his citizenship papers in 1887. In that year, also, he was offered a position by George Westinghouse. He was assigned to the Fuel Gas & Electric Engineering Co., Pittsburgh, which had been formed by Mr. Westinghouse and associates to develop the gas producer machine. A variety of gas burning appliances for domestic and industrial use were also developed, among them the automatic gas water heater, which was first manufactured in 1888 and 1889. With the increasing production of natural gas about this time, Mr. Westinghouse turned his attention to the problems involved in its practical utilization. The Fuel Gas & Electric Engineering Co. was reorganized as the Pittsburgh Meter Company and Mr. Ruud developed one of the first small accurate proportional meters for measuring the flow of gas from a well.

Mr. Westinghouse was also deeply interested in the development of the gas engine as a prime mover and after a time assigned Mr. Ruud to this work. The Westinghouse gas engine, for which he was largely responsible, was widely used until the steam turbine and turbo-generator took its place.

After being with the Westinghouse companies for a number of years Mr. Ruud purchased the patents for the automatic gas water heater and also an automatic water distiller which had been taken out in his name and assigned to the Westinghouse companies. Other projects had held greater interest for Mr. Westinghouse and these two inventions had never been pushed. In collaboration with James Hay, a Pittsburgh plumber, Mr. Ruud improved these appliances and began to put them on the market, the first heater, under the trade name of the Pittsburgh water heater, being built in 1895. The Ruud Manufacturing Company was formed two years later and offered two types of heaters, the automatic storage system and the instantaneous automatic water heater.

These heaters were designed for use with natural gas and it was not until 1902 that Mr. Ruud perfected improvements making them suitable for artificial gas. During the next two years a sales force was built up and branch offices and agency connections established in many large cities in the United States and Canada. In 1905 Mr. Ruud retired from his association with the Westinghouse companies and had since devoted his entire time to the Ruud organization. He had invented many devices to make the Ruud heater adaptable to various needs and built up a highly successful and widely known company.

Mr. Ruud was honored by the king of Norway's decoration, the Order of St. Olaf, and was a Commander of the Horten technical college. An honorary Doctor of Science degree was conferred upon him by the University of Pittsburgh in 1927. He had been a member of the A.S.M.E. since 1889.

Surviving Mr. Ruud are his widow, Minna (Kaufmann) Ruud, and a stepson, John Henry Sorg, of Pittsburgh, as well as two sisters in Norway. He visited his summer home at Galten, Norway, each year, enjoying the fishing there. He also had a camp in Forest County, Pennsylvania. His interest in music led him to establish a fund to aid young singers in Norway.

CHARLES MacCAUGHEY SAMES (1866–1933)

Charles MacCaughey Sames, since 1916 associate editor of The American Society of Mechanical Engineers, New York, N.Y., died suddenly of heart failure at his residence, the Hotel Robert Fulton, New York, on March 8, 1933.

Mr. Sames was born on May 12, 1866, at Rockford, Ill. He was the son of Peter and Mary E. (MacCaughey) Sames. Matriculating at the Worcester Polytechnic Institute, Mr. Sames soon transferred to the newly formed Rose Polytechnic Institute at Terre Haute, Ind., from which he was graduated, in 1886, with the degree of Bachelor of Science.

Following graduation, Mr. Sames came east and entered the Thomson-Houston Electric Company, Lynn, Mass., where he worked as a draftsman and in the testing department under Professor Elihu Thomson. In 1887 he returned to his native town to enter business with his father, Peter Sames, who was a manufacturer of agricultural implements. He continued in the business until 1900 when he entered upon his editorial career.

During his manufacturing experience, at first as superintendent and from 1894 to 1900 as business manager, Mr. Sames was in responsible charge of designing jigs, fixtures, and special tools, and the repair and alteration of the buildings, power plant, and machinery. He also designed and built various special machines and labor-saving devices, such as gang boring machines, eye benders, and a line of small direct-current generators.

Mr. Sames's first venture in literary and editorial work was the compilation and editing of a "Pocket Book of Mechanical Engineering," published in 1905, and republished in its fourth edition in 1911. This "pocket book" included valuable data gleaned from publications in foreign languages and for that reason not available to the average engineer.

In 1906 he became editor of book publications of the Engineering News Publishing Company, New York. From 1907 to 1913 he acted as associate editor of *Technical Literature*, and its successors, *The Engineering Digest* and *Industrial Engineering*, for which his experience as a designer, manufacturer, and editor of the "pocket book" provided him with an unusually valuable and comprehensive background.

Returning to the work of editing handbooks, Mr. Sames, from 1913 to 1916, assisted Professor Lionel S. Marks, of Harvard, in the preparation of Mark's "Mechanical Engineers' Handbook."

In July, 1916, Mr. Sames joined the staff of The American Society of Mechanical Engineers, as associate editor, a position which he held until his death. His talents were employed on the Society's "Journal," now known as *Mechanical Engineering*, and on the editing of engineering and technical papers for the Transactions of the Society.

Bringing to this work a broad and comprehensive knowledge of the theory and practice of the profession of mechanical engineering and an extraordinary experience in the editing of engineering literature, Mr. Sames gave the publications of the Society a deserved reputation for high quality and accuracy.

It was Mr. Sames's rare combination of editorial skill, knowledge, and experience, and familiarity with the technical literature in foreign languages as well as in English, that made him especially competent to aid in the successful publication of The Engineering Index which the A.S.M.E. acquired in 1918. His meticulous editorship of engineering papers published in the Transactions and *Mechanical Engineering* transformed hundreds of indifferently written and amateurishly prepared manuscripts into accurate and creditable contributions to the literature of engineering. And with the coming of the *A.S.M.E. News*, in 1921, his talents were employed in the final

scrutiny of its pages. On all of these publications he left the imprint of his literary craftsmanship, in the apt turning of a phrase, a remarkable clarity and conciseness of expression, a high degree of professional and editorial dignity, a meticulous accuracy, and a tastefulness in typographical arrangement.

On December 20, 1899, Mr. Sames married Lida Oliphant Falkinburgh, of Jersey City, who survives him. He is also survived by his brother, Judge Albert M. Sames, of Tucson, Ariz. He became a member of the A.S.M.E. in 1918 and also belonged to the Sons of the Revolution, New York, and to several clubs, including the Carteret and University Clubs of Jersey City, N.J. He was a Protestant and a Republican.

The following editorial appeared in the April, 1933, issue of *Mechanical Engineering:*

"For many years every page of *Mechanical Engineering* has borne the imprint of the editorial craftsmanship of Charles MacCaughey Sames, whose valued services were unexpectedly cut off in the midst of the preparation of the present issue. Elsewhere will be found a brief outline of the life of this unique figure in technical journalism. These few inadequate words are intended as a tribute to the nobility of character and the loyalty of service of one who strove to make this magazine as nearly perfect as it was in his power to do and who maintained for it traditions of worth, dignity, and accuracy.

"The combination of his qualities was unique. The dignified urbanity of his manner cloaked a warm and gracious courtesy. A sparkling sense of humor brought an informal kindliness to his relationships with his colleagues, and with the thoroughness of his culture, based on natural inclinations and an educational and professional experience that wide reading and extensive travel in other lands had augmented, made him a true gentleman, keenly sensitive to human values. An inborn love for the fine arts was expressed at times in his life by playing the piano and painting in water colors. Working for the intellectual enjoyment of the task, he developed a superior craftsmanship, but did not, as others might have done, sacrifice quantity for quality; he was a rapid and an indefatigable worker.

"Anticipating one day the time when the infirmities of old age might force his retirement from active life, he expressed to one of his colleagues the hope that some way might be found whereby he could edit an occasional paper, for he could imagine no happier way in which to end his days. His wish was answered, but not as he had anticipated, for he laid down his pencil one night and left his office in good health and with his usual vigor. Before it was time for him to return for the next day's work, without premonition, illness, or pain, he died.

"Thousands of engineers are in his debt for the papers that through him were spread upon the record, and for the skill with which he prepared their generally inept writings for publication."

EDWIN NASH SANDERSON (1862–1932)

Edwin Nash Sanderson, a member of the firm of Sanderson & Porter, New York, N.Y., and president and a director of the Federal Light & Traction Co. and of its subsidiary companies, died on November 9, 1932, at the New York Hospital.

Mr. Sanderson was born in Brooklyn, N.Y., on December 2, 1862, the son of Elnathan Lawrence and Mary Elizabeth (Nash) Sanderson. He prepared for college at the Brooklyn Collegiate and Polytechnic Institute and was graduated from Rensselaer Polytechnic Institute, Troy, N.Y., in 1886 with a civil engineering degree. He was awarded a mechanical engineering degree at Cornell University the following year and in 1925 Colgate University conferred upon him the honorary degree of Doctor of Laws.

Following his graduation from Cornell Mr. Sanderson took a position as draftsman for the Westinghouse Electric & Manufacturing Co., Pittsburgh, Pa. In 1888 he was transferred to the New York office where he worked as engineering salesman until 1894. He then spent a year at Boston, Mass., as manager of the New England District, after which he was made assistant to the general manager at Pittsburgh. He resigned in 1896 to form, with H. Hobart Porter, the firm of Sanderson & Porter, which specialized in the construction, management, and operation of electric railway, light, and power properties, and later undertook like work for industrial organizations.

Mr. Sanderson's firm began to assemble utility properties soon after its formation, and in 1910 a number of their holdings were assembled as the Federal Light & Traction Co., controlling a group of electric light, power, railroad, gas, and water properties, now more than thirty in number, in the United States and Canada. Mr. Sanderson became a director of the company in 1910 and its president in 1914.

Mr. Sanderson became a member of the A.S.M.E. in 1903. He also belonged to the American Institute of Electrical Engineers, the Rensselaer Society of Engineers, and the Cornell Society of Engineers. He was a life member of the Board of Trustees of Cornell University and served as chairman of the alumni committee for the university's semi-centennial celebration in 1919. Among his clubs were the University, City Midday, Columbia Yacht, St. Andrew's Golf, and Cornell Club of New York (of which he was president from 1916 to 1921); the Westchester Country, Town and Gown of Ithaca, Union Club of St. John, N.B., Adirondack Mountain, Orchard Lake, in the Adirondacks, and the St. Bernard Fish and Game Club of Quebec. He was a member of the Zeta Psi and Sigma Xi fraternities.

Surviving Mr. Sanderson are his widow, Mildred (Hays) Sanderson, whom he married in 1907, and three daughters by his former wife, Sarah Elizabeth Rogers, who died in 1905. The daughters are Helen (Sanderson) Chamberlain, Sybil (Sanderson) Sloane, and Katharine (Sanderson) McCaddon.

KURT G. SANDWALL (1902–1933)

Kurt G. Sandwall, who died on July 2, 1933, after a year's illness, was born on October 24, 1902, in New York, N.Y., and attended public school and Cooper Union there. Since 1920 he had been employed as a draftsman. He was with the New York Edison Company from 1920 to 1924 and again from 1928 to 1930. In the interim he worked for Thomas E. Murray, Inc., Philadelphia, Pa., and Jabez Burns & Sons, New York, except for the summer of 1926, which he spent abroad. During 1930 he was with the Wilputte Coke Oven Corporation, New York, and the following year worked for the Turner Construction Company of that city.

Mr. Sandwall became a junior member of the A.S.M.E. in 1930.

AUGUSTUS MOIR SAUNDERS (1860–1933)

Augustus Moir Saunders, for many years connected with the National Tube Company, McKeesport, Pa., died in Los Angeles, Calif., on May 23, 1933. He retired from business several years prior to his death.

Mr. Saunders was born at Tunbridge Wells, Kent, England, on March 13, 1860, a son of Francis and Sophia Caroline (Wucherer) Saunders. He attended Malvern College, Malvern, England, and served an apprenticeship in the drafting room and shops of Ormerod Grierson & Co., in London, and St. Georges Iron Works, Manchester, before coming to the United States in 1883.

Here he entered the employ of the National Tube Works Company as a draftsman. He was made assistant superintendent of the pipe mill in 1887, took charge of the mechanical department in 1896, and for 25 years was superintendent of the pipe mills, or Upper Division of the National Tube Company. He was also secretary of the Patent Department of the company for more than seven years. Either in his own name or jointly with Peter Boyd he held patents on pipe drawing and well sinking apparatus, well casing, couplers, and drill tubes.

Mr. Saunders became a member of the A.S.M.E. in 1898. He belonged to the Keystone Athletic Club, Pittsburgh, Pa., and was a charter member and for many years chairman of the Grounds Committee of the Youghiogheny Golf Club, McKeesport. He also found recreation in wood carving, water colors, and ship models.

Surviving Mr. Saunders are his widow, Harriett Gillespie (Knapp) Saunders, and four sons, Kenneth, Francis, and William Hurford Saunders, by a former marriage, and Frederick I. Saunders.

WILLIAM LAPHAM SAUNDERS (1875–1933)

William Lapham Saunders, vice-president of D. Saunders Sons, Inc., manufacturers of tools and pipe, Yonkers, N.Y., died at the St. John's Hospital there on June 22, 1933, following an automobile accident.

Mr. Saunders was born at Yonkers on October 25, 1875, and prepared for college in the schools there. He studied mechanical engineering for two years at Cornell University, in the Class of 1899, then returned to Yonkers to associate himself with the firm of D. Saunders Sons, Inc. After working several years as a machinist he was made secretary of the company in 1901. In 1910 he also took the office of vice-president, continuing as secretary until the next year, then serving six years, until 1917, as general manager, as well as vice-president.

Mr. Saunders became a member of the A.S.M.E. in 1928. He also belonged to a number of clubs in New York, Yonkers, and vicinity, including the Bankers, Cornell, and Engineers' in New York, Corinthian Yacht and Amackassin, Yonkers, and Highland Country, Garrison, N.Y. He was a member of the Masonic fraternity.

Surviving Mr. Saunders are his widow, Elizabeth (Stevens) Saunders, three sons, David, Alexander, and James, and two daughters, Eliza and Jean.

WILLIAM F. SELLERS (1856–1933)

William F. Sellers, who retired in February, 1933, as president of the Edge Moor Iron Company, Edge Moor, Del., and who was a director of William Sellers & Co., Philadelphia, Pa., died on June 14, 1933.

Mr. Sellers was born in Philadelphia on March 27, 1856, the eldest son of William Sellers, the founder of both these companies. He attended private schools and was graduated from the University of Pennsylvania in 1876 with a B.S. degree. He immediately entered the employ of the Edge Moor Iron Company as a clerk in the receiving and shipping department. Subsequently he held respectively the position of draftsman, head inspector and shipper, and engineer in charge of the construction, erection of machinery, and operation of the rolling mill. In 1886 he was elected secretary of the company, and two years later, when the Edge Moor Bridge Works was formed, taking over the bridge work of the company, Mr. Sellers was also elected its secretary. He was made treasurer of the Edge Moor Iron Company in 1897 and in 1905 also became its president. Until 1928, when his health began to fail, he directed design and production, planning and erecting buildings, and improvements in plant, machinery, and methods of manufacture. He had been a director of Wm. Sellers & Co., Inc., since 1911.

Mr. Sellers became a member of the A.S.M.E. in 1917 and also belonged to the National Association of Manufacturers and several other organizations.

JAMES A. SHEPARD (1864–1933)

James A. Shepard, who died on June 10, 1933, at his summer home, Kayutah Lake, N.Y., was born at Ohio, Herkimer County, N.Y., on January 6, 1864. At the age of 16 he joined with his father and older brother in establishing a foundry and machine shop in Montour Falls, under the name of W. H. Shepard & Sons, for the manufacture of agricultural implements and for producing special castings.

Four years later, in 1884, he became general manager of the business, which then consisted chiefly of making steam engines and boilers and building bridges. In 1895 the name of the company was changed to the Havana Bridge Works, and he continued as its general manager and chief engineer. The company was sold in 1903 and Mr. Shepard founded the General Pneumatic Tool Company, taking over the business of the machine shop of the bridge works. Mr. Shepard served as general manager and chief engineer for the first two years, then resigned the former position in order to have more time for general engineering work. He continued to act as chief engineer for the company and its successor, the Shepard Electric Crane & Hoist Co.

Several years later the Shepard Company purchased the Sprague Electric Hoist Company and the Niles Crane Company, and reorganized under the title of the Shepard Niles Crane & Hoist Corp. Mr. Shepard was actively engaged with this company as vice-president and consulting engineer up to the time of his death.

Mr. Shepard was a director of the Watkins Glen State Bank and of the Montour National Bank. For many years he was chairman of the Child Welfare Committee of Schuyler County. During the World War he was a county food administrator, and at the time of his death president of the Schuyler County Economic Council. In 1928 he was elected Assemblyman for Schuyler County in the New York Legislature, and served two terms.

Mr. Shepard became a member of the A.S.M.E. in 1914. He was active in the work of the Materials Handling Division, serving on its executive committee for some years, as chairman in 1925–1926. He also served on several subcommittees of the Division, including the Subcommittee on Formula, that on Equipment, and the Materials Handling Manufacturer's Committee. He was also a member of the Society of Terminal Engineers, and the Elmira City and Elmira Country Clubs.

Mr. Shepard is survived by his widow, Frances (Hinman) Shepard, whom he married in 1897.

HJALMAR E. SKOUGOR (1884–1932)

Hjalmar E. Skougor, consulting engineer for the Anglo-Chilean Consolidated Nitrate Corporation, New York, N.Y., died at his residence in Neshanic, N.J., on November 7, 1932. His most recent work was the design of two large nitrate plants constructed by the corporation at Maria Elena and Pedro de Valdivia, Chile.

Mr. Skougor was born at Copenhagen, Denmark, on August 12, 1884, and was graduated from the Technical Institute of that city in 1903 with an M.E. degree. His work during the next few years related to the design of steel structures, including office and loft buildings, warehouses, railroad stations, pier sheds, and theaters. He also assisted in the design of coal and ore handling machinery. For some years he was chief engineer on such construction work.

From 1913 to 1920 Mr. Skougor was associated with the companies directed by Guggenheim Bros., New York. For their Chile Exploration plant at Chuquicamata, Chile, he was designing engineer in connection with the planning and construction of a haulage system, crushing plant, leaching equipment, electrolytic plant, and the various camp facilities. He also directed the design of plants and equipment for the Braden Copper Company at Sewell, Chile.

Mr. Skougor had been responsible for other important industrial design in the course of his work as an independent consultant since 1920. He gained recognition for his original proposals regarding port, terminal, transportation, heating, and lighting projects in the metropolitan area, and presented important plans for the development of the Port of New York. He also designed complete townsite facilities for the Rosita, Mexico, property of the American Smelting & Refining Co., and designed the layout of a complete industrial city, Arvida, Canada, for the Aluminum Company of America.

Mr. Skougor became a member of the A.S.M.E. in 1921 and also belonged to the American Institute of Mining and Metallurgical Engineers.

CHARLES HEAD SMOOT (1878–1933)

Charles Head Smoot, president of the Smoot Engineering Corporation, New York, N.Y., died on January 6, 1933, at the Orange (N.J.) Memorial Hospital. He was the inventor of more than thirty devices for the regulation of steam pressure. Perhaps his best known apparatus was that for automatic steam control used in nearly all large power plants throughout the country.

Mr. Smoot was born at Ilion, N.Y., on December 6, 1878, the son of William Sidney and Mary Bunker (Head) Smoot. He attended Harvard University and the University of California and was employed for a time by small power plants on the Pacific Coast and by the Western Electric Company, Chicago, designing electrical machinery. In 1905 he engaged in designing steam turbines and kindred apparatus as American representative of Professor Rateau. From 1908 to 1922 he was engineer and director of the Rateau Steam Regenerator Company, and from 1911 to 1923 held the same position with the Rateau, Battu, Smoot Company. He became president of the Smoot Engineering Corporation in 1923.

Mr. Smoot became a member of the A.S.M.E. in 1919, and accepted the chairmanship of the newly organized Committee No. 10 on Centrifugal and Turbo-Compressors and Blowers, continuing to serve in that capacity until the committee was discharged in April, 1928. At the time of his death he was a member of the Power Test Codes Committee No. 2 on Definitions and Values. He also belonged to the Inventors' Guild, Engineers' Club, New York, Braeburn Country Club (N.J.), and the Beta Theta Pi fraternity.

Surviving Mr. Smoot are his widow, the former Katherine Elizabeth Ryan, of Freeport, Ill., whom he married in 1910, and three children, Mary Katherine, Charles Head, Jr., and William Sidney Smoot. His home was at Maplewood, N.J.

NORMAN LESLIE SNOW (1881–1933)

Normal Leslie Snow, of New Canaan, Conn., president of the Diamond Power Specialty Corporation, manufacturers of boiler accessories, New York, N.Y., died on January 27, 1933.

Mr. Snow was born on April 18, 1881, in Albany, N.Y., a son of Dr. Norman Leslie Snow and Elizabeth (Smith) Snow. He prepared for college at the Phillips Andover Academy, and received a B.S. degree from the Sheffield Scientific School, Yale University, in 1902, and a Ph.B. from the Massachusetts Institute of Technology two years later.

After leaving college Mr. Snow worked for a time for the Mosher Water Tube Boiler Company, New York, was resident engineer for about two years on the Erie Barge Canal project for the Empire Engineering Corporation, and worked in 1907, 1908, and 1909, respectively, for the Rotary Engineering Company, Sirocco Engineering Company, and American Blower Company, all of New York.

From 1909 to 1922 Mr. Snow was connected with the Terry Steam Turbine Company of Hartford, Conn., working up from the position of assistant general sales engineer to that of vice-president, general manager, and director which he held during the years 1916–1922.

Mr. Snow had been president of the Diamond Power Specialty Corporation since 1922. He was located at the Detroit office of the firm for the first four years and had been in the New York office since then. He was the inventor of many improvements on boiler apparatus.

Mr. Snow became a junior member of the A.S.M.E. in 1910 and a

member in 1926. He belonged to the Tokeneke Club and the Ox Ridge Hunt Club, of Darien, Conn. He was an excellent horseman and played on polo teams in his vicinity.

Surviving Mr. Snow are his widow, the former Helen F. Harris, whom he married in 1909, and two sons, Norman H. Snow and William H. Snow.

CHARLES AUSTIN SOARS (1895–1933)

Charles Austin Soars, president of Soars & Lovelace, Inc., Kansas City, Mo., died on July 13, 1933. Mr. Soars was born on November 5, 1895, in Philadelphia, Pa., the son of Charles A. and Margaret (Wells) Soars. He prepared for college at the Norristown (Pa.) High School, and was graduated from Bucknell University in 1917 with a B.S. degree in chemical engineering.

During the first two years after his graduation Mr. Soars was serving in the Supply Corps of the United States Navy, working for the first year at the Navy Department on the design and construction of coal storage plants and bunkering stations at seaboard points and for the second year at sea as a Supply Officer, and attaining the rank of Lieutenant.

From 1919 to 1926 Mr. Soars was employed by the Standard Oil Company of New Jersey as chemical engineer in the Development Department at Elizabeth, N.J., where he did important experimental work, including the design, construction, and experimental operation of the Ellis cracking units for refineries of the company and its subsidiaries. He was in charge of the construction of a battery of these units at the Bayway Refinery in 1922 and subsequently directed their operation.

During the years 1926–1929 Mr. Soars was connected, first, with the Louisiana Oil Refining Corporation, at Shreveport, La., as manager of refineries, and subsequently as sales and development engineer with the M. W. Kellogg Co., New York, N.Y. He went to Kansas City in 1929 as vice-president and general manager of the Refinery Engineers, Inc. He became president of Soars & Lovelace, Inc., the following year.

Mr. Soars became an associate-member of the A.S.M.E. in 1924. He also belonged to the American Institute of Chemical Engineers and the American Chemical Society, as well as to the Phi Gamma Delta fraternity.

Surviving Mr. Soars are his widow, Gladys A. (Child) Soars, whom he married in 1924, and two daughters, Margaret Helen and Gladys Jean Soars.

CARL GUSTAV SPRADO (1871–1933)

Carl Gustav Sprado, for many years associated with the Allis-Chalmers Manufacturing Company, Milwaukee, Wis., died in that city on April 11, 1933.

Mr. Sprado was born in Hamburg, Germany, on February 21, 1871, and came to the United States in 1883 with his parents, William A. and Elizabeth (Suebberstedt) Sprado, who located in Racine, Wis. Mr. Sprado attended the public schools in Racine until 1890, when he returned to Germany to complete his engineering education, graduating in mechanical engineering in 1892 from the Technikum Einbeck at Hanover.

Returning to this country after graduation he worked on the design of mining machinery for the Ottumwa Iron Works, as mechanical engineer for the Litchfield Car & Machine Co., in charge of all machinery design, on machine design for Fraser & Chalmers, for the Bucyrus Steam Shovel & Dredge Co. on dredging machinery, and for the Nordberg Manufacturing Company as designer of pumps, compressor engines, and other machinery. He entered the employ of the Allis-Chalmers Company as mechanical engineer in the engine department in 1902.

During his thirty-one years with the Allis-Chalmers organization Mr. Sprado devoted his energies almost exclusively to the design of internal-combustion engines and did important pioneer work in the development of large engines for blast-furnace-gas operation. For the last twenty years he was engineer in charge of the internal-combustion engineering division of the company. He held many patents on steam and gas engine parts, and developed one of the first successful motor cycle engines. He had contributed various articles to the technical press.

Mr. Sprado became a member of the A.S.M.E. in 1903 and had served on the Power Test Codes committees on Displacement Compressors and Blowers and Internal Combustion Engines. He was director and charter member of the Engineers' Society of Milwaukee, and belonged to the Westmoor (Milwaukee) Country Club.

Surviving Mr. Sprado are his widow, Anna (Wille) Sprado, whom he married in 1898, and two children, Erma (Sprado) Lubenow and Walter A. Sprado.

LOUIS ALVA STATES (1867–1933)

Louis Alva States, consulting engineer, Gastonia, N.C., was killed in an automobile accident there on April 25, 1933. He is survived by his widow, Annie E. (Williams) States, whom he married in 1906, and by two sons, Louis Alva States, Jr., and Thomas William States, all of Gastonia.

Mr. States was born near Wilmington, Ohio, on January 1, 1867, the son of Abram Henry and Louisa A. (Johnson) States. He attended the public schools of Livingston County, Cornell, Ill., and served a four-year apprenticeship in a power plant under his father, who was a former marine engineer. He then spent a year in the locomotive shops of the Santa Fe Railroad at Streator, Ill., and subsequently was engineer for the Streator Water Works for a short time. Consulting work from 1890 to 1900 took him to many points in the Middle West and East. During this period he made his headquarters at Chicago.

Since 1900 Mr. States had been located in Gastonia. He served as a consulting engineer to a considerable number of cotton mills in Gaston County and elsewhere in North Carolina, remodeling power plants and installing new equipment. He was instrumental in introducing the turbo-electric drive in southern cotton mills and was the inventor of the States sectional grate. At the time of his death he was consulting engineer for the American Yarn & Processing Co., Mt. Holly, N.C., Textiles, Inc., Gastonia, Merco Mills and Glenn Mills, Lincolnton, N.C.; and president of the Eureka Iron Works, Lincolnton, and the States Grate Company, Gastonia. He had contributed articles on steam engineering and combustion to *Power*.

Mr. States became a member of the A.S.M.E. in 1917 and belonged to civic and social organizations in Gastonia and to the Methodist Episcopal Church South there. Total deafness for 35 years prevented military service, but he enjoyed such sports as hunting and fishing and was a violinist.

HORATIO WARD STEBBINS (1878–1933)

Horatio Ward Stebbins, associate professor of mechanical engineering at Stanford University, California, died on February 2, 1933. He had been on the staff of the Department of Mechanical Engineering at Stanford since 1914 and in addition to his teaching duties served as chairman of the committee appointed by President Wilbur to formulate plans for the establishment of a School of Engineering. The following paragraph is taken from a memorial notice by his associate, Prof. Guido H. Marx, published in the Stanford Illustrated Review of March, 1933.

"As a teacher, his work was characterized by a thorough attention to fundamentals. Quite wisely he argued that the superstructure could take care of itself if the foundations were sound, and that no superstructure, however impressive or ornate, could long endure if erected on unsound, insecure foundations. His students always found him friendly and helpful, every ready to give his time to an unhurried clearing-up of difficulties. He had just completed a syllabus for his course in thermodynamics which was a model of selection and logical and compact presentation."

Professor Stebbins was born at San Francisco, Calif., on March 26, 1878. His father, the Rev. Dr. Horatio Stebbins, was a Unitarian minister in San Francisco who was one of those selected by Senator Stanford to aid and advise him in his plans for the foundation of Stanford University and who served on the Board of Trustees from its inception in 1886 until his death in 1902. His mother was Lucy E. (Ward) Stebbins.

Professor Stebbins attended the San Francisco public schools and was graduated from the University of California in 1899 with an A.B. degree and with Phi Beta Kappa honors. He then entered the Massachusetts Institute of Technology, completing his engineering course in 1902 and receiving the degree of B.S.

Returning to the Pacific Coast, he entered the employ of the Southern Pacific Company, Sacramento, as assistant to the engineer of tests, Mr. Howard Stillman. He engaged in general laboratory work, making physical tests and chemical analyses, and was in charge of the operation of water softeners for locomotive water supply. This work aroused in him an interest in railway transportation problems which always remained with him.

From 1905 to 1913 he was connected with the San Francisco Bridge Company as engineer and estimator. While with this company he participated in making the cost estimates for the Fort Mason Transport Docks, San Francisco, and the Pearl Harbor Dry Dock, Hawaiian Islands, designed and built three highway bridges for Lyon and Esmeralda Counties, Nevada, made a complete test of a 20-in. dredge for the company at Los Angeles, and directed other harbor improvement and hydraulic dredging work.

Professor Stebbins became a member of the A.S.M.E. in 1920. His intellectual interests covered a broad field and his reading was exten-

sive, which made his selection as a member of the Palo Alto Public Library Board a most logical and admirable one. He also belonged to the American Association for the Advancement of Science and American Association of University Professors; Engineers and Bohemian Clubs of San Francisco; and the Alpha Tau Omega and Sigma Xi fraternities.

Surviving Professor Stebbins are his widow, Elsa C. (Thompson) Stebbins, whom he married in 1906, and a daughter, Amelia Adams Stebbins.

OSCAR CARL PEDERSEN STENMAR (1893–1933)

Oscar Carl Pedersen Stenmar, who was in charge of research and development work for the Jos. Stokes Rubber Co., Trenton, N.J., died on January 17, 1933. Mr. Stenmar was born at Gosmer, Denmark, on April 1, 1893. He was educated in that country, coming to the United States in the fall of 1913. From then until 1918 he was engaged in general shop work connected with the manufacture of firebrick at the Dedier March Company, Perth Amboy, N.J. He was next engaged for short periods as draftsman on heating and power plant design for the T. A. Gillespie Loading Co., Morgan, N.J., and M. W. Kellogg Co., Jersey City, N.J., and on the design of an automatic wrapping machine for the Any Wrapping Machine Company, Newark, N.J. From 1919 to 1921 he was with the Charles Burroughs Company, Newark, during the latter part of the time as chief draftsman, working on the design of hydraulic machinery and automatic molding dies for bakelite and other compounds.

In 1921 Mr. Stenmar became supervisor of the drafting room and machine shop of the India Rubber Company, New Brunswick, N.J., working particularly on special machinery for hard rubber manufacture. About two years later this plant was transferred to Providence, R.I., as a part of the U.S. Rubber Company. Mr. Stenmar's duties there were the same as at New Brunswick. In 1930 he returned to the Burroughs Company in Newark as chief engineer. He had been with the Jos. Stokes Rubber Co. since 1931.

Mr. Stenmar became a junior member of the A.S.M.E. in 1922 and an associate-member three years later.

ROBERT LEROY STREETER (1880–1932)

Robert Leroy Streeter, consulting engineer and formerly vice-president and general superintendent of the United States Aluminum Company of Pittsburgh, Pa., died at the Veteran's Administration Hospital, Hines, Ill., on December 10, 1932.

Mr. Streeter was born at White Haven, Pa., on March 18, 1880, the son of William Faulkner and Mary Elma (Frear) Streeter. He prepared for college in the White Haven schools and entered Pennsylvania State College in 1899, graduating in 1903 with the degree of B.S. in mechanical engineering. In 1908 he received the degree of M.E. from the same institution. He served as mechanical engineering laboratory assistant for one year at the university and then entered the testing and experimental department of the Packard Motor Car Company, Detroit, Mich., where he remained for a year.

From 1905 to 1910 Mr. Streeter was employed in the construction department of the Lackawanna Steel Company, Buffalo, N.Y. This plant was then under construction and Mr. Streeter devoted his time there for four years to power research investigations and to erection work combined with testing, covering the first large installation of Koerting blast-furnace-gas engines for blowing and power purposes. This was a pioneer installation of large blast-furnace-gas engines in this country. For several years he also had charge of steam and electrical engineering courses in the Buffalo Technical Night High School, and when the attendance became so large that a separate day school was built he was also placed in charge of its machine design and experimental engineering courses.

In 1910 Mr. Streeter joined the teaching staff of Rensselaer Polytechnic Institute, Troy, N.Y. He was assistant professor of mechanical engineering for four years and professor of steam and gas engine design for three years. During this time he was engaged in consulting work and wrote many articles for the technical magazines. His book entitled "Internal Combustion Engines" has had three printings and has been widely adopted as a college textbook.

Mr. Streeter was commissioned a captain in the Ordnance Department of the U.S. Army in April, 1917, and stationed at Rock Island Arsenal. He was at first put in charge of testing and experimental work on automotive equipment and artillery materiel. Subsequently he served as armament officer for nineteen states, chief engineer, works manager, and general manager. The arsenal had about 14,000 civilian employees. His rank was advanced to that of major and he was discharged in 1919 as a lieutenant-colonel.

After his discharge Mr. Streeter joined the Aluminum Company of America and formed the mechanical engineering department. He directed this work for one year. He was then elected vice-president and general superintendent of the United States Aluminum Company, a subsidiary. During the following eleven years he was general superintendent of all manufacturing plants, making sheet, tubing, rod, wire, transmission cable, foil, powder, bottle caps and seals, extruded and rolled sections, heavy plates, and many other specialties. During this time he had general supervision of the mechanical engineering department. He was responsible for the expenditure of between fifteen and twenty million dollars used in the building of new mills and modernizing old ones, and directed the development of many new manufacturing processes which reduced cost and improved quality. The work also included the design and manufacture of many kinds of machines, rolling mills, stamp mills, printing presses, automatic machinery, and special machines peculiar to the fabrication of aluminum and its alloys.

Mr. Streeter joined the A.S.M.E. as an associate in 1907 and had been a member since 1913. He was also a member of the main Research Committee of the Society from 1926 to 1930 and its chairman in 1929-1930. At the time of his death he was a representative of the A.S.M.E. on the Division of Engineering of the National Research Council and an associate member of the Executive Committee of the Iron and Steel Division of the Society.

Mr. Streeter was co-author with Dr. P. V. Faragher of a paper entitled "Aluminum and Its Light Alloys," presented at the Milwaukee, 1925, meeting of the A.S.M.E. and revised and published by the authors in pamphlet form in 1927. He presented a paper on "The Rolling and Extrusion of Aluminum and Its Alloys" at the December, 1932, meeting of the Society.

Surviving him are his widow, Louise (Rapalje) Streeter, whom he married in 1907, and four daughters, Mrs. Paul Franklin Eves, Oakmont, Pa., Jean Rapalje Streeter, Barbara Frear Streeter, and Anne Richards Streeter. He also leaves one son, Robert Leroy Streeter, Jr., of Oakmont, Pa.—Curtis C. Myers.[1]

ARTHUR CHARLES TAGGE (1870–1932)

Arthur Charles Tagge, a member of the Board of Directors of the Canada Cement Company Limited, Montreal, Quebec, Canada, died at his home in Monroe, Mich., on December 6, 1932. He retired as president of the company in 1930.

Mr. Tagge was born on January 31, 1870, in Ann Arbor, Mich. He received a B.S. degree from the Engineering Department of the University of Michigan at the age of twenty-seven, several years of teaching in Monroe having delayed the completion of his course.

After securing some drafting and shop experience at the Frontier Iron Works in Detroit and with Bissell, Dodge and Erner in Toledo, he took a position as draftsman with the Link-Belt Machinery Company, Chicago, where he worked until January, 1900. For the next fifteen months he was employed by the Osborn Engineering Company, Cleveland, in the design and construction of a cement plant for the Peninsula Portland Cement Company, Woodstock, Mich. He was mechanical engineer and mill superintendent for this plant in 1901 and 1902.

Mr. Tagge then became associated with the group which formed the International Portland Cement Company, of Ottawa, Ontario, and remained with that company for three years in the capacity of engineer and operating advisor. He was next connected, in a similar capacity, with the Western Canada Cement & Coal Co. A few years later, when the Canada Cement Company Limited was formed as a consolidation of the principal cement plants of the Dominion, Mr. Tagge became its general superintendent. The consolidated company operated a chain of 14 plants, then the most extensive cement mill operation of any single corporation, and Mr. Tagge distinguished himself in the work of standardizing and securing greater economy of operation.

He subsequently became general manager and later vice-president and director of the company. After six years as vice-president he was elected to the presidency in 1927 and in that capacity directed the very outstanding program of rehabilitation which the company carried out, entirely rebuilding a number of its principal manufacturing units and modernizing others.

Since his retirement in 1930 Mr. Tagge had made his home at Monroe, where he enjoyed his flowers and art treasures. His death was the result of a heart ailment with which he had suffered for some time.

During his active years in the cement industry Mr. Tagge held many important committee appointments in the Portland Cement Association, the most outstanding of which was his long chairmanship of the committee on accident prevention and insurance. A year after his retirement he was unanimously elected an honorary member

[1] Buffalo, N.Y. Mem. A.S.M.E.

of the Portland Cement Association, being one of only three men who have ever been accorded this distinguished recognition. Mr. Tagge became a member of the A.S.M.E. in 1901.

JOHN EVAN TAYLOR (1889–1933)

John Evan Taylor, since 1927 connected with the Central Railroad Company of New Jersey, died on May 31, 1933. He was at first estimator in the Motive Power Department at Jersey City, N.J., and at the time of his death locomotive draftsman in the office of the mechanical engineer at Elizabethport, N.J.

Mr. Taylor was born at Picton, Ontario, Canada, on August 25, 1889. He was graduated from the College of Applied Science of Syracuse University with an M.E. degree in 1912 and during the next two years was employed at the Depew Shops of the New York Central Railroad, Depew, N.Y. For several months in 1914 he was with the chief mechanical engineer of the road, in charge of locomotive road tests and locomotive design. He was then transferred to the DeWitt Engine House at East Syracuse as assistant foreman.

From 1915 to 1918 Mr. Taylor was connected with the Locomotive Superheater Company, New York, as engineering inspector in charge of the manufacture, installation, and inspection of locomotive superheaters at various plants of the American Locomotive Company, Lima Locomotive Works, and Canadian Locomotive Works.

Mr. Taylor enlisted in the United States Army in April, 1918, and served for more than a year in France with the Transportation Corps. After his discharge in 1919 he returned to the employ of the Locomotive Superheater Company, working in the New York office on superheater design. He left there in 1922 to take a position in the Service Department of the Simmons-Boardman Publishing Company, New York, where he remained for several years before entering the employ of the Central Railroad Company of New Jersey.

Mr. Taylor became a junior member of the A.S.M.E. in 1914 and an associate-member in 1921.

LEON IRVING THOMAS (1884–1933)

Leon Irving Thomas, vice-president and secretary of the Gage Publishing Company and editor of *Electrical Manufacturing*, New York, died on July 30, 1933, at his summer home at Pocasset, Mass.

Mr. Thomas was born on October 2, 1884, at Brockton, Mass., the son of Myron Franklin and Mary M. (Tallman) Thomas. He attended the Brockton High School and took the electrical engineering course at Worcester Polytechnic Institute, receiving his B.S. degree in 1907.

During the first two years after his graduation Mr. Thomas was personal laboratory assistant to Dr. Lee De Forest, wireless telephone and telegraph expert and inventor, and in 1909 was appointed factory superintendent of the De Forest Radio Telephone Company in Newark, N.J. The following year, after working for a few months on wireless design and construction with Mr. Fritz Lowenstine, consulting engineer, he took a position in the traffic department of the American Telephone & Telegraph Co. He was associated with this company for two years, the most of which time he spent as assistant traffic chief in the Chicago office.

Mr. Thomas entered the publishing field in 1912, when he joined the A. W. Shaw Company, Chicago, as associate editor of *Factory*. In 1915 he became managing editor of that magazine and in 1925 was appointed editor of *Industrial Power*. Meanwhile he had also been an advisory editor of *System* and was an editor and co-author of the "Library of Factory Management" and of several business administration textbooks for La Salle Extension University. In 1929 he left Chicago and joined the Gage Publishing Company as managing and engineering editor. He had been vice-president and secretary and editor of *Electrical Manufacturing* for the past three years.

Mr. Thomas had been an associate-member of the A.S.M.E. since 1916. He also belonged to the Society of Industrial Engineers, the New York Electrical Society, Engineers' Club, New York, and the Sigma Alpha Epsilon fraternity. He is survived by his widow, Grace (Howe) Thomas, and by two daughters, Barbara and Priscilla Thomas. His home was in Montclair, N.J.

SIR HENRY WORTH THORNTON (1871–1933)

Sir Henry Worth Thornton, who resigned as president of the Canadian National Railways in 1932, died at the Doctor's Hospital, New York, N.Y., on March 14, 1933. He was internationally known as a railroad executive, having been associated with leading roads in the United States, Canada, and England, and a prominent figure in transportation work during the World War.

Sir Henry was born at Logansport, Ind., on November 6, 1871, the son of Henry Clay Thornton and Millamenta C. (Worth) Thornton. He was sent to St. Paul's School, Concord, N.H., to prepare for college, and was graduated from the University of Pennsylvania as a civil engineer in 1894, having not only made a brilliant scholastic record but also taking a leading part in athletics, playing football and breaking records in various track meet events. He was a tall, heavily built man, and throughout his life continued to enjoy sports, playing tennis, golf, and handball, and riding and hunting.

He coached the Vanderbilt University football squad during the autumn after his graduation and then found work as a draftsman in the office of the chief engineer of the Southwest System of Pennsylvania Railroad lines west of Pittsburgh. The next year he was made assistant engineer of construction of the Pennsylvania's Cleveland and Marietta line and subsequently was supervisor of the yards at Columbus, assistant engineer of the Cincinnati Division, engineer of maintenance of way, Erie & Ashtabula Division, and superintendent of the Cleveland, Akron & Columbus R.R. Early in 1911 he was sent to New York, and later in the year was made general superintendent of the Long Island Railroad.

When Mr. Thornton had been with the Long Island Railroad for about three years he was invited to England to take over the management of the Great Eastern Railway, in an endeavor to build up its business. Although the appointment of some one outside England was regarded with disapproval in many quarters, his ability to handle the task was soon recognized and he was later made a member of the executive committee of railroad managers which, under the direction of the government, controlled and worked the English railways during the World War. He was made an honorary lieutenant colonel in the Royal Engineers when he entered upon war work, and in 1915 was promoted to the rank of colonel and placed in charge of cross-Channel transportation. His next assignment was that of deputy director of inland water transportation in charge of navigation in northern France, Egypt, and Mesopotamia. In 1917 he was promoted to assistant director general of movements of railways, with headquarters in Paris, and received the rank of brigadier general. During the last year of the war he was inspector general of transportation with the rank of major general.

Mr. Thornton had become a British citizen during the war and in 1919 he was knighted by the King. France made him a companion of the Legion of Honor, Belgium conferred upon him the cross of an officer of the Order of Leopold, and his native country gave him the Distinguished Service Medal. He was given a D.Sc. degree by the University of Pennsylvania in 1923.

In the years immediately following the war, in addition to railway reorganization, Sir Henry served on a committee to investigate operations and financial conditions of the Metropolitan Water Board of the City of London.

His return to this continent came in 1922 when he was asked to become president and chairman of the board of the Canadian National Railways. He spent several months traveling over the various lines, moved the headquarters from Toronto to Montreal, and at the end of the first year showed a net operating income of more than three million dollars, as against a deficit of more than eleven million on the previous year's income account.

The improvement continued year by year until, in 1928, net operating revenues reached 60 millions—sufficient to pay the interest on all the securities of the system held by the public. Sir Henry's greatest service to the Canadian National Railways, perhaps, was his welding of the several separate constituent companies into a unified and harmonious system. There is no more difficult managerial problem than that of making two or three organizations into one, with the conflicts of precedence which inevitably follow. This task Sir Henry accomplished in a remarkably short space of time and in such a way that the morale of the staff not only did not suffer, but was greatly improved, and the C.N.R. as a result of his policies soon drew attention by the enviable esprit de corps shown by all ranks of its employees.

Since his resignation in 1932 Sir Henry had spent the most of his time in Florida and Cuba, endeavoring to restore his failing health.

In 1901 Mr. Thornton married Virginia Dike Blair, of New Castle, Pa., from whom he was divorced in 1926. He is survived by their two children, Anna Blair and James Worth Thornton, and by his second wife, Martha (Watriss) Thornton.

Sir Henry became a member of the A.S.M.E. in 1917.

JOSEPH JAMES TYNAN (1871–1933)

Joseph James Tynan, who died in San Francisco, Calif., on June 6, 1933, was born in County Tyrone, Ireland, on October 8, 1871, a son of Robert and Elizabeth Tynan. He had the equivalent of a grammar and high school education in that country and after coming to the United States in 1890 attended the Spring Garden Institute,

Philadelphia, Pa., and served an apprenticeship at the Philadelphia Engineering Works. He was then employed as a journeyman at the Wm. Cramp & Sons Ship & Engine Building Co., Philadelphia, subsequently rising to the position of general superintendent. He became a naturalized citizen in 1896.

Mr. Tynan had been with the Bethlehem Shipbuilding Corporation, Ltd., San Francisco, since 1906, becoming vice-president in 1909. He was the builder of the Columbia River-Longview Bridge, and among his other achievements was the building of ten submarines in five months' time for the British Admiralty in Montreal, Canada, during the World War. He was awarded a gold medal by Charles M. Schwab, then director of the Emergency Fleet Corporation, for merchant vessels delivered during the War.

Mr. Tynan became a member of the A.S.M.E. in 1922 and belonged to a number of clubs in San Francisco. He was a member of the Board of Police Commissioners of San Francisco in 1930 and had been a member of the Board of Harbor Commissioners of the State of California since 1931.

Surviving Mr. Tynan are his widow, Ruth (Williams) Tynan, whom he married in 1922, and their daughter, Ruth P. Tynan, and two children by a former marriage, Joseph J. Tynan, Jr., and Mrs. Margot (J. Curtis) Taylor. His first wife, whom he married in 1902, was Margaret McGinty.

WILLIAM CAWTHORNE UNWIN (1838–1933)

In 1890, when the Cataract Construction Company began laying plans for the large-scale development of power at Niagara Falls, the problem of the engineering features involved was referred to an international commission consisting of Sir William Thomson (Lord Kelvin), president, Dr. Coleman Sellers, Prof. E. Mascart, of Paris, France, Col. Theodore Turrettini, of Geneva, Switzerland, and Prof. William Cawthorne Unwin, secretary.

The modern age to which the younger engineers now practising belong finds it hard to understand the uncertainties that faced this commission. For the generation of electricity in large amounts by hydraulic turbines, the transmission of the current generated over long distances, its distribution and use in mechanical and chemical industries, and hundreds of technical problems such as the relative advantages of alternating and direct current were being attacked in pioneer fashion. Nor was it certain that the development should be an electrical one. Electricity was new; it had never been generated centrally in large quantities for distribution over long distances to points where it could be used. While lighting by electricity had been broadly introduced, industrial power was still largely secured by mechanical means. The Evershed project, upon which the Niagara scheme was based, was entirely hydraulic and contemplated a community of industries deriving their power from individual hydraulic turbines fed from a common canal—the use of power at the site. Mechanical (telodynamic) and pneumatic transmission systems were in a position to contend for consideration with hydraulic, steam, and gas methods of transmission and distribution. Moreover, the machinery and auxiliary apparatus, as well as the construction of the hydraulic details, were of a scale heretofore untried, so that the stakes, engineering as well as financial, were high and hazardous. Professor Unwin's book, "On the Development and Transmission of Power From Central Stations," comprising the Howard lectures delivered before the Society of Arts in 1893, contains his reflections on the methods in use and proposed at that time, and is indicative of the state of the art when the Niagara development was under consideration.

Professor Unwin, as secretary of the international commission conducting, on behalf of the Cataract Construction Company, the contest for the best solution of the Niagara problem, received the great variety of plans and proposals that were offered and, in 1893, wrote the report in which they were analyzed and appraised. It was this service that brought him into most intimate relationship with engineering on this continent and won for him, in 1898, honorary membership in The American Society of Mechanical Engineers.

Writing 25 years later of the work of the Commission, Professor Unwin said: "The projects were of extremely varied character. Hydraulic turbines of impulse and reaction types of from 2000 to 10,000 horsepower; distribution by electricity, by compressed air, and by wire ropes. Most of the electrical schemes proposed direct-current production and distribution with varying current and constant voltage. Messrs. Siemens proposed constant direct current at varying voltage; Professor Forbes only proposed alternating current. From the first, electrical distribution of the power was in favor, but was not definitely decided upon until May, 1893." Of the significance of the project itself he wrote: "Civilization may be measured by the degree in which human labor is replaced by power derived from natural sources of energy. . . . At Niagara some 7,000,000 horsepower which might have been available for industrial purposes was being wasted. The conditions were favorable for utilization in other respects, for the fall was a high one and the Great Lakes from which the water flows act as reservoirs equalizing the supply. The installation has been carried out with complete success, and it is the first large-scale undertaking of the kind. It has been the parent of many others in different parts of the world, or at any rate showed the way to others to achieve a similar success. But the risk of misadventure in so novel and complicated an enterprise in the days when it was carried out was great, and that no serious mistake of judgment or calculation occurred witnesses to the remarkable care with which the preliminary investigations and discussions were conducted."

The Niagara decisions were momentous ones and have had their effect on the industrial and engineering development not only of the district immediately surrounding Niagara Falls and the city of Buffalo, but of the rest of the country and the world at large. For success at Niagara led the way to future developments, and gave a decisive answer to the major policies affecting the generation, transmission, and distribution of hydro power for years to come. It made feasible the development of sources of hydro power that are remotely located with respect to centers of population and ultimate use. It raised social, economic, and political problems in controversies over which this country in particular is still enmeshed. While many engineers and financiers were engaged in the historic events of those days, Professor Unwin played an important part that was in keeping with his character, training, and methods of work. For Professor Unwin was primarily a teacher and an investigator who analyzed and rationalized engineering science and practice and put the results of his studies and experiences in such a form as to make them available for all men, in all lands, and for all time.

William Cawthorne Unwin was born on December 12, 1838, at Coggeshall, Essex, the son of Dr. W. J. Unwin, principal of Homerton College. Following his education at the City of London School, he was, by good fortune, associated in Manchester with Sir William Fairbairn, whose contributions to engineering literature and research have kept his memory alive. Fairbairn found in the young Unwin a man of similar aptitude and zeal for research and rational statement of empirical practices. Together they conducted a series of tests on the properties of steam, the strength of plate girders, and the collapse of tubes. By 1861 Unwin was manager of an engineering works manufacturing the vortex hydraulic turbine, where he acquired that personal contact with men and engineering practice without which the research worker and scholar are likely to remain impractical theorists.

Professor Unwin's career as a teacher began in 1868 with an appointment as professor at the Royal School of Naval Architecture and Marine Engineering in South Kensington. Four years later he was made professor of hydraulic engineering at the Royal Indian Engineering College, Coopers Hill, and in 1884 became the first professor of engineering at the Central Technical College of the City and Guilds of London. In the fulfilment of this office he rendered notable services to the school and to engineering education, and continued with his researches on the steam engine and the mechanics of materials.

No student of engineering can have escaped the influence of Professor Unwin's work. If his most notable textbooks, "The Elements of Machine Design," "Wrought Iron Bridges and Roofs," and "Testing Materials of Construction," are today not actually studied, for indeed they have been replaced by more modern texts, no later books on any of these subjects, or upon hydraulics, can be found without reference to his work, or without a formula bearing his name. For it was his especial ability to study the underlying theory, the practice, and the experimental researches in connection with these subjects and to evolve fundamental formulas upon which engineers and designers could place reliance. While no great engineering structure stands today called by his name because his genius brought it into being as concrete evidence of a man's ability to perform spectacular engineering feats, it would not be an exaggeration to say that his work influenced those who have erected such monuments and provided at least some of the tools wherewith the designer worked.

One other factor of Professor Unwin's interests deserves comment in this brief review because of the importance that engineers in this country are today attaching to it. This is his work for the advancement of the professional status of the engineer and the esteem in which the profession is held. He was president, in 1911, of the Institution of Civil Engineers, and, in 1915, of the Institution of Mechanical Engineers. To both of these institutions he devoted much time and labor in the development of examinations for membership. His addresses before these institutions will repay careful reading, particularly those parts that refer to engineering education, research, the induction of young engineers into the profession, and the value of engineering societies to their members. On this final topic a paragraph from his 1915 address is worthy of quotation. He said: "The Institution as a corporate body of men of similar avocations is a

source of strength to all its members. It gives publicity to the work of engineers, which is essential in creating the estimation in which they are held by people outside the profession. It is able to secure facilities and gifts, and it elicits and records information of great value which would otherwise remain private property. One has heard of persons who think that because they cannot attend the meetings in London, and have no time to study the Proceedings, they can get no benefit from the Institution. The case is rather an extreme one. Bacon said that every man is a debtor to his profession, and it follows that he has a duty to support whatever benefits it. Most of us subscribe to objects from which we expect no direct recompense, and few engineers could say that they receive no indirect benefit from the work done here. Knowledge diffuses itself in various channels, and improvements in industrial methods bring advantage to many who do not know where they originate."

Professor Unwin died on March 17, 1933. In an appreciative obituary in *Engineering* it is said: "In him has passed away a great teacher, a sound engineer, and a fine character."—G. A. S.

ROBERTO JUAN URIE (1886–1933)

Roberto Juan Urie, technical director of illuminating, electrical, and mechanical engineering for the city of Tucumán, Argentina, South America, died on April 30, 1933. He was born at Ayacucho, Province of Buenos Aires, Argentina, on February 6, 1886. He secured his elementary education at English and North American schools in the city of Buenos Aires, and in 1903 completed the national college course of secondary education in that city. In 1910 he completed the first year in civil engineering at the Buenos Aires University. From 1911 to 1915 he studied electrical and mechanical engineering at the Royal Technical College, Glasgow, Scotland, acquiring practical experience at the same time in various departments of the North British Locomotive Company in Glasgow. During the next year he was assistant in the technical office of the Argentina State Railways Works at Tafi Viejo. He was then appointed "Director Técnico de Alumbrado e Instalaciones Eléctricas y Mécanicas," Tucumán, Argentina.

Mr. Urie became an associate-member of the A.S.M.E. in 1930. He also belonged to the American Institute of Electrical Engineers and the Asociacion Argentina de Electro-Técnicos.

ANTON E. WEINGARTNER (1870–1933)

Anton E. Weingartner, designing engineer with the American Engineering Company, Philadelphia, Pa., died on February 5, 1933.

He was born in Budapest, Hungary, on September 12, 1870, and attended the Arad, Hungary, high school and the technical institute in Funfkirohen. After his graduation as a construction engineer in 1889 he was draftsman and assistant to the master mechanic of the Edmond Hendl Brass Foundry and General Machine Shop in Arad for a year, and spent the following year as junior foreman with the National Harvester Company, in Budapest, manufacturing portable engines, locomobiles, and agricultural machinery.

Mr. Weingartner came to the United States in 1891 and for 26 years was associated with the Bethlehem Iron Company and Bethlehem Steel Company, Bethlehem, Pa. During the first ten years his work included drafting for plant construction, designing heavy machine tools and other plant equipment, and reconstructing blast furnaces. He spent three years in designing and building hydraulic press equipment and power machinery and two in rolling mill engineering, in the staybolt mill and crucible steel plant, after which, in the summer of 1905, he visited a number of countries abroad, investigating steel and rolling mill practice in general and the manufacture of steel products. After his return he assisted in the reconstruction of the Saucon Plant of the Bethlehem Steel Company, and then for nearly ten years was engaged in plant construction and ordnance equipment work. In 1916 he entered upon sales engineering work for the company, in the heavy machinery department, becoming sales agent in charge of the machinery department the following year.

Mr. Weingartner terminated his connection with the Bethlehem Steel Company in May, 1918, and for a short time carried on a machinery business of his own in Bethlehem. Since then he had been with the American Engineering Company.

Mr. Weingartner was credited with the design of the electro-hydraulic steering gears used on the navy airplane carriers, the *Lexington* and the *Saratoga*. He also designed and patented a device intended to allow men imprisoned in a sunken submarine to make their escape without assistance and was the inventor of a water motor for washing machines and patented numerous inventions in connection with stoker and marine equipment.

Mr. Weingartner became a member of the A.S.M.E. in 1923.

WILLIAM WALLACE WEST (1877–1933)

William Wallace West, who died at his home in Elyria, Ohio, on May 20, 1933, was born at Johnstown, Pa., on July 13, 1877, the son of Emery and Amanda (Berry) West. He attended the Johnstown public schools and the Rowe Business College there, and in later years took correspondence, Y.M.C.A., and library courses in technical subjects.

His first employment, at the age of 17, was with the Cambria Steel Company, Johnstown, and he continued with that company until 1910. He then spent four years with the Colorado Fuel & Iron Co., Pueblo, three with the Crucible Steel Company, Midland, Pa., and two with the Wilmington Steel Company, Wilmington, Del. Since 1919 he had been with The Elyria Iron & Steel Co., Elyria, Ohio, as general superintendent for the past 12 years.

Mr. West became an associate member of the A.S.M.E. in 1922. He served in Company H of the 5th Pennsylvania Volunteer Infantry in the Spanish-American War and belonged to the Veterans of Foreign Wars and the Spanish-American War Veterans. He also was a member of the Sons of the American Revolution and of the Elks and the Masonic fraternity. He was director of the Elyria Chamber of Commerce and attended the Methodist Church.

Surviving Mr. West are his widow, Bertha M. (Patterson) West, whom he married in 1899, and two daughters.

CLARENCE E. WHITNEY (1869–1933)

Clarence E. Whitney, a leading manufacturer of Hartford, Conn., died suddenly of a heart attack at his home in that city on January 22, 1933. He was president of the Whitney Manufacturing Company, the Hartford Faience Company, and the Liberty Street Realty Company, and secretary-treasurer of the Hanson-Whitney Machine Company. He started the Whitney Manufacturing Company in 1896, taking over the small Woodruff Manufacturing Company at Colt's West Armory, and helped to found all of these companies. He was also a director of the S.K.F. Ball Bearing Company, for some time located in Hartford.

Mr. Whitney was born in Hartford on November 26, 1869, the son of Amos Whitney, one of the founders of the Pratt & Whitney Co. He attended the Hartford public schools and at the age of eighteen entered the Massachusetts Institute of Technology, where he studied mechanical engineering for three years. He worked in the Pratt & Whitney shops for a year between the completion of his high school work and entrance to M.I.T. and again during the summer of 1890. In the fall of that year, instead of returning to college, he took advantage of an opportunity offered him by his father to spend a year in Europe. He went to Germany and from then until July, 1891, worked in the designing department of Ludwig Loewe & Co., in Berlin, while studying industrial methods there and at other plants in Germany. He then returned to Hartford and until 1896 was part of the Pratt & Whitney organization, working in many departments and in the office and on the road for the company.

The Whitney Manufacturing Company at first conducted tests on the use of roller bearings for bicycles, for the Hyatt Roller Bearing Company. This work led Mr. Whitney into the manufacture of bicycle chains, and later the manufacture of automobile chains was undertaken. It was not long before larger quarters were necessary and the company built its own plant. Under Mr. Whitney's direction new types of chains were developed as required by the automotive industry, in which the company has taken a leading place.

In 1894 at the request of Eugene Atwood, Mr. Whitney helped to form the Atwood Faience Company, which made slow progress at first and from which Mr. Atwood withdrew after a few years. It was reorganized as the Hartford Faience Company and has continued the manufacture of this special type of earthenware.

The Hanson-Whitney Machine Company was organized in 1919 for the manufacture of taps, gages, and hobs.

Mr. Whitney was a supporter of the principle of the open shop and devoted a considerable share of his time and money to the cause. He constantly sought to increase the efficiency of his plants and was recognized and respected as an energetic and courageous leader, devoted to the maintenance of Hartford's prestige in industry.

Mr. Whitney was very active in the National Metal Trades Association and was affiliated with the National Association of Manufacturers and the Manufacturers' Association of Hartford County for many years. He was instrumental in forming the Employers' Association of Hartford and was its first president. During the World War he was a leader in Liberty Loan and Red Cross campaigns and shortly afterward conducted a drive for funds for new buildings for the Newington (Conn.) Home for Crippled Children.

Mr. Whitney became a member of the A.S.M.E. in 1911. He was a member of the Question Club, a group of 75 leading manufacturers in the United States and Canada, the Engineers' Club, New York,

the Masonic and Theta Delta Chi fraternities, Sons of the American Revolution, and a number of clubs in Hartford and vicinity.

Surviving Mr. Whitney are his widow, Nellie (Hurlburt) Whitney, whom he married in 1900, and four children, Mrs. Robert P. Stevens, Plainfield, N.J., Mrs. John L. Hawkinson and Lawrence Amos Whitney, Hartford, and Winthrop Hurlburt Whitney, Los Angeles, Calif.

FLOYD ELLIS WILDER (1878–1933)

Floyd Ellis Wilder, chairman of the Executive Committee of the Printing Industries Division of the A.S.M.E., died on August 12, 1933, at his home in New York, N.Y., after an illness of several weeks. Mr. Wilder, who became a member of the Society in 1930, had been active in the work of the Division for several years, assisting in preparing the programs for its annual conferences and furthering its activities in other ways. He had been chairman of the Executive Committee during the past year.

Mr. Wilder was born at Wacousta, Mich., on September 27, 1878, the son of Jason and Louisa (Tyler) Wilder, the latter a descendant of President Tyler. He was graduated from the Wacousta High School and studied mathematics and mechanical drawing under private tuition for about a year. He then obtained a position as general assistant to the plant engineer of the Lake Lumber Company, Lake, Mich., working in different mills for a year prior to the Spanish-American War. He was in service during the War and subsequently in the Philippines and then was commissioned a captain in the 14th Infantry of the New York National Guard.

In 1900 Mr. Wilder went to New York where he learned the printing trade in the plant of the Robert L. Stilson Company. In 1907 he entered the employ of the P. F. Collier & Son Company, New York, as assistant superintendent. In 1909 he was made superintendent, and a year later director of production and assistant to the president, which position he held until 1925. During that period he designed and supervised the entire manufacture of many pieces of machinery. Among these was a complete conveying system for handling roll paper on the ceiling, using a monorail track. He helped to design several improvements for the Hoe web press and designed and manufactured the equipment necessary for instantaneous splicing of paper rolls used on web presses. Other equipment designed by Mr. Wilder include an automatic feed for book smashing machines, an attachment for Smythe casemaking machines for making flexible cases for books, and an automatic metal furnace for use in backing up electrotypes.

After leaving the Collier company Mr. Wilder was associated briefly with the Conde Nast publications and in 1925 became production manager in charge of printing for the International Magazine Company, Inc., New York, publishers of the Hearst magazines.

Mr. Wilder was one of the organizers and a former vice-president of the New York Club of Printing House Craftsmen, now the National Association of Printing House Craftsmen, and was secretary of the New York Employing Printers Association, Inc.

Surviving Mr. Wilder are his widow, Martha (Middleton) Wilder, and a son by a previous marriage, Robert Wilder.

AAGE E. WINCKLER (1881–1933)

Aage E. Winckler, president and chief engineer of the Winckler Engineering Company, Milwaukee, Wis., died suddenly at his home in that city on January 25, 1933.

Mr. Winckler was born in Copenhagen, Denmark, on November 7, 1881, a son of Oscar and Laura Winckler, and received his early education there. After a year's apprenticeship in a Copenhagen factory he entered the technical high school in Ilmenau, Germany. For his university training he went to Zurich, Switzerland, and later to Karlsruhe, Germany, where he secured a mechanical engineering degree in 1904.

For a short period after his graduation Mr. Winckler studied factory organization and automotive manufacturing at the Daimler Motoren Gesellshaft (manufacturers of the Mercedes car), Stuttgart, Germany, and Rheinische Automobilwerke, Aachen, Germany. In 1905 he returned to Copenhagen and became mechanical engineer for the Dansk-Automobil-Selskab, organizing automobile mail and passenger routes and supervising the construction of buses for use on them at several automobile plants in France. From 1906 to 1909 he was engaged in developing a taxicab service for Copenhagen. Under his supervision the cabs were designed and built at Uhren Cotthaus & Co., Cologne, Germany, and the service was introduced and managed by the Aktieselskabet Automobil Korsel Kompagniet, of which he was president and general manager.

Mr. Winckler came to the United States in 1909 and during the next few years handled development work on a rotary airplane motor and racing cars, as chief engineer of the automobile department of the J. I. Case Threshing Machine Co., Racine, Wis. The Lorenz Motors Company, Racine, which was organized in 1912 and of which he was president, carried on special development work on motors and automobiles for the Case company during the following year, and Mr. Winckler again served the company as chief engineer from 1913 to 1916.

In 1916 Mr. Winckler visited Europe and after returning to this country spent half a year with the Pittsburgh Model Engine Company, after which he returned to the Lorenz Motors Company to take charge of development and research work on aeronautical motors for the United States Navy.

In 1920 the Lorenz Motors Company was reorganized under the name of The Winckler Engineering Company, with Mr. Winckler as president. The company was located in Milwaukee, Wis., and specialized in the development of small, light-weight, high-speed compression-ignition automotive motors and direct, synchronized, airless-fuel-injection systems for them. He held patents on his work in the United States and a number of foreign countries.

Mr. Winckler became a member of the A.S.M.E. in 1930 and also belonged to the Society of Automotive Engineers.

He is survived by his widow, Else (van Norde) Winckler, whom he married in 1905, and by two children, Per van Norde and Margot van Norde Winckler.

ROBERT WOOD (1874–1932)

Robert Wood, consulting engineer, specializing in problems relating to superheat, locomotives, and internal-combustion engines, died suddenly of heart failure on November 24, 1932, at Newlands, Garwick, Isle of Man, England, where he had lived since his retirement in 1921. He is survived by his widow, Pearl F. Wood.

Mr. Wood was born on September 8, 1874, in Edinburgh, Scotland. After a five-year apprenticeship he was employed by the firm of Hick Hargreaves & Co., Ltd., of Bolton, Lancashire, England, to install and supervise plants for the company. He also was engaged to supervise the installation of bleaching machinery for the firm of Jackson Bros. Wharf Foundry, Bolton, which likewise dealt in paper manufacturing and rolling machines.

At the age of thirty, Mr. Wood opened an office in Bolton for consulting engineering, his specialty being the lubrication of steam-engine cylinders, and the firm of Robert Wood & Co., Ltd., was established to manufacture his patent lubricators. After a visit to the United States in 1908 he decided to return to this country to live. In 1911 he gave up his Bolton office and went to Montreal, Canada, to complete some consulting work for the Robert Mitchell Co., Ltd. Two years later he allied himself with the Nathan Manufacturing Company, New York, as works manager. He specialized on the locomotive from a lubrication standpoint and also designed the company's mechanical equipment, such as balance valves, coal sprinklers, vacuum breakers, flange oilers, pumps, injectors, etc.

In 1919 he took a similar position with the Fletcher Works, Inc., of Philadelphia, Pa., where he remained for about two years before going to Garwick. Since his retirement he had been experimenting with a device designed to utilize superheated steam in internal-combustion engines. This superheater, which can be fitted to any automobile engine and is also suitable for stationary and marine engines of the internal-combustion type, is said to effect a considerable saving in running costs, increase engine efficiency, and eliminate the necessity for decarbonizing. Mr. Wood had secured patents on the superheater in Great Britain and the United States.

Mr. Wood became a member of the A.S.M.E. in 1915 and also belonged to the Masonic fraternity.

HERBERT WALDO YORK (1864–1932)[1]

Herbert Waldo York, who died on November 21, 1932, was born at West Roxbury, Mass., on February 18, 1864. He was the son of John and Julia A. (Hinckley) York. He attended the public schools and was graduated from high school at Washington, D.C., where his father, who came to the United States from England in 1850, was employed in the office of the Commissioner of Customs, United States Treasury Department.

From November, 1882, to November, 1885, Mr. York served as assistant to Charles E. Emery, consulting engineer for the United States Revenue Marine (now United States Coast Guard Service). As such, his duties involved work on plans and specifications for new machinery and alterations and repairs to old equipment.

It was urged upon him at this time that he should acquire the sea

[1] Extracted from memoir prepared by John Barnard, Lt-Com. (Retired), U.S.N.R., New York, N.Y., for the Memoirs of the American Society of Civil Engineers.

service prerequisite to an examination for a sea-going Marine Engineer, and it was arranged that he should go out in the Engineer's Department of that famous old United States Revenue Cutter, *Bear*, then being sent from the Atlantic Coast to the Pacific for the beginning of her internationally known services in the Behring Sea and the Arctic. Upon this ship's arrival in San Francisco, Calif., in the spring of 1886, Mr. York's sea service was still inadequate for promotion, and he continued on the ship for her first summer's patrol in the Arctic. Upon the *Bear's* return to San Francisco, Mr. York successfully passed the examinations for, and was commissioned as, a Second Assistant Engineer in the United States Revenue Marine.

From this service he resigned in December, 1886, to return East, where he entered the employ of the New York Steam Company, of New York, N.Y., as assistant engineer in charge of building service connections, repairs to street mains, tests, etc., for one year, until November, 1887. He then engaged in private consulting work until July, 1889, when he became assistant superintendent of the Phoenix Construction Company, on the construction of electrical subways for The Consolidated Telegraph & Electric Subway Co. Mr. York was in charge of all construction south of Twenty-Third Street, New York, and, to January, 1890, had built about 110 miles of ducts. He then again engaged in private work until May, 1890, when he was employed for about six months as superintendent on the construction of new shops for The Yale & Towne Manufacturing Co., Stamford, Conn.

In November, 1890, Mr. York joined The United Electric Light & Power Co., from which were run the first alternating-current circuits in the city of New York. This company bought the old Brush Electric Illuminating Company and with it The United States Illuminating Company was merged. He joined the company as assistant engineer and in May, 1892, was made chief engineer in charge of operation and maintenance of all stations and of the design, construction, and operation of a new station on East Twenty-Eighth Street and the East River.

In these days alternating-current generating plants have replaced the earlier and simpler direct-current stations, and much is now commonplace which then presented problems. Although today these problems are largely forgotten, they were serious in the older days and had to be solved if success was to result. Accordingly, it is interesting to hear from the first electrical engineer of the Twenty-Eighth Street Station, of some of the devices originating with Herbert York for synchronizing those reciprocating engines. The first of these devices consisted of little whistles blowing at a given point of the stroke so that as the engineer brought up to speed an engine about to be cut in, the operator at the switchboard would hear its whistle gradually come into unison with the others. This method Mr. York later replaced by a control on the valve gear which automatically accomplished synchronization. On this, he obtained a patent which was acquired by the Westinghouse Company.

On April 1, 1903, Mr. York became chief engineer of the United Lead Company, holding that position until May 1, 1905, when he accepted the position of engineering manager for The J. G. White Engineering Corp., which had undertaken the function of consulting engineers for the American Smelting & Refining Co., coupled with an understanding that Mr. York personally should handle its work. The attempt, however, proved too taxing, and on June 30, 1906, he transferred to the American Smelting & Refining Co. as consulting engineer, in which capacity he continued until his retirement on April 1, 1930.

Mr. York was elected a Junior of the American Society of Civil Engineers in 1888 and a Member in 1896. Shortly after his election as a Junior he submitted a paper on "The Twenty-Eighth Street Central Station of the United Electric Light & Power Company," which was accepted for publication.[2] As a result, in 1896, he was honored by the society's Collingwood Prize for Juniors. He became a member of the A.S.M.E. in 1894, and also belonged to The Franklin Institute and the American Institute of Mining and Metallurgical Engineers. His clubs included the Engineers', New York Yacht, and Bankers, New York.

In 1900 he joined the First Battalion of the Naval Militia of New York State as Lieutenant (Junior Engineer), serving as Assistant Engineer of that Battalion, and transferring in 1904 to the duties of Gunnery Officer. In these positions he continued until 1911, when he was promoted to the rank of Lieutenant Commander, and served as Ordnance Officer on the Staff of the Commanding Officer of the New York Naval Militia. In 1917 he wished to enter active service in the World War and was keenly disappointed when the Navy Department deemed him too important a factor in munitions production. After the war he continued his active efforts in the State Naval Service until he was retired at his own request in 1927, and was transferred to the State Reserve List with the rank of Commander. He also held at his death the rank of Lieutenant-Commander on the Honorary Retired List of the United States Naval Reserve.

Mr. York was married on June 18, 1930, to Mrs. Jane Dolen-Lenz, who survives him.

---

Indexes to A.S.M.E. Papers and Publications

THE following pages contain indexes to papers and publications of the A.S.M.E. during 1933. A considerable number of papers and reports presented at meetings of the Society during the year were issued in mimeographed or photo-offset form, but at the time this index was prepared had not been included in any of the A.S.M.E. publications. Complete sets of these are on file for reference purposes at the office of the Society and the Engineering Societies Library, New York, under the title of "Miscellaneous Papers Presented at A.S.M.E. Meetings in 1933." Photostatic copies of any of the papers may be secured from the Library at regular rates. A list of these papers and reports is furnished here, grouped under headings corresponding to the Sections of Transactions.

This section of the Record and Index also includes a list of regular and special publications, and indexes to *Mechanical Engineering* and the Transactions.

Miscellaneous Papers Presented at A.S.M.E. Meetings in 1933

	Author	Paper No.
Aeronautical Engineering		
Progress in Aeronautical Engineering		1
Applied Mechanics		
Influence of Rate of Shear on Shearing Strength of Lead	James Jamieson	2
Stability of the Web of Plate Girders	S. Timoshenko	3
Rational Design of Steel Columns	D. H. Young	4
Fuels and Steam Power		
The Thermal Performance of the Detroit Turbine Using Steam at 1000 Deg Fahr	W. A. Carter; F. O. Ellenwood	5
The Determination of Dissolved Oxygen	C. H. Fellows	6
The Relation Between Pulverizing Capacity, Power and Grindability	R. M. Hardgrove	7
The Accuracy of the Cleanliness Factor Measurement for Surface Condensers	P. H. Hardie; W. S. Cooper	8
Theoretical Steam Rate Tables	E. E. Harris	9
Transfer Rates on Condensing, Reboiling, and Miscellaneous Heat Exchange Services	Max B. Higgin	10
Progress in the Removal of Sulphur Compounds From Waste Gases	H. F. Johnstone	11
Heat-Transfer Rates in Refrigerating and Air-Cooling Apparatus	W. J. King; W. L. Knaus	12
Heat Transfer in Air Heaters and Economizers	Henry Kreisinger	13
The Design of the Radiant Heat Absorption Section of Pipe Still Coils	Charles E. McCulloch	14
Slags From Slag-Tap Furnaces and Their Properties	P. Nicholls; W. T. Reid	15
Report of Committee on Power Plant Betterment		16
Preliminary Report of Committee on Power Plant Costs and Records		17
Progress in Fuels Engineering		18
Progress in Steam Power Engineering		19
Leaving Velocity and Exhaust Loss in Steam Turbines	Ernest L. Robinson	20
The Solubility of Sodium Sulfate in Boiler-Water Salines as Related to the Prevention of Embrittlement	W. C. Schroeder; Everett P. Partridge	21
Burning Characteristics of Pulverized Coals and the Radiation From Their Flames	Ralph A. Sherman	22
Developing the Balanced Natural-Flow Surface Condenser	John H. Smith	23
Moisture Problem in Steam Turbines	C. Richard Soderberg	24
A New Boiler-Water Treatment for the United States Navy	Thorvald A. Solberg; Robert C. Adams, Jr.	25
Standby and Reserve Operation of a Pulverized Fuel Plant	E. H. Tenney	26
Fundamentals of Drying Methods	C. W. Thomas	27
High-Temperature Steam Experience at Detroit	P. W. Thompson; R. M. Van Duzer, Jr.	28
Surface Condenser Design and Operating Characteristics	Townsend Tinker	29
Application of Air. Water Mixture Chart	A. Weisselberg	30
The Design of Piping for Flexibility by the Use of Graphs	E. A. Wert; S. Smith; E. T. Cope	31
Oil Firing in Pulverized Coal Furnaces	James F. Muir	32a
The Principles of Underfeed Combustion and the Effect of Preheated Air on Overfeed and Underfeed Fuel Beds	P. Nicholls; M. G. Eilers	32b
Correlation of "Grindability" With Actual Pulverizer Performance	Martin Frisch; G. C. Holder	32c
The Measurement and Properties of Cinders and Fly-Ash	Arthur C. Stern	32d
Supersaturated Steam	John I. Yellott, Jr.	33
Power and Heat Cost Analysis for Industrial Plants	Louis A. Offer	34
Hydraulics		
Water Measurement With Current Meters in Hydraulic Turbine Plants	W. Hahn	35
Current-Meter Testing and Performance	John C. Hoyt	36
Machine Shop Practice		
Can the Cutting of Metals Be Made a Science?	Robert C. Deale	37
Recent Progress in the X-Ray Inspection of Welds	Herbert R. Isenburger	38
Cemented Carbide Cutting Tools	Malcolm F. Judkins; William C. Uecker	39
Progress in Machine-Shop Practice		40
Management		
Importance of the Product in the Recovery Period	W. E. Freeland	41
Noise Elimination and Air Motion	C. B. Graves	42
Progress in Management		43
Principles of Coordinated Visual Control	Eugene Szepesi	44
The Plant and Its Equipment	Earl Whitehorne	45
Oil and Gas Power		
Speed Regulation of Diesel Engines	Irl C. Martin	46a
Welding of Diesel Engines	Everett Chapman	46b
Causes and Effects of Pressure Waves in Fuel Injection System	Ralph Miller	46c
Reducing the Performance of a Solid Injection Diesel Engine	H. A. Everett	46d
Improvements in Scavenging and Supercharging Two-Cycle Diesel Engines	Charles G. Curtis	46e
Compression-Ignition Tests With a Sleeve-Valve Engine	C. Fayette Taylor; Myron S. Huckle	46f
Low Compression Spark Ignition Oil Engines	F. H. Dutcher	46g
Choice of Auxiliaries for a Diesel Plant	Ralph Troseth	46h
Preliminary Report on Oil Engine Power Cost for 1932		47
Progress in Oil and Gas Power Engineering		48
Present Status of the Humphrey Gas Pump for Pumping Water by Displacement	F. DuP. Thomson	49

	Author	Paper No.
Petroleum		
Errors and Corrections in Viscosity Measurement	W. J. Albersheim, H. S. Konheim, C. M. Larson	50
Viscosity Classification for Industrial Lubrication	A. E. Becker	51
Investigation of Properties of All-Year Car Oils	C. M. Larson	52
Progress in Petroleum Engineering		53
Orifice Discharge Coefficients for Viscous Liquids	G. L. Tuve, R. E. Sprenkle	54
Printing Industries		
An Analysis of Printing Research	Henry D. Hubbard	55
Program of Cooperative Printing Research in America	Arthur C. Jewett	56
Printing Progress	B. D. Stevens, Floyd E. Wilder, George H. Carter	57
Railroads		
Locomotive Counterbalancing	Lawford H. Fry	58
Progress in Railroad Engineering		59
Research Accomplished by Railroads	C. D. Young	60a
Research Accomplished by Industry	Samuel O. Dunn	60b
A Review of Forty Years of Railway Engineering Research	G. A. Young	60c
Railway Research at the University of Illinois	Edward C. Schmidt, Everett G. Young	60d
Standardization of Freight Equipment Cars by the Mechanical Division of the American Railway Association	F. H. Hardin	60e
Development of Passenger Cars	Peter Parke	60f
Railroad Equipment of High Tensile Steel	E. G. Budd	60g
Car Trucks and the Development of Steel Castings	Harry M. Pflager	60h
Development of the Locomotive Boiler	Henry B. Oatley	60i
Locomotive Running Gear and Counterbalancing	A. B. Trumbull	60j
Research in the Railroad Braking Art	S. W. Dudley	60k
Automotive Engines and Cars	L. G. Coleman	60L
Research and Development in Car and Locomotive Materials	Lawford H. Fry	60m
Research as Related to Locomotive Development	W. E. Woodard	60n
Research and Progress Made in the Development of Draft Gears	L. P. Michael	60o
The Development of Locomotive and Car Wheels	Charles T. Ripley	60p
Locomotive Accessories	Charles H. Bilty	60q
Steam Locomotive Valve and Valve Gears Progress Study	George S. Edmonds	60r
Anti-Friction Bearings in Railway Service	J. R. Jackson	60s
Textiles		
Progress in Textile Engineering		61
Wood Industries		
Compressed Air in Woodworking Machinery	R. F. Onsrud	62
The Preservative Treatment of Wood	George M. Hunt	63a
Creosote and Creosote Mixtures	R. S. Belcher	63b
Zinc Chloride as a Wood Preservative	L. C. Drefahl	63c
Sodium Fluoride and Fluoride-Phenol Mixtures for the Preservation of Wood	Howard B. Bishop	63d
European Experience With Fluorides and Fluoride-Phenol Mixtures as Wood Preservatives	Adolph Rabanus	63e
Zinc Meta-Arsenite as a Wood Preservative	Leo P. Curtin	63f
Fire-Retardant Treatments for Wood	Ernest F. Hartman	63g
Wood Preservatives	George M. Hunt	63h
Official Programs		
A.S.M.E. Meeting at Century-of-Progress Exposition, June 25–July 1, 1933, Chicago, Ill		64
A.S.M.E. Annual Meeting at New York, N. Y., December 4–8, 1933		65

List of Publications

REGULAR SOCIETY PUBLICATIONS

Mechanical Engineering, monthly (see index on pages 89–95)
A.S.M.E. Transactions (see index on pages 96–103)
Mechanical Catalog, 1933–1934 edition
The Engineering Index for 1932

SPECIAL PUBLICATIONS

Boiler Codes

Power Boiler Code, Sections I, II, VI, and Appendix, A.S.M.E. Boiler Construction Code, September, 1933
Revisions and Addenda to Power Boiler Code, Locomotive Boiler Code, Low-Pressure Heating Boiler Code, and Unfired Pressure Vessel Code, August, 1933
Suggested Rules for the Care of Power Boilers, Section VII, A.S.M.E. Boiler Construction Code, March, 1933

Power Test Codes

Instruments and Apparatus
Part 3, Temperature Measurement—Chapter 8 on Optical Pyrometers, August, 1933
Part 4, Head Measuring Apparatus, March, 1933

Research

Report of Tests on Electrical Equipment for Drilling Rotary-Drilled Oil Wells, April, 1933
Determination of Carbonate, Phosphate and Hydroxide in Boiler Waters, September, 1933
Fluid Meters, Part 3, Their Selection and Installation, December, 1933

Standards

Wrench Head Bolts and Nuts and Wrench Openings (revision of 1927 edition), March, 1933
